Welcome Message by the ESB President
Pamela Habibović

Dear members of the European Society for Biomaterials,
Dear colleagues and friends,

It is my pleasure to welcome you to ESB2021, the 31st Annual Conference of our society, to be held 5-9 September, 2021. We had all very much looked forward to spending five days in Porto, Portugal, where the conference was planned to be held, to enjoy one of the most beautiful European cities and the well-known Portuguese hospitality. Unfortunately, the Covid-19 pandemic continues to restrict our freedom to travel and meet at large events. Therefore, the organizing committee, in agreement with the ESB Council, had to take the difficult decision to turn the conference into a virtual event.

This is the second time that an ESB Conference is hosted by a Portuguese team. In 1995, the 12th Annual ESB Conference was also held in Porto, and it was a great success. Portugal has a long and successful track record in biomaterials research, and participation and contribution of Portuguese scientists to the ESB has been significant since the society’s foundation.

Despite the fact that we will not be able to meet in person, I am convinced that the ESB2021 Conference will offer plenty of opportunities to discuss recent exciting research and development achievements in the field of biomaterials. Our hosts, Ana Paula Pêgo, M. Cristina L. Martins and Pedro L. Granja have developed a truly impressive scientific program, with plenary and keynote speakers from all over the world and covering a great range of exciting topics. Moreover, several special symposia will be organized, including the full-day ESB symposium on research translation. The organizers have done their utmost best to accommodate oral and poster presentations of as PhD candidates and post-doctoral fellows and give them the opportunity to showcase their work at one of the most important scientific events in the field of biomaterials.

Together with the rest of the ESB Council, I look forward to meeting you at the virtual ESB2021!

Kind regards,

Pamela Habibović
ESB President
Welcome Message by the ESB 2021 Chairs
Ana Paula Pêgo, M. Cristina L. Martins, Pedro L. Granja

Dear friends and colleagues,

On behalf of the Organizing Committee, we would like to cordially welcome you to the 31st Annual Conference of the European Society for Biomaterials (ESB 2021), taking place virtually from September 5 to 9, 2021. This is the second time this event is organized in Portugal (in 1995, it has been already organized in Porto being chaired by Mário Barbosa). This year it also accommodates the 43rd Annual Congress of the Iberian Society for Biomechanics and Biomaterials (SIBB).

The motto of our Conference is “Futuring Biomaterials”, as a challenge to our community to explore biomaterials in conjunction with advanced technologies, such as Nanotechnology, Biofabrication, Microfluidics and Bioimaging to develop the clinical combination products and functionalities of the future. These conferences, whose first event took place in Strasbourg (France) in 1977, are held annually and are interspersed every 4 years by the World Biomaterials Congress. The ESB Conferences aim to bring together researchers, clinicians and companies for the presentation and discussion of the most recent advances in the areas of Science and Engineering of Biomaterials, both in terms of more fundamental research, as well as clinical and industrial research. It is intended that this multidisciplinary environment can promote scientific and technological knowledge for innovation in health.

As you know, at the beginning of this adventure we have planned to host the ESB 2021 Conference in Porto, as a live and lively event. However, the COVID19 pandemic drastically altered our plans. Despite our massive effort to organize the event live, after numerous discussions and with the support of the ESB Council, we have taken the difficult decision to move ESB 2021 to a fully virtual format. From then on, all our energies were put into making ESB 2021 a VIRTUOUS VIRTUAL successful event!

Despite the current pandemic the support of our community has been massive. We have received 795 abstracts and 39 proposals for symposia. This allowed us to prepare an exciting program that really leaves to our motto!

In quantitative terms, we have 975 registered participants, from 48 countries, including 15 from outside Europe, proving the truly international character of the event. The program includes 10 plenary presentations, including 3 given by invited renowned speakers and 7 by scientists awarded by the ESB in 2020 and in 2021. In addition, it also includes 98 invited lectures and 795 presentations, of which 348 oral and 447 posters (as of August 24, 2021). We really boosted the number of oral presentations to assure that as many teams as possible could see their works discussed in a podium presentation. Best oral and poster presentations made by young researchers, will also be awarded. To promote networking, we will provide access to a very interactive tool – Gathertown. Please, do actively participate in the poster sessions and be prepared to see old friends and meet new ones! As in every Conference, the Translation Symposia will address timely topics. We have a session dedicated to the recent alterations observed in the regulatory framework of medical devices and another that involves Business Angels. Finally, we actively involved the YSF in all aspects of the event and this year you will see the introduction of YSF chairs in all our oral sessions. You will also be able to meet our sponsors during the event.

We really need to leave here a word of thanks to all those that worked hard to make this Conference a reality: speakers, reviewers, special session organizers, sponsors, the local organizing committee, and all the volunteers.
Despite the fact that we will not be able to welcome you live in Porto, we organized a virtual Social Program that will give you a flavor of our city. We have a wine expert explaining what makes our Portuguese wines so special, and we have also a musical show recorded specially for our event. We have also planned yoga sessions during the lunch breaks. So, enjoy!

On behalf of the Organizing Committee, we thank you very much for your participation and wish you a pleasant virtual "stay" in Porto!

Ana Paula Pêgo (Chair), M. Cristina L. Martins (Co-Chair) and Pedro L. Granja (Co-Chair)

Institute for Research and Innovation in Health (i3S) and INEB – Instituto de Engenharia Biomédica, University of Porto, Portugal
Welcome Message by the SIBB Chairs
Enrique Navarro & Inês Gonçalves

On behalf of the organizing committee, we would like to warmly welcome all of you to the 43rd Annual Congress of the Iberian Society for Biomechanics and Biomaterials (SIBB).

In an attempt to bring closer the Portuguese and Spanish scientific communities in our fields, this year we have organized our annual conference in Portugal, embracing the opportunity of joining the 31st Annual Conference of the European Society for Biomaterials (ESB2021), held in Porto, Portugal.

Up to now, we have 270 Iberian participants, including 153 from Portugal and 92 from Spain in the Biomaterials field and 5 from Portugal and 20 from Spain in the Biomechanics field. From these, 161 are young scientists, and whom we expect to join efforts to strengthening this society in the future.

The SIBB biomaterials sessions are fully integrated within the ESB2021, with a huge variety of topics with plenary and keynote speakers. Given the interesting and high number of works from several Portuguese and Spanish groups in the areas of “Biomaterials for Cancer Models and Treatment”, and in “Antimicrobial Biomaterials”, we have dedicated 2 joint symposiums from ESB-SIBB to these topics. The SIBB biomechanics sessions will occur in the last day of the conference (September 9th), being dedicated to “Anatomo-functional bases of entesopathies in sports” and to “Swimming Biomechanics”.

In the very end of the last day, we will have our SIBB general assembly, where we will have a chance to discuss important points regarding our society and have the awards ceremony.

Unfortunately, due to the COVID-19 pandemic that prevented us from having a face-to-face meeting, this year it will not be possible to perform the workshops, which are so typical of our annual congresses.

Despite you were not able to sense the beautiful city of Porto and the Portuguese hospitality, we still hope that after these days of conference, you are able to meet and chat with colleagues and friends during the online sessions and in our virtual “coffee shops”, and that you feel inspired by the scientific atmosphere of the conference.

Abraços,

Enrique Navarro (SIBB President)

The organizing committee would like to thank our Sponsors and partners for the support of the conference:

**Gold Sponsor & Exhibitor**

**Rousselot Biomedical**

Rousselot® Biomedical
www.rousselot.com/biomedical

As the most recent strategic segment within Rousselot, we have drawn upon Rousselot’s 125+ years of worldwide expertise and proven track record of pharmaceutical gelatins and collagens to develop X-Pure®, an innovative range of purified gelatins and collagens specifically designed for (bio)medical applications. Offering unique advantages to assure performance, quality and safety, X-Pure is backed by strong scientific data and on-going research. Rousselot Biomedical is committed to facilitating the use of X-Pure in your applications and to help “Advancing medical science”.

**Further Sponsors**

**Elsevier**

https://www.journals.elsevier.com/biomaterials

Biomaterials is an international journal covering the science and clinical application of biomaterials. It is the aim of the journal to provide a peer-reviewed forum for the publication of original papers and authoritative review and opinion papers dealing with the most important issues facing the use of biomaterials in clinical practice. The scope of the journal covers the wide range of physical, biological and chemical sciences that underpin the design of biomaterials and the clinical disciplines in which they are used. These sciences include polymer synthesis and characterization, drug and gene vector design, the biology of the host response, immunology and toxicology and self assembly at the nanoscale. Clinical applications include the therapies of medical technology and regenerative medicine in all clinical disciplines, and diagnostic systems that reply on innovative contrast and sensing agents. The journal is relevant to areas such as cancer diagnosis and therapy, implantable devices, drug delivery systems, gene vectors, bionanotechnology and tissue engineering.

**FLUIDINOVA, S.A.**

www.fluidinova.com/congress

FLUIDINOVA is a specialized manufacturer of synthetic nano-hydroxyapatite and tricalcium phosphate materials marketed as nanoXIM®. FLUIDINOVA provides companies and research institutions around the world with unique and high quality calcium phosphates for the development of medical devices, oral care cosmetics and food products. Particularly, for medical applications, our products are successfully used as bone graft substitutes with improved regenerative performance. Our focus on customer satisfaction and innovation helps us to establish close relationships with clients to develop the best solutions to incorporate our materials in their final products to address a vast number of applications.

**Biomaterials Science, Royal Society of Chemistry**

www.rsc.org/journals-books-databases/about-journals/biomaterials-science/

*Biomaterials Science* is the official journal of the European Society of Biomaterials. Published on a not-for-profit basis by the Royal Society of Chemistry, the journal presents high impact work focused on exploring the design, function, and interactions of biomaterials. Its scope encompasses new concepts in biomaterials design, studies into the interaction of biomaterials with the body, and the use of materials to answer fundamental biological questions. The journal is led by Editor-in-Chief Jianjun Cheng, alongside an international Editorial Board of expert Associate Editors.
Enzifarma S.A. is a leading Portuguese company operating in niche healthcare segments, namely in the import and commercialization of state-of-the-art solutions for the laboratory area, considered a PME Líder '20 with Quality Control in compliance with ISO 9001:2015. Founded in 1996, with headquarters in Lisbon and warehouse operation in the Porto region, where there is also an office that offers administrative support in the commercialization, storage and dispatch processes. We consider our mission to know how to be rigorous and efficient with us and our suppliers, as a way to achieve and maintain a leadership position in the quality of the products and services provided, for a better satisfaction of our customers, shareholders, society and all interested parties, namely the companies we represent. Thus, we strive to understand, satisfy and anticipate customers' needs, building with them a strong and stable relationship. In organizational terms, the company operates according to a business area strategy, and a cross-logic of marketing and product applicability (technical-scientific).

From IOP Publishing, our multidisciplinary journal *Multifunctional Materials* (MFM) serves an emerging field that now connects the materials science, physics, chemistry, bioscience and engineering communities, and translational multifunctional sciences. As a highly selective journal, it’s primary aim is to publish original research of the highest quality, including fundamental concepts to integrate multiple functions, characterisation of functions, novel applications and manufacturing techniques, with the expectation for lasting scientific and technological impact. Discover more about our experienced top-level editorial board, and high-quality online production today. https://iopscience.iop.org/journal/2399-7532

Specanalítica is one of the leading companies in the Portuguese analytical market supported by a motivated and highly qualified team. Focused on the Commercialization of internationally renowned brands in the fields Analytical Chemistry, Material and Life Sciences, customer support and after-sales services are our priorities! We have Accredited Training Certification since 2012 for our customers! Our mission: work in a partnership with our customers offering specialized analytical solutions to meet their analytical needs, keeping leadership as one of the most respected customer partners in the Portuguese industrial, analytical and life science market! Our ambition is to be recognized for the excellent product range we offer and for the technical support provided!

Ceramics (ISSN 2571-6131) is an international peer-reviewed open access journal of ceramics science and engineering published quarterly online by MDPI. It is indexed within Emerging Sources Citation Index (Web of Science), and other relevant databases. It provides a forum for publishing papers which advance the in-depth understanding of the relationship between the structure, the microstructure, the properties and the applications of ceramic materials. It publishes reviews, regular research papers (articles) and short communications. Our aim is to encourage scientists to publish their ex-perimental and theoretical results in as much detail as possible so that the results can be reproduced. Therefore, there is no restriction on the length of the papers. We are committed to drive Ceramics to a position in which it is recognized for its high-quality, cutting-edge research and scientific influence, and strongly encourage and invite your participation and manuscripts.
Brad Nelson has been the Professor of Robotics and Intelligent Systems at ETH Zürich since 2002. He has over thirty years of experience in the field of robotics and has received a number of awards in the fields of robotics, nanotechnology, and biomedicine. He serves on the advisory boards of a number of academic departments and research institutes across North America, Europe, and Asia and is on the editorial boards of several academic journals. Prof. Nelson is the Department Head of Mechanical and Process Engineering at ETH and has been the Chairman of the ETH Electron Microscopy Center and a member of the Research Council of the Swiss National Science Foundation. He also serves on boards of three Swiss companies. Before moving to Europe, Prof. Nelson worked as an engineer at Honeywell and Motorola and served as a United States Peace Corps Volunteer in Botswana, Africa. He has also been a professor at the University of Minnesota and the University of Illinois at Chicago.

Linda Gay Griffith, (BS Georgia Tech, PhD UC Berkeley, Chemical Engineering) is the School of Engineering Teaching Innovation Professor of Biological and Mechanical Engineering and MacVicar Fellow at MIT, where she directs the Center for Gynepathology Research. She led development of the Biological Engineering SB degree program, which was approved in 2005 as MIT’s first new undergraduate major in 39 years. She has pioneered approaches in tissue engineering, including the first tissue-engineered cartilage in the shape of a human ear; commercialization of the 3DP™ Printing Process for manufacture of FDA-approved scaffolds; commercialization of the 3D perfused “LiverChip” for drug development; and synthetic matrices for morphogenesis. A major current focus is gynecology applications, integrating mechanistic disease stratification and tissue-engineered models of lesions for drug development in endometriosis and adenomyosis. She is a member of the National Academy of Engineering, the recipient of a MacArthur Foundation Fellowship, Radcliffe Fellowship and several awards from professional societies. She currently serves on the Advisory Board of the Society for Women’s Health Research and has served on several NIH Advisory Councils including the Advisory Committee to the Director.
Laura De Laporte combines engineering, chemistry and biology to design biomaterials that control and direct the interaction with cells. She is a Chemical Engineer from Ghent, where she got the tissue engineering microbe. To follow her dream, she did her PhD with Lonnie Shea at Northwestern University and engineered guiding implants for nerve regeneration. At EPFL, she learned about hydrogels in Jeffrey Hubbell’s group during her post-doctoral research. Currently, she is a Leibniz Professor at the RWTH University in Aachen, Germany, where she works on Advanced Biomedical Systems at the DWI-Leibniz Institute for Interactive Materials. In the framework of the ERC Starting Grant Anisogel, her team designs low-invasive, polymeric regenerative hydrogel therapies, consisting of nano- and micron-scale building blocks that orient after injection to repair anisotropic tissues. In addition, dynamic hydrogels are created to study mechanobiology.
George Winter Award

The George Winter award is established by the European Society for Biomaterials to recognize, encourage and stimulate outstanding research contributions to the field of biomaterials. The nominee must have contributed significantly to the knowledge in the field of biomaterials through basic, experimental and/or clinical research. The award will be presented annually during the ESB conference.

João Mano

Awardee George Winter Award 2020

University of Aveiro, Department of Chemistry, CICECO – Aveiro Institute of Materials, Aveiro, Portugal

Talk: GW AW-01 | Design of biomaterials/cells structures for bottom-up tissue engineering strategies – less is more
Date: Monday, 6 September, 2021, 9:30 AM
Track: 01

João F. Mano, PhD in Chemistry (1996, Technical Univ. Lisbon), D.Sc. in Tissue Engineering Regenerative Medicine and Stem Cells (2012, Univ. Minho), is a full professor at the Department of Chemistry of the University of Aveiro (Portugal). During his career he has been teaching courses related to biomaterials science and technology, tissue engineering and physical chemistry of polymers and materials, in both undergraduate and graduate levels. He is the director of both Master and Doctoral Degrees in Biotechnology at the Univ. of Aveiro. He has also an appointment as Invited Professor (classe exceptionelle, since 2014) at University of Lorraine (France), and Visiting Professor in KAIST (South Korea) – 2019.

He belongs to the associate laboratory CICECO – Aveiro Institute of Materials where he is directing the COMPASS Research Group, founded in April 2016. His current research interests include the use of biomaterials and cells towards the development of transdisciplinary concepts especially aimed at being used in regenerative and personalised medicine. In particular, biomimetic and nano/micro-technology approaches have been applied to natural-derived biomaterials and surfaces in order to obtain biomedical devices with improved structural and (multi-)functional properties, or in the engineering of microenvironments to control cell behaviour and organization, to be used in therapies or in drug screening.

João F. Mano is author of 630+ original research or review papers in international journals (26000+ citations, h=81 – Web of Science) and about 40 book chapters. João F. Mano co-edited 9 special issues in international journals and 3 books. João F. Mano has been invited to review manuscripts from 275+ different international journals and to routinely evaluate projects from numerous private and state funding agencies from 18 different countries. João F. Mano supervised or co-supervised 60 MSc, 22 PhD students, and 40+ post-doctoral fellows. He filed 6 patents as senior inventor.

He is the Editor-in-Chief of Materials Today Bio (Elsevier). He has been also part of a series of scientific societies and editorial boards of about 10 international journals. He has been coordinating or involved in many national and European research projects and participated in the organization of scientific events in the area of polymer/materials science and biomaterials/tissue engineering.

Professor João F. Mano has been member of scientific committees, organizing committees, referee and chairman in different international meetings. He was invited to present more than 100 invited/keynote/plenary talks in international conferences including: EUROMAT, ESTAC, TERMIS (EU and AP chapters and World conferences), BIOMED, FBPS, NANOMED, COLAOB, ESB, SFB, World Biomaterials Conference, E-MRS, ESAO, EPF, ACS, CBECIMAT, NICE, Inter. HYMA, APME, APCChE, PPM, EPNOE, SELECTBIO.
João F. Mano has received different honours and awards: (i) fellow of the IUPAC (International Union of Pure and Applied Chemistry) since 2004; (ii) the Stimulus to Excellence Award by the Portuguese Minister for Science and Technology in 2005; (iii) the Materials Science and Technology Prize, attributed by the Federation of European Materials Societies (FEMS) in 2007; (iv) UNESCO Chair on Biomaterials attributed in 2008 from the University of Havana (Cuba); (v) the major BES innovation award in 2010 (at that time, one of the most recognised innovation prize in Portugal); (vi) recipient an Advanced Grant from the European Research Council (ERC-AdG), in 2015; (vii) received the title of Professor@Lorraine from the University of Lorraine, France, in 2018; (viii) recipient a Proof of Concept Grant from the European Research Council (ERC-PoC), in 2018; (ix) title of Doctor Honoris Causa, given by University of Lorraine, in 2019; (x) awarded with a Gutenberg Chair, supported by the Great East Region of France, in 2020; (xi) recipient a second ERC-AdG, in 2020; (xii) recipient a second ERC-PoC, in 2020; (xiii) elected fellow of the European Academy of Sciences.

Pekka Kalevi Vallittu

Awardee George Winter Award 2021

University of Turku (UTU), Department of Biomaterials Science, Turku, Finland

Talk: GW AW-02 I Development of fiber-reinforced composites for dental and medical reconstructive biomaterial

Date: Wednesday, 8 September, 2021, 9:30 AM

Track: 01

Pekka Vallittu (www.utu.fi/en/people/pekka-vallittu) has earned his degrees in Dental Technology in 1988, Doctor of Dental Surgery and Doctor of Philosophy in 1994, received Adjunct Professorship in 1995 and specialized in prostodontics and stomatognathic physiology in 2000. Presently, he is a Full Professorship and Chair of Biomaterials Science in the Faculty of Medicine, University of Turku, Finland and works as Dean of the Institute of Dentistry at the University of Turku and as the Director of Turku Clinical Biomaterials Centre. He holds Honorary Professorship at the University of Hong Kong, Pokfulam and Visiting Professorship at the King Saud University in Riayadh, Saudi Arabia.

His predominating research activity on fiber-reinforced composites has lasted over 30 years since 1980’s. The first clinical applications of fiber-reinforced composites were found in clinical dentistry and thereafter in combination with bioactive glass components and surface coatings in bone surgical applications as non-metallic bioactive implants. Pekka Vallittu has over 640 ISI Web of Science Indexed publications, more that 140 granted patents based on 32 inventions and his h-index is 92. He has established two companies (Stick Tech Ltd – GC Group and Skulle Implants Corp.) for getting newly developed composite materials for clinical use.
Jean Leray Award

The Jean Leray award is established by the European Society for Biomaterials to recognize, encourage and stimulate outstanding research contributions to the field of biomaterials by early-career scientists. The nominee must have contributed significantly to the knowledge in the field of biomaterials through basic, experimental and/or clinical research. The award will be presented annually during the ESB conference.

Jeroen Leijten

Awardee Jean Leray Award 2020

Dept. Developmental BioEngineering, Faculty of Science and Technology, Technical Medical Centre, University of Twente, The Netherlands

Talk: JL AW-01 I Cell fate controlling micromaterials for the engineering of multiscale tissues
Date: Monday, 6 September, 2021, 10:15 AM
Track: 01

Jeroen Leijten is currently an associate professor in the Developmental BioEngineering department in the Technical Medical Centre of University Twente. He earned his Master’s degree in Biomedical Sciences at Leiden University in 2007, and his PhD degree in Tissue Engineering with Prof. Blitterswijk at University of Twente in 2012, where he continued to work as a postdoc for an additional year with Prof. Karperien. In 2013, he joined Prometheus, the division of Skeletal Tissue Engineering of the KU Leuven, to work with Prof. Luyten. As a self-funded postdoc, he worked on the development of microtechnological platforms to produce and investigate the potential of stem cell based micro-organoids and smart micromaterials. In 2014, he joined the Khademhosseini lab at Harvard-MIT as senior postdoctoral researcher where he worked on microfluidics, instructive biomaterials, and organ-on-chips. In 2016, he accepted a tenure track position at University Twente. His lab focuses on developing novel microtechnologies with a particular interest in microfluidics, micromaterials, and on-demand tunable biomaterials, which he leverages to create 3D spatiotemporal microenvironments to control (stem) cell behavior. He has published 59 peer reviewed papers in renowned journals including Cell Stem Cell, Nature Communications, Small, Advanced Functional Materials, and PNAS, resulting in >2100 citations and a H-index of 28. He received >7.5 million euro in funding including a Veni award, Vidi award, and ERC Starting grant, multiple presentation awards/honors including the best-idea-of-2018 by the Dutch academy of Engineers, and was twice selected as a top 10 Young Scientific Talent by New Scientist.
Riccardo Levato

Awardee Jean Leray Award 2021

Department of Clinical Sciences, Faculty of Veterinary Medicine, Utrecht University and Department of Orthopedics, University Medical Center Utrecht, the Netherlands

Talk:  JL AW-02 | Driving complex and synthetic tissue development via volumetric biofabrication technologies

Date:  Tuesday, 7 September, 2021, 10:15 AM

Track:  01

Riccardo Levato is currently associate professor of Translational Bioengineering and Biomaterials at the Department of Clinical Sciences (Faculty of Veterinary Medicine, Utrecht University), and a principal investigator both at the Regenerative Medicine Center Utrecht and at the Department of Orthopedics of the University Medical Center Utrecht.

His research interests focus on the development of novel biofabrication strategies and cell-instructive biomaterials to create bioprinted, lab-made tissue models and transplantable engineered grafts, particularly for the regeneration of the musculoskeletal system. Integrating expertise in engineering, materials science and stem cell biology, these efforts aim both to understand and mimic the multifaceted architectural and biochemical structure of living tissues in order to develop effective treatments for human and veterinary healthcare. In 2020 he was awarded a Starting grant from the European Research Council on the development of a novel volumetric bioprinting technology for organoid research and to engineer functional bone marrow analogues in vitro. In addition, since 2021, he is coordinator of a European consortium (ENLIGHT), funded under the Future and Emerging Technologies scheme (European Innovation Council pilot), aiming at developing biofabricated pancreas units to study treatments for diabetes. To date, he has published 49 peer-reviewed articles international journals (H-index=21), co-authored 2 book chapters and 2 patent applications, and he secured > 13 million euros in research funds for his group and related consortia. In total, he has been (co-)supervisor of 13 PhD students (4 completed, 9 ongoing). For his work, he was conferred several awards including a Orthoregeneration Network Fellowship by the International Cartilage Repair Society (ICRS), the Wake Forest Institute for Regenerative Medicine Young Investigator Award, multiple presentation and travel awards, and the Julia Polak doctoral award from the European Society for Biomaterials. Riccardo is an active member of the ESB, TERMIS, ICRS, and he is serving on the Board of Directors of the International Society for Biofabrication. Prior to moving to Utrecht, he worked and received training in several research groups working in the fields of Biomaterials, Regenerative Medicine and Biofabrication: 3Bs, University of Minho (Portugal); BioMatLab, Technical University of Milan (Italy), the Biomaterials for Regenerative Therapies group at the Institute for Bioengineering of Catalonia (IBEC, Spain), and he holds a cum laude PhD in Biomedical Engineering from IBEC and from the Technical University of Catalonia (Barcelona, Spain).
International Award 2021

The International Award is a prestigious recognition by the ESB of scientists who have generally spent their career outside Europe, who have been internationally recognised, have a high scientific profile, and have made major contributions to the field of biomaterials. Strong evidence of collaborations with members of our scientific community in Europe throughout their career is expected.

David Mooney

Awardee International Award 2021

Wyss Institute for Biologically Inspired Engineering and John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, USA

Talk: IntAW-01 | Cells, Viscoelasticity and Medical Devices
Date: Wednesday, 8 September, 2021, 5:45 PM
Track: 01

David Mooney is the Pinkas Family Professor of Bioengineering in the Harvard School of Engineering and Applied Sciences, and a Founding and Core Faculty Member of the Wyss Institute. He earned his B.S. at the University of Wisconsin, Madison, and his Ph.D in Chemical Engineering at the Massachusetts Institute of Technology. His laboratory designs biomaterials to promote tissue regeneration and immunotherapy, and has made significant advances in tissue engineering, drug delivery, and mechanotransduction. The laboratory emphasizes the education of students and fellows, with over 120 Ph.D. students and post-doctoral fellows to date; 40 lab alumni hold faculty positions with the remainder largely in the biotechnology, pharmaceutical, and medical device industries. He has an H-index of 158, with over 100,000 citations to date of his publications. He has won numerous awards, including the Clemson Award from the SFB, MERIT award from the NIH, Distinguished Scientist Award from the IADR, Phi Beta Kappa Prize for Excellence in Undergraduate Teaching, and the Everett Mendelsohn Excellence in Mentoring Award from Harvard College. He is a member of the National Academy of Engineering, the National Academy of Medicine, and the National Academy of Inventors. In 2019 he was named one of the Top 10 translational researchers in biotech by Nature Biotechnology. His inventions have been licensed by over 18 companies, leading to commercialized products and founding of companies, and he is active on industrial scientific advisory boards.
Klaas de Groot Award

The Klaas de Groot award is a prestigious recognition by the European Society for Biomaterials of scientists who have shown a distinct ability to provide excellent mentorship and guidance to young researchers, helping them to establish their own independent career. We look for colleagues who have nurtured young talent, and who have selflessly invested in this talent, creating a next generation biomaterials scientists in Europe. The award will be presented annually during the ESB conference.

Mário Adolfo Barbosa

Awardee Klaas de Groot Award 2020

Instituto de Ciências Biomédicas Abel Salazar (ICBAS), University of Porto, Porto, Portugal; I3S Instituto de Investigação e Inovação em Saúde, University of Porto, Porto, Portugal

Talk:  KdG AW-01 | Keep Learning: Advantages of Age in Science (KLAAS)
Date:  Tuesday, 7 September, 2021, 9:30 AM
Track:  01

Mário Barbosa took his PhD at Leeds University (UK). He is Full Professor at the Instituto de Ciências Biomédicas Abel Salazar (ICBAS), University of Porto, where his area of lecturing is bioengineering. From 2015 to December 2019, and following an application led by him, he was the Director of the I3S (Instituto de Investigação e Inovação em Saúde) of Porto University. I3S was evaluated by the FCT (Fundaçãa para a Ciência e a Tecnologia) with the highest marks (Outstanding in 2015 and Excellent in 2019). I3S is the largest R&D research institute in Portugal, with >1300 investigators, 460 of them holding a PhD degree. Mário was a founding member of Instituto de Engenharia Biomédica (INEB) set up in 1989, which is part of the i3S consortium. Mário has taken leading positions in Portugal, namely as President of the national agency for research (1992 to 1994) and Chairman of its Engineering Sciences Scientific Council (2002 to 2005).

The main topic of Mário’s research is the modulation of inflammation in tissue repair/regeneration, namely through the design of immunomodulatory microenvironments. At i3S he leads the Microenvironments for New Therapies (MiNT) group. MiNT bioengineers microenvironments that promote tissue regeneration/functional restoration through modulation of the host response.

At the post-graduate level Mário has taken a leading role in launching undergraduate and post-doctoral programmes (e.g. the Doctoral Programme in Biomedical Engineering, in 1996, one of the first to operate in Portugal). He is the Director of the International Doctoral Programme on Molecular and Cellular Biotechnology Applied to Health Sciences (now in its 7th edition), that provides research training in bioengineering in top level institutions. Mário has been always strongly committed to advanced training in the area of biomaterials. For instance, from 1988 to 1992 he run a series of European Intensive Courses, funded by the European Commission, which resulted in the publication of four books published by Elsevier (1991, 1992, 1993 and 1994). During 10 years in a row (1999-2009), he organized Advanced Summer Course in Cell/Material Interactions, with an important hands-on component and a large number of international participants. After a short break in 2010, the Summer Schools re-emerged under the general topic of Interrogations at the Biointerface with the goal of bringing together different fields around one topic of interest. The 7th edition took place in 2019.

Among several awards is the George Winter Award of the European Society for Biomaterials (ESB), the ESB award for outstanding work of an established researcher, received in 2001. Mário is a Fellow of the International Union of Societies for Biomaterials Science and Engineering. From 2007 to 2016 he was the representative of the ESB for the Acta Biomaterialia Gold Medal award and from 2007 to 2013 the chairman of the awards committee of the ESB. He was a member of the Directive Council of the ESB (1991-1995). Mário organized several international conferences, including the 12th European Conference on Biomaterials (1995) and Bioceramics 16 (2003). Presently, he is the Secretary of the International Union of the Societies of Biomaterials Science and Engineering (IUSBSE). Former postdocs and students have leading positions in research institutes, both in Portugal and abroad (e.g. China, USA, Brazil and Spain). He has published more than 280 papers in refereed journals (>9000 citations; h index 52).

Clemens A. van Blitterswijk

Awardee Klaas de Groot Award 2021

Professor of Complex Tissue Regeneration, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, the Netherlands

Talk: KdG AW-02 | Some reflections on scientific progeny
Date: Wednesday, 8 September, 2021, 10:15 AM
Track: 01

Prof. Dr. Clemens A. van Blitterswijk (born 1957, The Hague, the Netherlands) graduated as a cell biologist from Leiden University (Leiden, the Netherlands) in 1982. He defended his PhD thesis in 1985 at the same university on artificial ceramic middle ear implants, for which he was awarded the Jean Leray award (European Society for Biomaterials), the Marie Parijs award (University of Leiden), and the Kleijn award (University of Utrecht) in the following years. Today, most of his research deals with tissue engineering and regenerative medicine and is based on multidisciplinary research between materials and life sciences. He founded the MERLN Institute for Technology-Inspired Regenerative Medicine in 2014 and acted as its Director until 2019. He is currently a Distinguished Professor of Complex Tissue Regeneration at Maastricht University.

Van Blitterswijk is one of the preeminent scientists in the Netherlands and is a leader of his field internationally. With >500 peer-reviewed published papers (h-index 114, >48,000 citations), van Blitterswijk is in the top-ten, most-cited scientists worldwide in the fields of biomaterials and tissue engineering (Web of Science) and holds the top position in Europe. He has published papers with authors from 25 different countries. He has edited four books, including the first dedicated to tissue engineering. He has received over 250 invitations to present at international conferences and workshops. In addition to his scientific achievements, van Blitterswijk has raised large national structural funding for research in biomaterials, tissue engineering, and regenerative medicine. For example, he has been involved in (often leading) the establishment of Translational Excellence in Regenerative Medicine (TeRM; €25M; main applicant), Netherlands Initiative for Regenerative Medicine (NIRM; €84M), and Biomedical Materials (BMM; €90M). He moved to Maastricht University as part of the triple-helix Kennis-As initiative (€25M) and founded the quadruple-helix, international RegMed XB consortium (with a commitment for €250M).

Van Blitterswijk is recognized at the highest level in the Netherlands as a member of the Royal Netherlands Academy of Arts and Sciences (KNAW) since 2012 and the Royal Holland Society of Sciences and Humanities (KHMW) since 2016. He has received many of the prestigious international awards in his field (e.g., the Career Achievement award of the EU-Chapter of TERMIS, appointment as a Fellow of the International Union of Societies for Biomaterials Science and Engineering, and both the Jean Leray and George Winter awards from the European Society for Biomaterials). He won the 2012 award for the most entrepreneurial scientist in the Netherlands and the 2015 Huijbersen award for performing ground-breaking science with societal impact. He has been granted some of the most prestigious research subsidies in Europe (e.g., the ERC Advanced Grant) and in the Netherlands (e.g., the NWO Gravitation). Van Blitterswijk has raised hundreds of millions in total for his research (~€175M), the major consortia he has (co-)founded, and his companies (~€150M).

During his career Prof. van Blitterswijk has also co-founded multiple biomedical companies and held several functions in these organizations. He acted as CEO of IsoTis (a public life sciences company in the Netherlands) from 1996 to 2002, a company that he co-founded and grew to 150 people. As a result of his work, 10 implant technologies have been brought into clinical evaluation in humans. He combines his professorship with being a Founding Partner of the new Health Economics Fund (LSP-HEF) of the European health care investment group Life Sciences Partners (LSP) in Amsterdam. The focus is on investments in mature innovative medical technology companies that can reduce costs in health care while providing high quality health care to patients.
Invited Keynote Speakers

Ovijit Chaudhuri

Associate Professor at the Department of Mechanical Engineering at Stanford University, Stanford, USA

Talk: K08-KL01 | Extracellular matrix viscoelasticity and its impact on cells
Date: Wednesday, 8 September, 2021, 3:45 PM
Track: 02

Ovijit Chaudhuri is an Associate Professor in the Department of Mechanical Engineering at Stanford University. He earned a B.S. in engineering physics with a minor in mathematics at UC Berkeley. Then, he obtained his Ph.D. in bioengineering at UC Berkeley and UC San Francisco, studying force generation and mechanics of actin cytoskeletal networks. From there, he went on to do a postdoctoral fellowship at Harvard University, studying cell mechanotransduction and developing engineered biomaterials for 3D culture. He joined Stanford in 2013. His group's research interests are broadly in cell biophysics and cell-matrix mechanotransduction in 3D microenvironments. More specifically, his group's work has focused on understanding the impact of extracellular matrix viscoelasticity on cell behaviors in the context of cell migration, cell division, breast cancer progression, cartilage tissue engineering, and stem cell differentiation, using engineered biomaterials for 3D cell culture. His honors include a National Science Foundation CAREER award, a DARPA young faculty award, an American Cancer Society research scholar award, and a National Institutes of Health MERIT award. More information about his group's work can be found at http://chaudhurilab.stanford.edu or be followed on twitter @theChaudhurilab.

Luisa De Cola

Professor at the University of Milan, Italy; Head of the unit Materials for Health at the Istituto di Ricerche Farmacologiche Mario Negri, IRCCS, Italy

Talk: K01-KL01 | Hybrid nanoparticles and hydrogels for biomedical applications
Date: Monday, 6 September, 2021, 11:30 AM
Track: 02

Luisa De Cola is since November 2020 Professor at the University of Milan and head of the unit Materials for Health at the Istituto di Ricerche Farmacologiche Mario Negri, IRCCS, Italy. She is also part time scientist at the INT-KIT, Karlsruhe, Germany. Since 2019 Honorary Professor at Tianjin University, China. She was born in Messina, Italy, where she studied chemistry. After a post-doc in USA she was appointed Assistant Professor at the University of Bologna (1990). In 1998 she was appointed Full Professor at the University of Amsterdam, The Netherlands. In 2004 she moved to the University of Muenster, Germany. In 2012 she has been appointed Axa Chair of Supramolecular and Bio-Material Chemistry, at the University of Strasbourg. She is recipients of several awards, the most recent being the ERC advanced grant, the International Prize for Chemistry “L. Tartufani” from Accademia dei Lincei, the Catalan -Sabatier prize from the Spanish Royal Academy of Science (2015), the Izatt–Christensen Award in Macrocyclic and Supramolecular Chemistry (2019), the gold Medal Natta (2020). She is one of the 39 selected women chemists, from all times, at the Science Museum of Valencia (Ciutat de les Arts y de les Ciencies), Spain. She has been Nominated “Chevalier de la Légion d’ Honneur” by the President of the French Republic, François Hollande, and she is a member of the German National Academy of Sciences Leopoldina, of the Istituto Lombardo Accademia di Scienze e Lettere and she has just been nominated fellow of the American Institute For Medical and Biological Engineering (AIMBE).
Her main interests are luminescent and electroluminescent systems and their assemblies and nano- and porous structures for biomedical applications. She has published more than 370 papers (H index =77), and filed 38 patents.
Jennifer H. Elisseeff

Professor and Director, Translational Tissue Engineering Center
Wilmer Eye Institute and Departments of Biomedical Engineering, Orthopedic Surgery, Chemical and Biological Engineering, and Materials Science and Engineering at Johns Hopkins University, Baltimore, USA

Talk: K05-KL01 | Mapping the immune and stromal response to biomaterials
Date: Tuesday, 7 September, 2021, 4:15 PM
Track: 01

Dr. Elisseeff is the Morton Goldberg Professor and Director of the Translational Tissue Engineering Center at Johns Hopkins Department of Biomedical Engineering and the Wilmer Eye Institute with appointments in Chemical and Biological Engineering, Materials Science and Orthopedic Surgery. She was elected a Fellow of the American Institute of Medical and Biological Engineering, the National Academy of Inventors, and a Young Global Leader by World Economic Forum. In 2018, she was elected to the National Academy of Engineering and National Academy of Medicine. Jennifer received a bachelor's degree in chemistry from Carnegie Mellon University and a PhD in medical engineering from the Harvard-MIT Division of Health Sciences and Technology. Later she was a Fellow at the National Institute of General Medical Sciences, Pharmacology Research Associate Program, where she worked in the National Institute of Dental and Craniofacial Research. She has published over 200 papers, book chapters, and patent applications and received a number of awards including the Carnegie Young Alumni Award and in 2002 she was named by MIT Technology Review as a top innovator under 35. Jennifer's research focus is the development of biomaterials for regenerative medicine applications in orthopedics, plastic and reconstructive surgery, and ophthalmology. She is now studying Biomaterials-directed Regenerative Immunology and the role of the adaptive immune system in tissue repair. She is committed to the translation of regenerative biomaterials and has founded several companies and participates in several industry advisory boards.

Peter Ertl

Vienna University of Technology, Vienna, Austria

Talk: K02-KL01 | Application of Organ-on-a-Chip Systems in Precision Medicine
Date: Monday, 6 September, 2021, 2:00 PM
Track: 02

Prof. Ertl holds an engineering degree in Biotechnology (University of Life Sciences, Austria), a PhD in Chemistry (University of Waterloo, Canada) and received his postdoctoral training as a biophysicist at University of California at Berkeley (US). In 2003 Dr. Ertl co-founded a biotech start-up company, where he served a number of years as Director of Product Development in Kitchener (Canada) developing benchtop-sized microbial analyzers. In 2006 Dr. Ertl moved to Austria where he worked as Senior Scientist in the Biosensor Technology unit at the Austrian Institute of Technology (AIT). Dr. Ertl was also granted a Fulbright Visiting Scholarship at UC Berkeley (2012) and conducted visiting scientist positions at Nanyang Technological University, Singapore (2013), the Medical Center of the University of California at San Francisco (2014) and Imperial College London (2019). In 2016 he was appointed Professor of Lab-on-a-Chip Systems for Bioscience Technologies at the Vienna University of Technology (TUW), where his research focuses on the development of advanced in vitro diagnostic microsystems and organ-on-a-chip systems. Dr. Ertl is also speaker of the Austrian Microfluidics Initiative, Editor-in-Chief of the open access journal Organs-on-a-Chip (Elsevier) and Chief Technology Officer (CTO) of SAICO Biosystems.
Gabor Forgacs

University of Missouri-Columbia; Scientific Founder, Organovo; CSO, Modern Meadow, USA

Talk: K03-KL01 | Biofabrication in commercial setting
Date: Monday, 6 September, 2021, 3:45 PM
Track: 02

Gabor Forgacs is a theoretical physicist turned biophysicist turned bioengineer turned innovator and entrepreneur. His academic affiliations include the George Vineyard Chair in Biophysics at the University of Missouri-Columbia and the Chanderna-Stirkey Chair in Theoretical Physics at Clarkson University, where he also served as the Scientific Director of the Shipley Innovation Center. He is the scientific founder of Organovo, Inc., Modern Meadow, Inc. and Fork & Goode, Inc. and is the Chief Scientific Officer of the latter. He was trained as a physicist at the Roland Eotvos University, Budapest, Hungary. He also has a degree in biology. His research interests and contributions span from topics in theoretical physics to physical mechanisms in early embryonic development. He is the author of over 200 scientific publications and 5 books, in particular the co-author of the celebrated text in the field, “Biological Physics of the Developing Embryo” that discusses physical mechanisms that guide embryonic development. He applies these mechanisms to build organ structures using bioprinting, a technology he pioneered. Such structures are already used for drug development and testing. The technology has also been adapted to engineer consumer products of animal origin such as leather and meat in environmentally friendly and ethically conscious manner. Dr. Forgacs has been recognized by numerous prizes and awards. In particular, he is a member of the National Academy of Innovators and was named as one of the “100 most innovative people in business in 2010” by FastCompany.

Ben M. Maoz

Department of Biomedical Engineering, Sagol School of Neuroscience, The Center for Nanoscience and Nanotechnology, Tel Aviv University, Israel

Talk: K09-KL01 | Organs-On-a-Chip: A New Tool for the Study of Human Physiology
Date: Thursday, 9 September, 2021, 11:45 AM
Track: 01

Dr. Ben Maoz is a faculty member in the Department of Biomedical Engineering, and Sagol School of Neuroscience at Tel Aviv University. Dr. Maoz did his Ph.D in Chemistry at Tel Aviv University under the supervision of Prof. Gil Markovich. He returned to Israel after completing his postdoctoral fellowship at the Wyss Institute at Harvard University at the lab of Prof. Don Ingber and Prof. Kit Parker where he did groundbreaking work in the field of Organs-on-a-Chip. Dr. Maoz received number of prestigious awards such as ERC, Harvard-Wyss technology fellow, Azrieli fellowship for excellence science and others. More information on the MaozLab can be found in https://www.maozlab.com/ and his publication list under https://www.maozlab.com/publications.
Massimiliano Papi

Associate Professor of Biophysics at the Università Cattolica del Sc in Rome, Italy

Talk: K04-KL01 | Optical reduction and shaping of graphene-oxide for controlled bone tissue regeneration and bacterial killing

Date: Tuesday, 7 September, 2021, 11:30 AM

Track: 01

Massimiliano Papi is an Associate Professor of Biophysics at the Università Cattolica del Sc in Rome, Italy. His interests lie at the nexus of physics, biology and biotechnology and he carried out research in the area of biophysics, from single molecules to cells and tissues. Current main research interests are: Development of antibacterial and antiviral surfaces and materials. In this field, new materials and biomaterials based on nanoparticles such as graphene, titanium, silver and mxene have been developed to acquire specific antiviral, bacteriocidal and bacteriostatic properties. Various techniques have been developed for the realization of new materials such as 3D printing for the creation of customized antibacterial and antiviral structures. The technology to integrate antimicrobial nanoparticles into tissues has also been optimized. Nanoparticles-based drug delivery. Numerous innovative approaches have been developed in this field for the transport of a pharmaceutical compound in the body to safely obtain the desired therapeutic effect. Several new biotechnological platforms have been created to optimize the achievement of the site within the body and to facilitate systemic pharmacokinetics. Current research activity in drug transportation includes the development of a targeted release in which the drug is active only in the target area of the body (e.g. in cancerous tissues) and prolonged-release formulations, in which the drug is released for a period of time in a controlled way. Discovery of clinical biomarkers. In this activity, different techniques and approaches of both microscopy and spectroscopy have been developed and refined. The new biomarkers developed in recent years are morphological biomarkers, biomechanical biomarkers and molecular biomarkers. 3D-Bioprinting of biological systems. In this field, an innovative facility in the Gemelli Technological Park has been recently realized. Several biological systems for tissue engineering has been developed: 3D scaffolds for bone and muscle reconstruction and regeneration, 3D tumor models for cancer research; 3D biological microenvironment for drug testing.

Milica Radisic

Professor at the Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, Canada

Talk: K07-KL01 | Optimizing synergy between materials and cell microenvironments using functional polyesters

Date: Wednesday, 8 September, 2021, 3:45 PM

Track: 01

Dr. Milica Radisic is a Professor at the University of Toronto, Canada Research Chair in Functional Cardiovascular Tissue Engineering and a Senior Scientist at the Toronto General Research Institute. She is also the Associate Chair-Research for the Department of Chemical Engineering and Applied Chemistry at the University of Toronto, Director of the NSERC CREATE Training Program in Organ-on-a-Chip Engineering & Entrepreneurship and Director of Ontario-Quebec Center for Organ-on-a-Cho Engineering. She obtained B.Eng. from McMaster University, and Ph.D. form the Massachusetts Institute of Technology. She is a Fellow of the Royal Society of Canada-Academy of Science, Canadian Academy of Engineering, the American Institute for Medical & Biological Engineering and Tissue Engineering & Regenerative Medicine Society. She received numerous awards and fellowships, including MIT Technology Review Top 35 Innovators under 35. She was a recipient of the Professional Engineers Ontario-Young Engineer Medal in 2011, Engineers Canada Young Engineer Achievement Award in 2012, Queen Elizabeth II Diamond Jubilee Medal in 2013, NSERC E.W.R Steacie Fellowship in 2014, YWC Toronto Woman of Distinction Award in 2018, and OPEA Research & Development Medal in 2019 to name a few. Her research focuses on organ-on-a-chip engineering and development of new biomaterials that promote healing and attenuate scarring. She
developed new methods to mature iPSC derived cardiac tissues using electrical stimulation. Currently, she holds research funding from CIHR, NSERC, CFI, ORF, NIH, and the Heart and Stroke Foundation. She is an Associate Editor for ACS Biomaterials Science & Engineering, a member of the Editorial Board of Tissue Engineering, Advanced Drug Delivery Reviews, Regenerative Biomaterials, Advanced Biosystems, Journal of Molecular and Cellular Cardiology and eLife. She serves on review panels for Canadian Institutes of Health Research and the National Institutes of Health. She is actively involved with BMES (Cardiovascular Track Chair in 2013 and 2104) and TERMIS-AM (Council member, Chair of the Membership Committee). She was a co-organizer of a 2017 Keystone Symposium, “Engineered Cells and Tissues as Platforms for Discovery and Therapy”. She served on the Board of Directors for Ontario Society of Professional Engineers and currently serves on the Board of Directors of Canadian Biomaterials Society. Her research findings were presented in over 200 research papers, reviews and book chapters with h-index of 61 and over 13,000 citations. Her publications appear in prestigious journals such as: Cell, Nature Materials, Nature Methods, Nature Protocols, Nature Communications, PNAS etc. In 2014, she co-founded an award winning company TARA Biosystems that uses matured human engineered heart tissues in drug development. TARA currently tests drugs for major pharmaceutical companies. In 2017, she founded Quthero Inc, a company focused on disrupting the skin regeneration and wound healing market through the use of proprietary Q-gel to promote scar-free wound healing.

Meital Reches

Associate Professor at the Institute of Chemistry and the Center for Nanoscience and Nanotechnology, the Hebrew University of Jerusalem, Israel

Talk:  K10-KL01 | Supramolecular peptide assemblies as a platform for antifouling, antimicrobial and antiviral materials

Date:  Thursday, 9 September, 2021, 11:45 AM
Track:  02

Meital Reches is an Associate Professor at the Institute of Chemistry and the Center for Nanoscience and Nanotechnology, the Hebrew University of Jerusalem. After completing her Ph.D. studies at Tel Aviv University in 2007 (supervisor: Prof. Ehud Gazit) and spending three years as an EMBO and a HFSP postdoctoral research fellow at Harvard University, (supervisor: Prof. George Whitesides), Prof. Reches established her independent research group at the Hebrew University in 2010. Research in the Reches group focuses on understanding the interactions of biological entities such as proteins, bacteria, viruses and cells with surfaces. In addition, her group develops surfaces to control these interactions. One example is a peptide-based coating that prevents bacterial adhesion and attracts mammalian cell. Altogether, Prof. Reches has over 80 papers in peer-reviewed journals (including Science, Nature Nanotechnology, Nature Communications, Advanced Materials, ACS Nano and PNAS), two book chapters and 13 families of patents. For her innovations, she was awarded by the Hebrew University with the prestigious Kaye Award for Innovation, the Marie Currie Alumni Association Best Innovator Award and the Tenne Family Prize in Nanoscale Sciences.
Goreti Sales received a degree in pharmaceutical sciences in 1994 and a PhD in analytical chemistry in 2000, from the Faculty of Pharmacy of Porto University. She is Associate professor in the Department of Chemical Engineering of the Faculty of Sciences and Technology of the University of Coimbra. Her research interests are focused on biomimetic nanomaterials and biosensing devices. She coordinates the research group BioMark@UC, since 2020, and she was the founder (in 2011) of the research group BioMark@ISEP. She was awarded (in 2012) a Starting Grant by the European Research Council, targeting a new technical approach that merges biosensors with solar cells, and she is currently coordinating the FET-Open project (H2020) MindGAP.
Khuloud Al-Jamal is a Chair of Drug Delivery & Nanomedicine and Head of Medicines Developments at the Institute of Pharmaceutical Science, King’s College London. She has developed an extensive experience in designing and developing novel nanoscale delivery systems including dendrimers, liposomes, quantum Dots, polymers, viral vectors, chemically functionalised carbon nanotubes and graphene oxide. Her current work involves pre-clinical translation nanomedicines with special interests in brain diseases and cancer. She received several awards including the Maplethrope Research and Teaching Award, BBSRC New Investigator Award, Royal Pharmaceutical Society of Great Britain Science Award, the Controlled Release Society Nanomedicine and Nanoscale Delivery Focus Group Young Investigator Award and Wellcome Trust Image Awards. She is a member of the General of Pharmaceutical Council. She is a management board member and is on the steering committee of the London Centre of Nanotechnology and the Children Brain Tumour Drug Delivery Consortium. She is on the Editorial Board of Biomaterials Science (RSC), MedBioMed (Wiley), Scientific Reports (Nature Publisher) and Journal of Drug Targeting. She is a member of the General of Pharmaceutical Council and a Fellow of Royal Society of Chemistry.

Ana Paula Rosifini Alves Claro, Ph.D., FSBE, is currently Principal Investigator, Head of the laboratory for Development of New Biomedical Materials, and Full Professor at the São Paulo State University (UNESP). Dr. Alves Claro has over twenty years of experience in the field of Biomaterials. She was elected Vice-president of SLABO in 2018. Dr. Alves Claro is a member of the Editorial Board In vitro Models. In the last years, she supervised Ph.D. and MSc students and is involved in mentoring postdoctoral research fellows.
Luigi Ambrosio

Institute of Polymers, Composites and Biomaterials (IPCB), National Research Council, Naples, Italy

ESB-French Society for the Development of Biomaterials (BIOMAT) Joint Symposium ESB-BIOMAT S-KL01 | Nano-biocomposites: from tissue repair/regeneration to therapeutic behaviour

Talk: What Will be the Future Biomaterials Implanted in Humans? Tribute to Prof. Charles Baquey
Date: Tuesday, 7 September, 2021, 11:30 AM
Track: 05

Luigi Ambrosio is Director of Institute of Polymer, Composites & Biomaterials, National Research Council, Naples, Italy. He received the doctoral degree in Chemical Engineering (1982) from University of Naples „Federico II”. He was Research Associate at University of Naples (1983-1985), Research Associate at University of Connecticut, USA (1985-1986), and Visiting Scientist at Kontron Medical Inc., USA (1986-1988). Adjunct Professor of University of Connecticut, USA (1997-2003) and of University of Naples „Federico II” (1997-2010). Qualified Full Professor in Bioengineering and in Materials Science and Technology. Director of Institute of Composites and Biomedical Materials, National Research Council, Naples, Italy (2008-2012). President of the European Society of Biomaterials (2007-2013), Past President (2013-2017), Honorary Member (since 2018). Director of Chemical Sciences & Materials Technology Department, National Research Council, Rome, Italy (2011-2017). Member of the High Level Group on Key Enabling Technologies, European Commission (2010-2015). Member of the International Advisor Board of Sichuan University and Co-Director of MPBRC, SCU-CNR Joint Research Centre. (since 2016). He is recipient of the „G. Winter Award”, for the high worldwide contribution to the Biomaterials Science, European Society for Biomaterials (March 2015). China-Italy Science and Technology Innovation Cooperation Contribution Award, China-Italy Technology Transfer Centre, Nov. 2017, Beijing, China. Member of the Scientific Committee on Chemical and Biomolecular Research of the Microbiome: Nutritional Applications and Impact on Metabolic Health. Université Laval, Quebec, Canada. (since 2016). Co-Chairmen of the Working group on “Advanced Materials and Nanotechnologies” Italy-USA Cooperation on Science and Technology, 12th Joint Commission Meeting. Italian Ministry of Foreign Affairs and International Cooperation (since 2016). He has been nominated Fellow of American Institute for Medical and Biological Engineering (2001), Fellow of Biomaterials Science and Engineering (2004) and Fellow of the European Alliance for Medical and Biomedical Engineering & Science (2018) and Member of the European Academy of Science (2019). Editor-in-Chief of Journal of Materials Science: Materials in Medicine (since 2017). Research interests include design and characterisation of polymers and composites for medical applications and tissue engineering, structural properties of natural tissue, properties and processing of polymers and composites and nanostructures, hydrogels and biodegradable polymers, additive technologies. Publications include over 320 papers on international scientific journals and book, 18 patents, over 170 invited lectures and over 500 presentations at international and national conferences, (Google Scholar H-Index: 73).
Daniel G. Anderson

Massachusetts Institute of Technology, David H. Koch Institute for Integrative Cancer Research / Institute for Medical Engineering and Science / Harvard and MIT Division of Health Science and Technology / Department of Chemical Engineering, Cambridge, USA

Talk: S11-KL01 | Nucleic acid delivery systems for RNA therapy and genome editing
Date: Wednesday, 8 September, 2021, 11:30 AM
Track: 04

Daniel G. Anderson is a Professor in the Department of Chemical Engineering, the Institute for Medical Engineering and Science, the Koch Institute for Integrative Cancer Research, and the Harvard-MIT Division of Health Science and Technology at MIT. The research done in Prof. Anderson’s laboratory is focused on developing new materials for medicine. He has pioneered the development of smart biomaterials, and his work has led to advances in a range of areas, including medical devices, cell therapy, drug delivery, gene therapy and material science. Prof. Anderson received a B.A. in mathematics and biology from the University of California at Santa Cruz and a Ph.D. in molecular genetics from the University of California at Davis. His work has resulted in the publication of over 400 papers, patents and patent applications. These advances have led products that have been commercialized or are in clinical development, as well as to the foundation of companies in the pharmaceutical, biotechnology, and consumer products space. Dr. Anderson is a founder of Living Proof, Olivo Labs, Crispr Therapeutics (CRSP), Sigilon Therapeutics, Verseau Therapeutics, Orna, and VasoRx.

Nasim Annabi

Department of Chemical and Biomolecular Engineering, University of California, Los Angeles (UCLA), USA

Talk: ESB-Biomaterials Science-KL01 | Multifunctional adhesive biomaterials for medical applications
Date: Wednesday, 8 September, 2021, 11:30 AM
Track: 06

Nasim Annabi is an Assistant Professor in the Department of Chemical and Biomolecular Engineering at University of California, Los Angeles (UCLA). She received a PhD in Chemical Engineering from the University of Sydney (Australia). From 2011-2014, she was a postdoctoral fellow at Harvard Medical School and the Wyss Institute for Biologically Inspired Engineering. Before joining UCLA in 2018, she was an Assistant Professor in the Department of Chemical Engineering at Northeastern University. Dr. Annabi’s group has expertise in the design and engineering of advanced biomaterials for applications in regenerative medicine. In addition, her research team has devised innovative strategies for the development of advanced bioadhesives and surgical sealants with high clinical translation for surgical applications. Dr. Annabi has published over 136 articles in peer-reviewed journals. She has been cited over 13,338 times and her H index is already at 58. Her innovations have resulted in 15 patents and generated significant commercial interest. Dr Annabi has been recognized with several national and international awards including the 2021 Young Investigator Award from the Society for Biomaterials (SFB), the 2020 Nanoscale Science and Engineering Forum (NSEF) Young Investigator Award of American Institute of Chemical Engineers (AIChE), the Australian Prestigious Endeavour Award, and the National Health and Medical Research Council Early Career Award. Her team has received major grants from the National Institutes of Health (NIH), the Department of Defense (DOD) and the American Heart Association (AHA).
Helena S. Azevedo is a Reader in Biomedical Engineering & Biomaterials at the School of Engineering & Materials Science in Queen Mary University of London where she leads her own research group. Her work focuses on self-assembling hyaluronan-peptide biomaterials for cell culture, drug delivery, regenerative medicine, and biosensing. She is author of >100 publications, including papers in Science, Nat Chem, Nat Comm, Adv Funct Mater, Nano Lett, Adv Health Mater, and has edited 3 books on natural-based biomaterials, self-assembling biomaterials and soft matter for biomedical application. She is a Fellow of the Royal Society of Chemistry (FRSC), Member of the Advisory Board of the RSC journal Molecular Systems Design & Engineering and Associate Editor of the Journal of Tissue Engineering and Regenerative Medicine (Wiley).

Aldo R. Boccaccini is Professor and Head of the Institute of Biomaterials at University of Erlangen-Nuremberg, Germany. He is also visiting Professor at Imperial College London, UK. He holds a nuclear engineering degree from Instituto Balseiro (Argentina), Dr.-Ing. (PhD) from RWTH Aachen University (Germany) and Habilitation from Technical University of Ilmenau (Germany). Prior to his current position, he spent 10 years at Imperial College London, Department of Materials, as Lecturer, Reader and Professor of Materials Science. He has held post-doctoral positions at University of Birmingham (UK) and University of California, San Diego (USA). He was Head of the Department of Materials Science and Engineering in Erlangen (2017-2019). The research activities of Prof. Boccaccini are in the field of ceramics, glasses and composites for biomedical, functional and/or structural applications. He is the author or co-author of more than 900 scientific papers and 25 book chapters. His work has been cited more than 46,000 times (h = 94, Scopus, “Highly cited researcher” 2014 and 2018). He is the Editor-in-Chief of the journal “Materials Letters” (Elsevier). He serves in the editorial board of more than 10 international journals. Boccaccini has been a visiting professor at different universities around the world. He is a Fellow of the Institute of Materials, Minerals and Mining (IOM3) (UK), the American Ceramic Society, the Society of Glass Technology (UK) and the European Ceramic Society. His achievements have been recognized with several awards including the Materials Prize of the German Materials Society (DGM) in 2015, the Turner Award of International Commission on Glass (2016) and Friedberg Lecture Award (2016) of American Ceramic Society. Boccaccini is also an elected member of the World Academy of Ceramics and of the National Academy of Engineering and Applied Sciences of Germany (acatech) and advisor to the Science and Technology Ministry of Argentina. Boccaccini serves in the Executive Committee of the Federation of European Materials Societies (FEMS) representing the German Materials Society and he has been a member of the Council of the European Society for Biomaterials (ESB) since 2015. He has served in several review panels of the European Research Council (ERC) and of the German Research Foundation (DFG).
Jan de Boer

Institute for Complex Molecular Systems and department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, the Netherlands

Talk: S13-KL01 | Biomaterial surface topography induces cell signaling events that control cell phenotype: how does it work and how can we use it?

Date: Wednesday, 8 September, 2021, 3:45 PM
Track: 04

Jan de Boer is chair of the BioInterface Science lab at the Institute for Complex Molecular Systems and department of Biomedical Engineering at Eindhoven University of Technology. He studied biology at the University of Utrecht and obtained his PhD in the lab of Jan Hoeijmakers at the Erasmus MC Rotterdam on mouse models for premature ageing in 1999. After a postdoc at the MRC Laboratory of Molecular Biology in Cambridge, UK, he started as a research associate at IsoTis B.V. where his research focused on bone tissue engineering, which was continued as associate professor at the University of Twente and as full professor at the University of Maastricht.

Jan studies the interplay between cells biomaterial, and how to use molecular circuits to control cell and tissue function. With a background in mouse and Drosophila genetics, he entered the field of biomedical engineering in 2002 and has since focused on understanding and implementing molecular biology in the field of tissue engineering, regenerative medicine and medical devices interface biology. His research is characterized by a holistic approach to both discovery and application, aiming at combining high throughput technologies, computational modeling and experimental cell biology to streamline the wealth of biological knowledge to real clinical applications.

He is former chair of the Netherlands Society for Biomaterials and Tissue Engineering, CEO and co-founder of Materiomics b.v., co-founder of the Platform for Therapeutic Biomaterials Discovery and co-founder of the Merln Institute for Technology-inspired Regenerative Medicine.

Horacio Cabral

Department of Bioengineering, Graduate School of Engineering, The University of Tokyo, Japan

Talk: ESB-CRS S-KL02 | Tumor-Targeted Nanomedicine Approaches for Enhanced Immunotherapy

Date: Tuesday, 7 September, 2021, 12:00 PM
Track: 04

Horacio Cabral is an Associate Professor in the Department of Bioengineering, Graduate School of Engineering, The University of Tokyo. He received his Ph.D. in Materials Engineering from The University of Tokyo in 2007 under the supervision of Prof. Kazunori Kataoka. Dr. Cabral was an Assistant Professor at the Center for Disease Biology and Integrative Medicine, Graduate School of Medicine, The University of Tokyo, until 2010, when he joined the Department of Bioengineering of The University of Tokyo as a Lecturer. In 2014, he was promoted to his current position.

Dr. Cabral’s major research interests relate to the development of nanomedicines for diagnosis and therapy, particularly systems directed to intractable cancers. He has made major influential achievements in the development of translatable polymeric nanocarriers. Particularly, his polymeric micelles targeting anticancer drugs to tumors have proceeded into human clinical studies, improving patients’ survival and reducing side effects. Moreover, he has accomplished seminal contributions in the understanding of the effect of nanocarrier design on activity, particularly through intratumoral and intracellular navigation. He has published more than 100 articles in refereed journals, including Nature Nanotechnology, Nature Reviews Clinical Oncology, Science Translational Medicine, PNAS, etc., and he is inventor of more than 30 patents.

Dr. Cabral has been recipient of several awards, such as the Asahi Glass Foundation and the Mochida Memorial Foundation for Medical and Pharmaceutical Research. He currently serves on the editorial board of Science and Technology of Advanced Materials, and Nanomaterials, and the advisory board of Macromolecular Bioscience and MedChem.

Page 42 of 2028
Gianni Ciofani
Senior Researcher Tenured, Istituto Italiano di Tecnologia, Smart Bio-Interfaces, Principal Investigator Center for Materials Interfaces, Coordinator, Pontedera (Pisa), Italy

Talk: S04-KL02 | Piezoelectric materials for biomedical applications: From tissue engineering to cancer nanomedicine
Date: Monday, 6 September, 2021, 2:30 PM
Track: 03

Gianni Ciofani is Senior Researcher Tenured at the Istituto Italiano di Tecnologia (Italian Institute of Technology, IIT, Italy), where he is Principal Investigator of the Smart Bio-Interfaces Research Line (https://www.iit.it/research/lines/smart-bio-interfaces) and Coordinator of the Center for Materials Interfaces (https://www.iit.it/centers/cmi-sssa).
He received his Ph.D. in Innovative Technologies (with honors) from the Scuola Superiore Sant'Anna (Italy) in 2010. From January 2010 to August 2013 he was Post-Doc at the IIT, Center for Micro-BioRobotics, where, from September 2013 to October 2015, he was Researcher in the framework of the Smart Materials Platform. From October 2015 to October 2019 he was Associate Professor at the Polytechnic University of Torino (Italy), maintaining at the same time his research activity in IIT, where he is Senior Research Tenured since November 2019. His main research interests are in the field of smart nanomaterials for nanomedicine, bio/non-bio interactions, and biology in altered gravity conditions. He is coordinator or unit leader of many grants/projects, and he was awarded an ERC Starting Grant and an ERC Proof-of-Concept Grant in 2016 and 2018, respectively. Gianni Ciofani is author of more than 140 papers on international journals (H-index 38), 3 edited books, and 16 book chapters. He serves as Reviewer for more than 180 international journals, and as Editorial Board Member of Nanomedicine UK, Scientific Reports, International Journal of Nanomedicine, Journal of Physics: Materials, Bioactive Materials, and Advances in Nano Research; he is Specialty Chief Editor (Nanobiotechnology) for Frontiers in Bioengineering and Biotechnology.

Matthew Dalby
Centre for the Cellular Microenvironment, Institute of Molecular, Cell & Systems Biology, MVLS, University of Glasgow, Glasgow, Scotland

Talk: ESB-CSBM S-KL02 | Nanoscale control by materials of mesenchymal stem cells for identification of bioactive metabolites
Date: Monday, 6 September, 2021, 2:30 PM
Track: 04

After a PhD at Queen Mary University of London on osteoblast response to bioactive composites. I moved to Glasgow to study cell-nanoscale interactions. In 2003 I became an independent researcher securing a BBSRC David Phillips Fellowship to explore mesenchymal stem cell response to nanotopography. Appointed to a lecturership in 2008 and a Readership in 2010, I became Professor of Cell Engineering at the University of Glasgow in 2014. I hold grants from EPSRC, MRC, BBSRC, Leverhulme Trust and Sir Bobby Charlton Foundation. I am director of the EPSRC-SFI IiETIME centre for doctoral training.
My research has focussed on developing insight into MSC differentiation and self-renewal using materials and mechanotransductive cues, making contributions in journals such as Nature Materials, Nature Biomedical Engineering, Advanced Materials, Chem, Science Advances etc (>200 papers). More recently I have become interested in using materials to find activity metabolites that can be used to control MSC phenotype. As well as basic science, I am interested in translational science and have been involved in veterinary bone regeneration trials and am working now towards a human bone regeneration trial.
In 2016 I was elected a Fellow of the Royal Society of Edinburgh and have won a number of awards – most recently the Biochemical Society Industrial-Academic Collaboration Award.
Paul Dalton

University of Oregon, USA

Talk: ESB-ISBF S-KL01 | Hybrid Biofabrication using Nano-, Micro- and Macro-scale Features

Date: Tuesday, 7 September, 2021, 4:15 PM

Track: 04

Paul Dalton is an Associate Professor at the University of Oregon who specializes in manufacturing technologies for biomedical applications. An early adopter of melt electrospinning and pioneer of melt electrowriting, his research targets advanced biomaterials that can translate to the clinic. Graduating from Curtin University in Perth, Australia, he was part of a bioengineering team at the Lions Eye Institute that successfully took an artificial cornea from concept to the clinic. His academic career has an international perspective, with post-docs at the University of Toronto and RWTH-Aachen followed by positions at the University of Southampton, Shanghai Jiao Tong University and University of Würzburg. He invented and developed melt electrowriting as a distinct class within 3D printing with the Queensland University of Technology and has over 25 years’ experience across several disciplines.

Nicola Döbelin

RMS Foundation, Bettlach, Switzerland

Talk: S12-KL01 | Biocompatibility assessment of medical devices according to ISO 10993

Date: Wednesday, 8 September, 2021, 3:45 PM

Track: 03

Nicola Döbelin studied Earth Sciences at the University of Bern, Switzerland, from 1998 to 2002. In 2000 he spent three months in South Africa for a field work project before receiving his Master’s degree in 2002 for a thesis on the thermal stability of ion-exchanged natural zeolites studied by single-crystal X-ray diffraction. From 2002 to 2006 he worked on his PhD thesis on ion exchange in synthetic titanosilicate phases under supervision of Prof. Thomas Armbruster at the University of Bern. During this time, he became an expert on X-ray powder diffraction and Rietveld refinement. After receiving his PhD in 2006, Nicola started working as a senior scientist at RMS Foundation in Bettlach, Switzerland, with a focus on research, development, and characterization of bioceramics, specifically of calcium phosphate bone-graft substitutes. In 2010 he became deputy quality manager at RMS and specialized on validation of analytical methods. From 2015 to 2019 he took a part-time position as a senior lecturer at the Institute of Geological Sciences, University of Bern. Since 2016, Nicola leads the bioceramics team at RMS. Thanks to his many years of research on synthetic bone graft substitutes, he is now a recognized expert for the synthesis and characterization of calcium phosphate bioceramics.
Silvia Farè

Department of Chemistry, Materials and Chemical Engineering “G. Natta”, Politecnico di Milano, Milan, Italy

Talk: S07-KL02 | Biomimetic 3D scaffold-based model for in vitro investigation of bone pathologies
Date: Tuesday, 7 September, 2021, 12:00 PM
Track: 03

Silvia Farè obtained her Master of Science degree in Management and Industrial Engineering, Politecnico di Milano, in July 1994. In May 1998, she obtained her PhD degree in Biomaterials (X^ cycle), Politecnico di Milano, with a thesis on the investigation of the mechanisms related to the in vitro oxidative degradation of medical-grade polyurethanes. Silvia Farè obtained a Post-doc research Fellowship (1998 –1999) within the project “Third generation artificial heart” and she was Research Assistant from 1999 to 2003, at the Bioengineering Department, Politecnico di Milano. From 2005 to 2014, she was Assistant Professor at the Bioengineering Department (2005-2012), and at the Department of Chemistry, Materials, and Chemical Engineering “G. Natta” (2013-2014), Politecnico di Milano. From December 2014 to March 2021, she was Associate Professor in Industrial Bioengineering at the Chemistry, Materials and Chemical Engineering, Politecnico di Milano. Starting from April 2021 she is Full Professor at the Department of Chemistry, Materials, and Chemical Engineering “G. Natta”, Politecnico di Milano. From February 1993 to February 1996, she was visiting Master and PhD student at the Joint Research Centre, Institute for Advanced Materials, Ispra (VA), Italy. From March 1996 to September 1996 and from January 1997 to March 1997, she was visiting PhD student at the University of Laval and Quebec Biomaterials Institute, Quebec, Canada under the supervision of Gaetan Laroche and Diego Mantovani. She was Member of National and International Congress Committee. From 2012 she is Associate Editor for the Journal of Applied Biomaterials and Functional Materials (JAB-FM) Sage Ed. In 2005 she was elected as member of the Council of the Italian Society for Biomaterials (SIB), in charge as treasurer, and now she is in charge as President. From 2017 she is one of the members of the Council of the European Society for Biomaterials. From 2001 and up to the current academic year Silvia Farè has been in charge of different courses in biomaterials and regenerative medicine fields at Master and Bachelor in Biomedical Engineering, Politecnico di Milano. Silvia Farè is author and co-authors of one hundred international and national scientific publications related to materials science, in particular to biomaterial and regenerative medicine fields.

Lino Silva Ferreira

CNC | Centro de Neurociências e Biologia Celular, CIBB | Centro de Inovação em Biomedicina e Biotecnologia, University of Coimbra, Coimbra, Portugal;
Faculty of Medicine, University of Coimbra, Coimbra, Portugal

Talk: NANOSTEM 01-KL01 | Modulation of stem cells using nanotechnologies
Date: Monday, 6 September, 2021, 10:40 AM
Track: 08

Lino Silva Ferreira holds a Ph.D. in Biotechnology from the University of Coimbra (Portugal). He did postdoctoral work at INEB (Portugal) and MIT (USA) in the group of Robert Langer in the areas of stem cells and nanotechnologies. He established his research group in 2008 at the University of Coimbra. Since then is the director of the Biomaterials and Stem Cell-Based Therapeutics research group, CNC coordinator of the MIT-Portugal Program and the founder of the biotech company Matera. He is also the associate editor of Biomaterials Science Journal (RSC). In 2012, he was awarded with a prestigious European Research Council starting grant and in 2016 a prestigious ERA Chair position at the University of Coimbra. His group has interest in the development of tissue models from stem cells and in the use of nanomedicine platforms to modulate the activity of endogenous (stem) cells.
Andrés J. Garcia

Executive Director, Parker H. Petit Institute for Bioengineering and Bioscience; Regents' Professor, George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, U.S.A.

Talk: ESB-SFB S-KL01 | Biosynthetic Hydrogels for Islet Engraftment and Immune Acceptance
Date: Wednesday, 8 September, 2021, 3:45 PM
Track: 05

My research program centers on integrating innovative engineering, materials science, and cell biology concepts and technologies to generate (i) novel insights into the regulation of adhesive forces and mechanotransduction, and (ii) biofunctional materials (hydrogels, coatings, and nanoparticles) to control protein/cell delivery and tissue repair. This cross-disciplinary effort has resulted in new biomaterial platforms that elicit targeted cellular responses and tissue repair in various applications (bone repair, therapeutic vascularization, pancreatic islet delivery, and infection), innovative technologies to exploit cell adhesive interactions, and new mechanistic insights into the interplay of mechanics and cell biology. My research has been funded by the NIH, NSF, Coulter Foundation, Arthritis Foundation and Juvenile Diabetes Research Foundation. I have supervised 28 Ph.D. graduates and 13 postdoctoral fellows who have continued onto successful careers in academia, industry and government agencies. I currently supervise 11 Ph.D. students and 4 postdoctoral fellows. I am a co-inventor on 5 issued and 8 pending U.S patents and a co-founder of 3 companies (CellectCell, CorAmi Therapeutics, iTolerance). I am a Fellow of Biomaterials Science and Engineering of the International Union of Societies of Biomaterials Science and Engineering, AIMBE, ASME, and AAAS. I served as President for the Society for Biomaterials for 2018-2019. I am an elected member of the National Academy of Engineering and the National Academy of Inventors.

Maria Pau Ginebra

Universitat Politècnica de Catalunya, BarcelonaTech, Department of Materials Science and Engineering, Barcelona, Spain

Talk: S14-KL01 | 3D printing synthetic bone grafts: challenges and opportunities
Date: Thursday, 9 September, 2021, 11:45 AM
Track: 03

Maria-Pau Ginebra is Professor and Head of the Department of Materials Science and Engineering at the Universitat Politècnica de Catalunya (UPC) in Barcelona, Director of the Biomaterials Division of the Biomedical Engineering Research Center of UPC (CREB) and Associate Researcher at the Institute of Bioengineering of Catalonia (IBEC). She is the author of more than 200 articles published in indexed international journals and 10 patents. In 2013 she founded the company Mimetis Biomaterials, a spin-off of the UPC. Her research lines include the design and development of new biomaterials for bone regeneration, tissue engineering and drug delivery, and the fundamental study of the biological mechanisms that control the interactions of biomaterials with cells and tissues. Her research group has made relevant contributions in the development and characterization of a new generation of biomimetic calcium phosphates, capable of mimicking the extracellular matrix of bone, which may incorporate synthetic or natural polymers, and / or bioactive molecules. She is also working on new biofabrication strategies, including injectable foams for bone regeneration and 3D printing of implants for regenerative medicine, as well as on the design of multifunctional surfaces with bioactive and antimicrobial properties. In 2013 she received the Racquel LeGeros Award from the International Society for Ceramics in Medicine for her contribution to the research in the field of calcium phosphates and in 2019 the Klaas de Groot Prize of the European Society for Biomaterials in recognition of her mentoring of young scientists.
Manuela E. Gomes

3B’s Research Group, I3Bs – Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho, Portugal

Talk: S05-KL01 | Magnetic Assisted 3D bioprinting and mechanoactuation technologies for achieving advanced biofunctionality of 3D constructs and precise models to engineer the regeneration of tendons

Date: Monday, 6 September, 2021, 3:45 PM
Track: 05

Manuela E. Gomes is Associate Professor and President of the I3Bs Research Institute of the University of Minho, Portugal. She graduated in Metallurgical and Materials Engineering, University of Porto, Portugal in 1997, obtained a MSc in Polymer Engineering, Univ. of Minho in cooperation with the company Isotis, Bilthoven (Holland), and a PhD in Materials Science and Engineering – Tissue Engineering/Hybrid Materials in collaboration with the Rice University (USA), in 2005. She was a co-founder of the 3B’s Research Group and one of the vice-directors of the group since 2011. Her research interests currently focus on tendon tissue engineering strategies, namely in the development of scaffold materials and bioinks based on biodegradable natural origin polymers, stem cells sourcing and differentiation (using biochemical and physical methods). Manuela Gomes has been involved in numerous European and national/regional projects as PI or team member. She currently coordinates a Consolidator Grant from the European Research Council (ERC CoG) to develop magnetically assisted tissue engineering technologies for tendon regeneration and with an EC funded Twinning Project – “Achilles: Overcoming specific weaknesses in tendon biology to design advanced regenerative therapies”, among others. Manuela Gomes is editor 2 books and co-editor of the Tissue Engineering Encyclopaedia (Elsevier, 2019) and author of 44 book chapters, over 200 full papers published in international refereed journals, and more than 300 communications in international conferences (7.900 citations, H-index of 47). She has received several awards, including the 2013 Young Investigator Award of the Tissue Engineering and Regenerative Medicine International Society – European Chapter (TERMIS-EU). Manuela Gomes is an active member of several international scientific organizations, being currently a member-at-large and chair of the membership committee of TERMIS, and Portugal Ambassador for the EORS.

Jinlian Hu

Director of Laboratory of Wearable Materials for Healthcare; Joint Professor of Materials Science and Engineering, Department of Biomedical Engineering, City University of Hong Kong, HKSAR, China

Talk: S04-KL01 | Shape Memory Biomaterials and Their Applications

Date: Monday, 6 September, 2021, 2:00 PM
Track: 03

Prof. Jinlian HU is a shape memory polymers, textiles and biomaterials scientist. Graduated from Donghua University in textile materials and received a PhD from Manchester University, she recently joined the Department of Biomedical engineering, City University of Hong Kong where she established a Laboratory of Wearable Materials for Healthcare. The laboratory focuses on unearthing scientific principles and providing solutions to key problems in Healthcare of Wearable Materials in three major areas: Traditional Chinese medical therapies and their materials, energy materials and healthcare as well as spider silks and their relatives as biomaterials as well as personal protective integration. As such, we apply advanced methods including custom-made wearable electronics as basic tools to examine materials, their application methods, and particularly their interactions with human body in terms of physical, chemical, biological, philological and informational relations. From the discoveries and models of basic research, applied investigation, product developments and standardization are envisaged, which can produce societal as well economic impact in addition to scientific advances. Before CityU, professor Hu worked at Hong Kong Polytechnic University for more than 20 years. Professor Jinlian HU is a Fellow of the Royal Society of Chemistry, Hong Kong Institution of Textile and Apparel and the British Textile Institute. She is the founding chairman of the Hong Kong Health Science and Technology Park, the executive vice chairman of the Hong Kong Invention and Innovation Federation and a Council member of the Hong Kong Far Infrared Association.

Wake Forest Institute for Regenerative Medicine, Wake Forest School of Medicine, Winston-Salem, USA

Talk: **S07-KL01 | 3D Bioprinting Strategies to Bioengineer Skeletal Muscle Constructs that Accelerate Muscle Function Restoration**

**Date:** Tuesday, 7 September, 2021, 11:30 AM
**Track:** 03

Sang Jin Lee, Ph.D. is currently a tenured Associate Professor at Wake Forest Institute for Regenerative Medicine (WFIRM), Wake Forest School of Medicine. Dr. Lee received his Ph.D. in Chemical Engineering at Hanyang University, Seoul, Korea in 2003 and took a postdoctoral fellowship in the Laboratories for Tissue Engineering and Cellular Therapeutics at Harvard Medical School and Children’s Hospital Boston and the WFIRM where he is currently a faculty member. He is also cross-appointed to the Virginia Tech-WFU Biomedical Engineering and Science. Dr. Lee has authored more than 150 scientific publications and reviews, has edited 2 textbooks, and has written 34 chapters in several books. Dr. Lee has extensive knowledge and experience in biomaterials science, especially, biodegradable polymers and tunable hydrogels, with specific training and expertise in key research areas for tissue engineering and regenerative medicine. His research team has developed various biomaterial systems that improve cellular interactions by providing appropriate environmental cues. These biomaterial systems consist of drug/protein delivery systems, nano/micro-scaled topographical features, and hybrid materials that can actively participate in functional tissue regeneration. Recently, his team is utilizing automated 3D bioprinting technology to manufacture complex, multi-cellular living tissue constructs that mimic the structure of native tissues. This can be accomplished by optimizing the formulation of biomaterials to serve as bioinks for 3D bioprinting, and by providing the biological microenvironment needed for the successful delivery of cells and biomaterials to discrete locations within the 3D structure.

Kam W. Leong
Columbia University, Department of Biomedical Engineering, New York, USA

Talk: **ESB-BMJ S-03 | ESB-Biomaterials Journal Joint Session: Meet the Editor Session**

**Date:** Tuesday, 7 September, 2021, 04:15 PM
**Track:** 05

Kam W. Leong holds the James B. Duke Professor of Biomedical Engineering in the Pratt School of Engineering of Duke University, at which he also holds a joint appointment in the Department of Surgery of the School of Medicine. He received his undergraduate degree in Chemical Engineering from the University of California at Santa Barbara and his PhD, also in Chemical Engineering, from the University of Pennsylvania. He then ventured into drug delivery research as a postdoctoral fellow in the laboratory of Professor Robert Langer at MIT, where he helped develop the biodegradable polyanhydrides as a drug carrier for brain tumor therapy. After his training at MIT, he joined the faculty in the Department of Biomedical Engineering at The Johns Hopkins School of Medicine, and rose through the rank to become a full professor in 1998. While based at Johns Hopkins, he served as a Program Director in the Institute of Materials Research and Engineering in Singapore to help develop biomaterials research in the Institute from 1998-2004. Around the same time, he also directed a lab in Johns Hopkins Singapore on Therapeutics and Tissue Engineering. He moved to Duke University in 2006 to join the Department of Biomedical Engineering, focusing on the development of nanotherapeutics. In particular, his research concentrates on understanding and exploiting the interactions of cells with nanostructures for therapeutic applications. Discrete nanostructures in the form of multi-functional nanoparticles are applied to deliver drugs, antigen, protein, siRNA, and...
DNA to cells for drug, gene, and immunotherapy. Continuous nanostructures in the form of electrospun nanofiber and imprinted nanopattern are applied to influence cellular behavior, including expansion of various stem cells. The major research projects of his lab are linked by innovative design of polymeric biomaterials and an effort to understand the mechanism of cellular interaction with nanomaterials.

Kam W. Leong serves on the editorial boards of major journals in the fields of biomaterials, drug delivery, nanomedicine, and gene and cell therapy. He owns more than 40 issued patents, and has published over 230 peer-reviewed research manuscripts. His research was recognized by the Young Investigator Research Achievement Award of Controlled Release Society in 1994, and several awards by the same Society on Excellence in Guidance of Graduate Student Research. He also received the Stansell Family Distinguished Research Award from Duke University in 2010.

Changsheng Liu  
Shanghai University, Academician of Chinese Academy of Sciences, Shanghai, China  

**Talk:** ESB-CSBM S-KL01 | Decoding the materiobiology: multiple roles of biomaterials in participating life activities  
**Date:** Monday, 6 September, 2021, 2:00 PM  
**Track:** 04

Changsheng Liu, PhD, Professor of Shanghai University, Academician of Chinese Academy of Sciences. Dr. Liu is director of Engineering Research Center for Biomaterial Materials of Ministry of Education, director of Key Laboratory for Ultrafine Materials of Ministry of Education etc.  
Dr. Liu has interdisciplinary academic background of biology and materials engineering. He has devoted for decades into the fundamental and application research of biological materials. His major research areas include biomaterials and tissue regeneration; fabrication of inductive growth factors and designing of bioactive skeletal substitutes for bone repair; and nano-biomaterials as well. Dr. Liu has obtained a few outstanding achievements in the field of biomaterials. He has published 5 books and more than 290 papers, including the TOP journal of the field, such as Chem Rev, Sci Adv, Biomaterials, Adv Mater, Adv Func Mater, and Acta Biomater, etc. Moreover, he has also applied 65 invention patents including 4 US patents. He developed a few novel biomaterials and got the approval from CFDA, and now widely used in clinic application. He achieved international Fellow of Biomaterials Science and Engineering (2012), American Institute for Medical and Biological Engineering (AIMBE) Fellow (2018), and Ho Leung Ho Lee Foundation-Prize for Scientific and Technological Innovation Award (2007). Furthermore, he won the Second-prize of National Award for Natural Science in 2014, the Second-prize of National Award for Science and Technology Progress in 2003.

Hai-Quan Mao  
Johns Hopkins University, Baltimore, USA  

**Talk:** ESB-BMJ S-03 | ESB-Biomaterials Journal Joint Session: Meet the Editor Session  
**Date:** Tuesday, 7 September, 2021, 04:15 PM  
**Track:** 05

Hai-Quan Mao is the associate director of the Institute of NanoBioTechnology (INBT) and a professor of materials science and engineering at Johns Hopkins University. He holds a joint appointment in the Translational Tissue Engineering Center and the Department of Biomedical Engineering at the School of Medicine. Prof. Mao’s research focuses on engineering novel nanomaterials for regenerative medicine and therapy delivery applications. He has developed nanofiber scaffolds from synthetic and natural biomaterials for liver tissue engineering; stem cell expansion and differentiation; and soft tissue regeneration. He also has discovered a synergistic effect between nanofiber topography and biochemical cues on the proliferation of human hematopoietic stem and progenitor cells.
(HSCs); invented a more efficient HSC expansion method that can enable various HSC-based cellular therapies; engineered different methods for promoting lineage-specific differentiation of neural (crest) stem cells; and developed tailored, nanofiber-based scaffolds for vascular engineering, skeletal muscle regeneration, spinal cord repair and peripheral nerve regeneration. His contributions in therapeutic engineering include understanding the assembly mechanism of nanoparticles from the polyelectrolyte complex of plasmid DNA, RNA or protein therapeutics with charged polymer carriers; engineering DNA nanoparticles with tunable shape and uniformity that mimic natural viral particles; the development of scalable production methods for these therapeutic nanoparticles; and their applications in local and systemic delivery of macromolecular therapeutics and vaccines.

Prof. Mao also serves on the editorial board of ACS Biomaterials Science & Engineering and Journal of Materials Chemistry B. He holds 28 U.S. patents and has published more than 190 peer-reviewed research manuscripts. He has been elected a Fellow of the Royal Society of Chemistry and the American Institute for Medical and Biological Engineering, and a senior member of the National Academy of Inventors. He was the recipient of the Young Investigator Award at the National University of Singapore in 2002 and the National Science Foundation faculty CAREER Award in 2008.

Jesús Martínez de la Fuente

Consejo Superior de Investigaciones Científicas, Instituto de Nanociencia y Materiales de Aragón, Zaragoza, Spain

Talk: ESB-CRS S-KL01 | Nanoactuators for Therapy and Diagnosis
Date: Tuesday, 7 September, 2021, 11:30 AM
Track: 04

Prof. Jesús Martínez de la Fuente (Barakaldo, 1975) created his own research group (BIONANOSURF Group) at the Univ of Zaragoza in 2007, becoming internationally recognized in nanomaterials and biofunctionalization. The multidisciplinary nature of the group facilitates research and development in numerous areas, including biosensors, gene therapy, magnetism, photochemistry, surface chemistry and molecular metal oxides, among others. He has extensive experience in the synthesis and characterization of novel nanomaterials and their biofunctionalization for the use and development of the next generation of nanobiosensors and nanotherapeutics. In 2009, he founded the spin-off Nanoimmunotech SL. He has also been a pioneer in the application of gold nanoparticles in gene therapy and he has developed a methodology for the use of gold nanoparticles functionalized with carbohydrates (glycan nanoparticles) for the study of biological processes (embryogenesis, cancer, inflammation, etc.). He has been PI of research projects with a total budget of more than 6 M€. 75% of this budget is derived from European projects (1 ERANET (Coord); 1 ERC-StG (Coord), 1 ERC-POC (Coord), 7 MSCA-IOF/IEF/IF (Coord), 1 ENMII, 1 TRANSCANII (Coord), 1 FP7, 3 H2020-NMBP); 10% comes from collaborations with companies (CASEN-FLEET, ORPHAN DRUG-RECORDATI, MECWINS, NB, NIT, PROTEOMIKA, BSH, VIRBAC); and the remaining 15% comes from research projects of national calls. In 2010 he was awarded the Aragón Investiga prize „Young Researchers”. In 2013 he was awarded by the Shanghai Administration with the 1000 Talent Plan program to be a visiting professor at the Jiao Tong University of Shanghai. Since 2014, he is a permanent researcher at the Instituto de Nanociencia y Materiales de Aragon-CSIC.
Jonathan Massera

Tampere University, Faculty of Medicine and Health Technology, Tampere, Finland

Talk:  S08-KL01 | Bioactive glasses-based biomaterials with potential in soft tissue engineering

Date:  Tuesday, 7 September, 2021, 4:15 PM

Track:  02

Jonathan Massera is Professor at Tampere University, Finland, in the Faculty of Medicine and Health Technology. He graduated his BSc in Materials Science and Engineering, from the university of Grenoble. He then received a double MSc degree from Polytech’Montpellier (France) and Politecnico di Torino (Italy). He obtained his PhD from Clemson University (SC, USA), in 2009. During his PhD he studied tellurite based fibers for Mid-IR applications. He then received a scholarship to perform his post-doctoral research on the crystallization of bioactive glasses and its impact on bioactivity at Åbo Akademi, Finland. He then was granted a post-doctoral researcher grant from the Academy of Finland. The aim of the project was to combine photonic and bioactive glasses for sensing application. Finally, he became assistant researcher (tenure) at Tampere University, in 2014, where he was also granted the Academy Research Fellow from the academy of Finland. He became full professor in 2021. As of today, Jonathan Massera is head of the bioceramics, bio-glasses and bio-composites research group and head of the international MSC degree programme in Biomedical Sciences and Engineering. His research group focuses on inorganic biomaterials development and their composites/hybrids as well as cell/materiels and protein/materials interactions. Another axis of research deals with combining photonic into bioactive glasses to develop new biophotonic materials for low light therapy, sensing and imaging. Currently his research is funded by the Academy of Finland, The Jane and Aatos Erkko Foundation and EU-H2020.

Clara Mattu

PolitoBIOMed Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Torino, Italy

Talk:  S11-KL02 | Leveraging polymer biomaterials to improve the design of nanomedicines

Date:  Wednesday, 8 September, 2021, 12:00 PM

Track:  04

Dr. Clara Mattu is Assistant Professor in the Department of Mechanical and Aerospace Engineering at Politecnico di Torino. She completed her Ph.D. in the group of Industrial Bioengineering at Politecnico di Torino in 2012. She has been visiting scientist at the Royal College of Surgeons in Ireland in 2011, visiting postdoctoral fellow in the department of Translational Imaging (2014) and in the department of Nanomedicine (2016-2018) at the Houston Methodist Research Institute, and co-founder of the spin-off Company Geltis. In 2012, she was awarded the Italian Working Capital National Innovation grant (30.000 €) to perform research on injectable hydrogels for drug delivery. In 2015, she received the prestigious Marie Curie International Outgoing Fellowship from the European Commission to design hybrid drug delivery systems for intra-cranial treatment of brain tumors. Her research interests are highly super-disciplinary, and span from biomedical polymer synthesis to cancer nanomedicine.
Lorenzo Moroni

Maastricht University, MERLN Institute, Dept. of Complex Tissue Regeneration, The Netherlands

Talk: S01-KL01 | Integrating biofabrication with organ-on-chip technologies: marrying micro with macro for improved 3D in vitro models.

Date: Monday, 6 September, 2021, 11:30 AM

Prof. Dr. Lorenzo Moroni studied Biomedical Engineering at Polytechnic University of Milan, Italy, and Nanoscale Sciences at Chalmers Technical University, Sweden. He received his Ph.D. cum laude in 2006 at University of Twente on 3D scaffolds for osteochondral regeneration, for which he was awarded the European doctorate award in Biomaterials and Tissue Engineering from the European Society of Biomaterials (ESB). In 2007, he worked at Johns Hopkins University as a post-doctoral fellow in the Elisseeff lab, focusing on hydrogels and stem cells. In 2008, he was appointed the R&D director of the Musculoskeletal Tissue Bank of Rizzoli Orthopedic Institute, where he investigated the use of stem cells from alternative sources for cell banking, and the development of novel bioactive scaffolds for skeletal regeneration. From 2009 till 2014, he joined again University of Twente, where he got tenured in the Tissue Regeneration department.

Since 2014 he works at Maastricht University, where he is a founding member of the MERLN Institute for Technology-Inspired Regenerative Medicine. In 2016, he became full professor in biofabrication for regenerative medicine. His research group interests aim at developing biofabrication technologies to generate libraries of 3D scaffolds able to control cell fate, with applications spanning from skeletal to vascular, neural, and organ regeneration.

In 2014, he received the prestigious Jean Leray award for outstanding young principal investigators from the ESB and the ERC starting grant. In 2016, he also received the prestigious Young Scientist Award for outstanding principal investigators from TERMIS. In 2017, he was elected as faculty of the Young Academy of Europe and in the top 100 Italian scientists within 40 worldwide by the European Institute of Italian Culture. Since 2019, he is chair of the Complex Tissue Regeneration department and vice-director of MERLN. From his research efforts, 3 products have already reached the market.

Willem J. M. Mulder

Department of Internal Medicine, Radboud Institute of Molecular Life Sciences (RiMLS) and Radboud Center for Infectious Diseases (RCI), Radboud University Nijmegen Medical Center, Netherlands;

Laboratory of Chemical Biology, Department of Biomedical Engineering and Institute for Complex Molecular Systems, Eindhoven University of Technology, Netherlands;

CSO, Trained Therapeutix Discovery; CTO, BIOTRIP.nl.

Talk: ESB-SFB S-KL02 | Taking control of innate immunity with nanobiologic therapeutics

Date: Wednesday, 8 September, 2021, 4:15 PM

Willem Mulder, Ph.D., a biomedical engineer with a background in chemistry, is Professor of Precision Medicine at the Radboud University Medical Center (Radboudumc) and the Eindhoven University of Technology (TU/e), The Netherlands. Mulder obtained an M.Sc. in Chemistry from the Utrecht University (2001) and a Ph.D. in Biomedical Engineering from TU/e (2006). He was professor and founding director of the Nanomedicine Lab at Icahn School of Medicine at Mount Sinai in New York from 2006 to 2020.

Mulder’s research focus is on nano-immunotherapy and precision imaging in cardiovascular diseases, cancer, infectious diseases and transplantation. He pioneered the exploitation of nanomaterials as highly tunable immunotherapeutics. Mulder established proprietary technology encompassing nanomaterials devised from natural apolipoproteins named nanobiologics. Using modular nanobiologic functionalization approaches and through in vivo
screening and immuno-imaging, his team meticulously builds precision immunotherapies. When appropriately designed, such nanobiologic immunotherapeutics can be applied to empower the immune system's ability to fight disease by targeting myeloid cell dynamics, by promoting or inhibiting molecular programs that regulate immune responses, or by 'training' macrophage function.

https://www.mulderlab.com

Mulder has published more than 175 scientific publications in top scientific journals, including Science Translational Medicine, Nature Nanotechnology, Nature Reviews Drug Discovery, Nature Biomedical Engineering, Immunity and Cell. His H-index is 73 and his work has been cited nearly 15,000 times. Mulder was the principal investigator of multiple National Institutes of Health grants. In 2013, Mulder received a Vidi grant and in 2018 he was awarded a Vici grant, both from the Dutch Research Council (NWO). In 2021, he won the prestigious ERC Advanced Grant. Mulder is a Founder and Chief Scientific Officer of Trained Therapeutix Discovery (https://ttxdiscovery.com) and a Founder and Chief Technology Officer of the Radboudumc-TU/e biotech incubator BIOTRIP (https://biotrip.nl)

Mariana B. Oliveira

CICECO – Aveiro Institute of Materials, Department of Chemistry. University of Aveiro, Portugal

Talk: S06-KL01 | Designing (almost) all-cellular living materials
Date: Tuesday, 7 September, 2021, 11:30 AM
Track: 02

Mariana B. Oliveira is a Junior Researcher at the COMPASS Research Group, part of CICECO – Aveiro Institute of Materials of the University of Aveiro, Portugal. She studied Biomedical Engineering at the University of Minho (Portugal), and obtained a PhD in 2014, from the same institution. Mariana Oliveira has focused her research on the development of biomaterials for the modulation of cellular response. She is the principal investigator and coordinator of two active research projects (>480 kEuros) focused on the exploitation of mesenchymal stem cells as scaffold-free and low-biomaterial structures to tailor pancreatic islet acceptance on transplantation scenarios, and for the promotion of tissue regeneration. She authors or co-authors 52 research and review publications, which include papers in Advanced Materials, Biomaterials, Trends in Biotechnology, and Advanced Healthcare Materials. She serves in the Young Career Board of ACS Biomaterials Sci & Eng, and is an Associate Editor of Frontiers in Bioengineering and Biotechnology and Frontiers in Materials.

Abhay Pandit

Scientific Director, CÚRAM, Centre for Research in Medical Devices, National University of Ireland, Ireland

Talk 1: S15-KL01 | Understanding the Regenerative Response Induced by Biomaterials Systems: Insight into the Role of Glycosylation
Date: Thursday, 9 September, 2021, 11:45 AM / Track: 04

Talk 2: ESB-BMJ S-01/S-02 | ESB-Biomaterials Journal Joint Session: Meet the Editor Session
Date: Tuesday, 7 September, 2021, 04:15 PM / Track: 05

Professor Abhay Pandit is an Established Professor in Biomaterials and Scientific Director of CÚRAM, the Science Foundation Ireland (SFI), funded Research Centre for Medical Devices at NUI Galway, Ireland. Prof. Pandit has over thirty years of experience in the field of Biomaterials. After a seven-year stint in industry, he has worked in academia for the last twenty-three years. Prof. Pandit's research has been funded by Science Foundation Ireland, the 7th EU Framework programme, Enterprise Ireland, Health Research Board, the AO Foundation and industry sources to the tune of €150 million. Prof Pandit built a critical mass of biomaterial expertise in Ireland by establishing the Network of Excellence for Functional Biomaterials (NFB). Later the centre was incorporated into a
Strategic Research Cluster (SRC) in 2007 with funding from Science Foundation Ireland (SFI) to establish collaborative partnerships with national and international universities and industries. Building on this critical mass of expertise and enormous success of CÚRAM Phase I, Prof. Pandit now leads phase II of CÚRAM. CÚRAM brings together more than 520 researchers with synergistic expertise in biomaterials, biomechanics, regenerative medicine, glycobiology, drug delivery and medical implant design, in addition to 50 plus industry partners.

Prof. Pandit has developed next-generation reservoir delivery vehicles with high payload capacity, programmable degradation profiles and inbuilt gradients of physical, chemotropic and protective cues, facilitating spatiotemporal localised sustained delivery of multiple biomolecules to target injury mechanisms at the molecular and cellular levels. His research integrates material science and biological paradigms in developing solutions for chronic diseases.

Prof. Pandit was elected to the American Institute of Medical and Biological Engineering (AIMBE) College of Fellows to recognise his outstanding contributions in creating a national centre to develop innovative device-based solutions to treat global chronic diseases. He is the first Irish academic to earn this distinction. He was inducted as an International Fellow in Biomaterials Science and Engineering by the International Union of Societies for Biomaterials Science and Engineering (IUSBSE) and Fellow of the Tissue Engineering Regenerative Medicine International Society. Prof Pandit is the first Irish academic to receive these honours. He was also inducted as a Fellow of the Irish Academy of Engineering.

Prof Pandit is the author of 27 patents and has licensed three technologies to medical device companies. Prof Pandit has published >305 papers in peer-reviewed high impact journals, >700 conference abstracts, and has over 15K citations. Prof. Pandit has successfully supervised 36 PhD students, 24 postdoctoral researchers with a current cohort of 8 Postdoctoral researchers, 20 PhD students and three research associates.

Ana Paula Pêgo

University of Porto, Instituto de Investigação e Inovação em Saúde (i3S), Porto, Portugal

Talk: ESB-BMJ S-03 | ESB-Biomaterials Journal Joint Session: Meet the Editor Session
Date: Tuesday, 7 September, 2021, 04:15 PM
Track: 05

Ana Paula Pêgo got her Ph.D. in Polymer Chemistry and Biomaterials from the University of Twente, the Netherlands, in 2002. In 2003 she moved to INEB – Instituto de Engenharia Biomédica, where she became a Principal Investigator in 2012. In 2015, INEB joined the i3S – Instituto de Investigação e Inovação em Saúde (Universidade do Porto), where Ana Paula Pêgo leads the nanoBiomaterials for Targeted Therapies (nBTT) Group.

By using nanomedicine strategies the nBTT Group, aims at providing in situ and in a targeted manner the required signals to promote nervous tissue regeneration. The research on new biomaterials for application in neurosciences includes the development of new polymers for the design of alternative vectors to viruses for efficient nucleic acid delivery, the preparation of nerve grafts for spinal cord injury treatment and the design of brain tissue engineered platforms. Societal and ethical issues that concern Regenerative Medicine and NanoMedicine are also topics in which Ana Paula Pêgo is involved.

She has been appointed the Scientific Director of the Bioimaging Centre for Biomaterials and Regenerative Therapies of INEB and she is an Invited Associate Professor at the Instituto de Ciências Biomédicas Abel Salazar (ICBAS) and at the Faculty of Engineering (FEUP) of the University of Porto.

Currently Ana Paula Pêgo is a member of the Board of Directors of i3S, being the Head of Strategy & Creation of Value Unit, is the Secretary of the Council of the European Society for Biomaterials (ESB), serves as an Associate Editor of Biomaterials (Elsevier journal) and is part of the Board of Reviewing Editors of Science (AAAS).

She received several distinctions that include the Neuroscience Awards by SCML (the most prestigious national award in the field) and the Young Scientist Award 2015 at the 5th China-Europe Symposium on Biomaterials and Regenerative Medicine (Hangzhou, China).

Dr. Pêgo has published more that 80 peer-reviewed articles in leading international journals in the biomaterials, nanotechnology and nanomedicine fields; authored 7 book chapters and is an inventor in 3 active patents (one licensed to Pharma) and 1 patent.

She is very proud of her mentoring/supervision duties actively contributing to the training of the next generation of bioengineers. To date, 22 PhD students, 7 post-doc and 47 MSc students are or have been supervised by her.
Julietta V. Rau

Institute of the Structure of Matter of the Italian National Research Council (ISM-CNR), Rome, Italy; Sechenov First Moscow State Medical University, Moscow, Russia

Talk: ESB-SLABO S-KL01 | New trends in multifunctional surface modification of stable and biodegradable biomedical implants
Date: Monday, 6 September, 2021, 3:45 PM
Track: 04

Julietta V. Rau (Dr, PhD, Prof.) is currently Principal Investigator, Head of the laboratory and research group at the Institute of the Structure of Matter of the Italian National Research Council (ISM-CNR, Rome, Italy) and Associate Professor at the Sechenov First Moscow State Medical University (Moscow, Russia). Dr. Rau has authored +160 international peer-reviewed journal publications and presented her research as Invited and Plenary talks at +30 International Conferences. She supervised PhD and MSc students and is involved in mentoring of postdoctoral research fellows. Dr. Rau received several international awards for her research achievements. She is the CHAIR and organizer of the biennial BioMaH “Biomaterials and Novel Technologies for Healthcare” International Conference (https://biomah.ism.cnr.it) and the Member of the International Scientific Committees of various International Conferences in the field of Materials Science, Nanoscience, Biomaterials and Medical devices. Dr. Rau is Associate Editor of the Bioactive Materials journal and the Member of the Editorial Boards of numerous scientific journals. Her present research interests regard biomaterials and novel technologies for healthcare, innovative biomaterials for regenerative medicine, among them calcium phosphates and glass-ceramic based materials for tissue engineering applications. One of her research topics is focussed on coatings for biomedical implant applications and, namely, on nanostructured coatings for orthopaedic and dental implants, which are developed via an interdisciplinary international collaborative network team.

http://orcid.org/0000-0002-7953-1853

Marina Resmini

Dept. of Chemistry, Queen Mary University of London, London, UK

Talk: NANOSTEM 02-KL01 | How do we create an inclusive and diverse research culture
Date: Monday, 6 September, 2021, 1:00 PM
Track: 08

Prof Resmini is Professor of Materials Chemistry in the Chemistry Department at Queen Mary University of London. Her research interests are focused in the area of functional nanomaterials with applications at the interface between physical and bio/medical sciences, particularly as sensors and drug delivery systems. She has a strong track record of assembling successful multidisciplinary consortia with academic teams both in the UK and Europe as well as with industrial partners. She has a distinguished publication record in the area of nanomaterials, more recently focusing on imprinted polymers, nanogels and understanding the relationship between structure and functional properties. She is passionate about equality and positive actions that can drive changes towards a more diverse and inclusive environment in the Chemical Sciences. In 2011 she was elected Fellow of the Royal Society of Chemistry and since 2019 she has been the Chair of the RSC Inclusion and Diversity committee and also a member of the RSC’s Board of Trustees.
Alberto Saiani

The University of Manchester, Department of Materials & Manchester Institute of Biotechnology, Manchester, UK

Talk: **S02-KL01 | Exploiting β-sheet peptides self-assembly to design hydrogels for biomedical applications**

Date: Monday, 6 September, 2021, 11:30 AM

Track: 04

Alberto Saiani is currently Professor of Molecular Materials at the University of Manchester (ORCID: 0000-0002-5504-8306). He graduated PhD in Polymer Physics from the University Louis Pasteur, Strasbourg, France. Following his PhD he held several post-doctoral positions in Japan, UK and Belgium before joining in 2002 the University of Manchester where he established the Polymers & Peptides Research Group (polymersandpeptides.co.uk). His work includes fundamental, industrial, and translational research and spans a wide area of experimental polymer and biopolymer science. In 2014 he co-founded a start-up company, Manchester BIOGEL (manchesterbiogel.com), which develops and commercialises advanced gel-based combination products for the life science and biomedical sector.

Manuel Salmeron-Sanchez

James Watt School of Engineering, University of Glasgow, Glasgow, UK

Talk: **S09-KL01 | Mechanochemical processes at the cell/material interface**

Date: Wednesday, 8 September, 2021, 11:30 AM

Track: 02

Prof Manuel Salmeron-Sanchez, FRSE is Head of Biomedical Engineering and co-director of the Centre for the Cellular Microenvironment at the University of Glasgow. He did a PhD in Valencia and postdoctoral work at the Institute for Macromolecular Chemistry in Prague and the Katholieke Universiteit Leuven. In 2005 he was appointed as Assistant Professor at Universitat Politècnica de València, promoted to Associate Professor in 2008 and Full Professor in 2010. He did a sabbatical year at the Georgia Institute of Technology and moved to the University of Glasgow in 2013 as the Chair of Biomedical Engineering. Manuel is an ERC (European Research Council) investigator. He was elected Fellow of the Royal Society of Edinburg, Scotland national academy of science and letters, in 2017. He is visiting Professor in Valencia (Spain) and Kyushu University (Japan). His work on materials for growth factor delivery has set up the basis for a programme of research to help civilians affected by landmines, funded by the Sir Bobby Charlton Foundation. Overall, his work spans fundamental mechanisms at the cell/material interface as well as translational research that saved from amputation the leg of a first veterinary patient, a dog called Eva (https://goo.gl/1Z3r8t). He has authored more than 160 papers in major journals including PNAS, Science Advances, Nature Biomedical Engineering, Nature Metabolism and Advanced Materials. He has had his research featured in newspapers, websites and TV channels around the world. He is editor-in-chief of Materials Science and Engineering C: Materials for Biological Applications.
Ankur Singh
Georgia Institute of Technology Wallace H Coulter, Department of Biomedical Engineering,, Atlanta, USA

Talk: ESB-BMJ S-03 l ESB-Biomaterials Journal Joint Session: Meet the Editor Session
Date: Tuesday, 7 September, 2021, 04:15 PM
Track: 05

Ankur Singh is a Woodruff Faculty Fellow and an Associate Professor of George W. Woodruff School of Mechanical Engineering at Georgia Institute of Technology and Wallace H. Coulter Department of Biomedical Engineering at Georgia Tech and Emory University. Before Georgia Tech, he was an Associate Professor at Cornell University, where he served on the Center for Immunology’s Executive Council and Cornell’s academic integration advisory council. He was the Associate Director of Cornell’s NIH Immunoengineering training grant. His laboratory develops immune organoids and enabling technologies to understand healthy and diseased immune cells and translate therapeutics. He has received funding from the National Institute of Health, National Science Foundation, Wellcome Leap HOPE, Department of Defense, Defense Threat Reduction Agency, and Lymphoma and Leukemia Society. He has published >60 articles in peer-reviewed journals, including Nature Methods, Nature Materials, Nature Nanotechnology, Science Advances, Nature Communications, Nature Reviews Materials, Nature Protocols, PNAS, Blood, Advanced Functional Materials, and Advanced Materials. He has written multiple editorials for Science Translational Medicine. He is a recipient of the NSF CAREER, Society for Biomaterials Young Investigator Award, CMBE Young Innovator Award, CMBE Rising Star Award, 3M Faculty Award, DoD Career award, Cornell’s Teaching Excellence Award, and Cornell’s Research Excellence Award. His immune organoids were identified among the Top 100 Discoveries of 2015 by Discover Magazine. He is the Founder and past-Chair of the Immune Engineering SIG at the Society for Biomaterials and Controlled Release Society. He serves on the editorial board of Biomaterials, Advanced NanoBiomed Research, Cellular and Molecular bioengineering, Scientific Reports, and J of Immunology and Regenerative Medicine journals.

Federico Soria Gálvez

ENIUS Chairman European Cooperation in Science & Technology Endoscopy Coordinator Centro de Cirugía de Mínima Invasión Jesús Usón, Cáceres, Spain

Talk: ESB-SIBB S01-KL01 l Urinary stents. Side effects in patients. Why do we need to improve them? Biofilm, Coatings and new stent designs.
Date: Tuesday, 7 September, 2021, 4:15 PM - 5:45 PM
Track: 03

Dr. Federico Soria is the European Network of Multidisciplinary Research to Improve the Urinary Stents (ENIUS) Chairman, European Cooperation in Science & Technology (COST Actions, CA16217) and Endoscopy Coordinator in Jesus Uson Minimally Invasive Surgery Centre (Cáceres-Spain). He leads a multidisciplinary research group focus in Biomaterials and new design in ureteral stents. Research topic: Ureteral stents, Biodegradable Ureteral stents and Ureteral Drug Eluting Stents. Principal investigator in more than 20 Research Grants in the area of Ureteral Stents and Translational Research (1999-2021). He is editor in two books and author of over 130 peer-reviewed scientific papers. He serves on the Editorial Board in BMC Urology and Act Urol Esp. Inventor of three patents in Urology medical devices. 12 Master’s Thesis Director and 4 PhD Thesis Director.
**Marianna Tryfonidou**

RMCU, Utrecht University, Utrecht, The Netherlands  
**Talk:** S15-KL02 | The iPSpine project: smart biomaterials escorting iPS cells to rejuvenate the degenerate disc  
**Date:** Thursday, 9 September, 2021, 12:15 PM  
**Track:** 04

Professor Tryfonidou (1973) joined the department of Clinical Sciences of Companion of the Faculty of Veterinary Medicine (1998), followed an annual Internship and finished thereafter her PhD (2002) Cum Laude. In 2007 she certified as a veterinary surgeon (European College of Veterinary Surgeons (ECVS)), in 2015 was appointed as Associate Professor and as off February 2018 appointed as Professor Regenerative Orthopedics. The focus of her research is on understanding the underlying pathophysiology, unravelling cellular communications and on developing treatment strategies for musculoskeletal diseases, including back pain and osteoarthritis. Challenges are addressed by combining their multidisciplinary clinical background, involving unique spontaneous diseased canine models, with cutting edge biomolecular techniques. Results of in vitro and in vivo studies are interpreted with a clinical directive; experiments are designed with the translation from bench to bed in mind.  
Her work is embedded in international scientific networks and the “Dutch Arthritis Society” (ReumaNederland) recognized the Tryfonidou lab as a Research Centre of Excellence. She has participated in large public-private partnerships (e.g. BioMedical Materials IDiDAS, LSH ArlADNE, AO Spine Research Spine Network) where she coordinated translation of therapeutic strategies, being successful at the cross road of industry, academia, clinicians and patients. She leads the Horizon 2020 consortium (iPSpine; 2019-2023) bringing a transdisciplinary team of 21 partners together to address the challenges and bottlenecks of iPS-based advanced therapies towards their transition to the clinic. Here, chronic back pain due to intervertebral disc degeneration is employed as a show case.

**Sandra Van Vlierberghe**

Polymer Chemistry & Biomaterials Group, Centre of Macromolecular Chemistry, Ghent University, Belgium; Brussels Photonics, Vrije Universiteit Brussel, Belgium  
**Talk:** S10-KL01 | Crosslinkable gelatins - From Innovative Chemistry and Valorization of Bioinks towards Human Trials: Utopia or Reality?  
**Date:** Wednesday, 8 September, 2021, 11:30 AM  
**Track:** 03

Prof. Dr. Sandra Van Vlierberghe holds a 10% professorship at Vrije Universiteit Brussel (VUB) and a full professorship (100%) at Ghent University (Polymer Chemistry & Biomaterials Group, Belgium). She has acquired expertise related to the synthesis, the modification and the processing of (bio)polymers including thermoplasts (e.g. polyesters) and hydrogels (e.g. proteins and polysaccharides) for a variety of tissue engineering applications. She is experienced in the field of polymer processing using 3D printing, electrospinning and two-photon polymerization (2PP). She received her PhD in Sciences in 2008 at Ghent University. She authored >170 Web of Science Core Collection cited papers, she has a h-index of 34 (WoS), is promoter of 20 PhD students (in addition to 12 defended PhDs) and she edited three books, authored 7 chapters in books of which 5 invited. She is treasurer of the Belgian Polymer Group (BPG), former spokesperson of the ‘Young Scientist Forum (YSF)’, TERMIS-EU council member and member of the independent ESB Awards Committee. She serves on the editorial board of several journals focussing on tissue engineering. In 2017, she received the Jean Leray award from the European Society for Biomaterials. She is also very active in research valorization as reflected by two ongoing spin-off projects (XpectINX (Xpect-Inx | Your Support in Bioprinting (xpect-inx.com) which will be launched in September 2021 and GelGraft Medical which is focussing on the translation of an injectable biomaterial for breast reconstruction from in vivo animal testing towards first in-human trials).
Dr. S.A.J. Zaat is Principal Investigator at the Amsterdam UMC, University of Amsterdam, Department of Medical Microbiology and Infection Prevention. His research line „Biomaterial-associated infection and novel antimicrobial strategies”, is focused on pathogenesis, prevention and treatment of biomaterial-associated infections, both in soft tissue (catheters, surgical meshes) and bone (implants, fixation devices). Based on research on the pathogenesis involving the (molecular) interactions between the pathogen, the host response and the biomaterial, novel preventive strategies are being developed. These include anti-infective coatings not subject to bacterial resistance development, prevention of biofilm formation, influencing the host immune response and enhancement of killing of bacteria hiding in tissue surrounding inserted or implanted medical devices. These approaches are aimed at maximally reducing the risk of biomaterial-associated infection for patients.

Dr. Zaat has been work package leader in the BMM NANTICO “Non-adherent ANTImicrobial Coatings” project, Principal Investigator of the BMM IBIZA “Imaging of Biomaterial-associated Infection using Zebrafish Analysis” project, coordinator of the EU FP7 BALI “Biofilm Alliance” project developing novel Synthetic Antimicrobial and Antibiofilm Peptides, and vice Working Group Chair of the EU COST Consortium IPROMEDAI “Improved PROtection Of Medical Devices Against Infection”. Currently he is leading or involved in a number of National and international consortium projects, including EU Horizon2020 Marie Curie training networks PRINT-AID and STIMULUS, EU Horizon 2020 Twinning project CEMBO, and Dutch National consortia SUPER-ACTIVE, PHOTO-TREAT, GDST, NEDSAP and DARTBAC.

Marcy Zenobi-Wong is a tenured Full Professor of Tissue Engineering and Biofabrication and Director of the Institute for Biomechanics at ETH Zürich in Switzerland. She is a Mechanical Engineer by training, and received her Bachelor degree from MIT and Master/PhD from Stanford University. She leads a multidisciplinary team with strong focus on biofabrication technologies including bioprinting, two-photon polymerization, and casting, and on the development of advanced biomaterials for tissue regeneration. She is the author of over 100 peer-reviewed publications (cited over 5000 times) and co-inventor on several licensed patents. She is currently President of the Swiss Society for Biomaterials and Regenerative Medicine (SSB+RM) and General Secretary for the International Society of Biofabrication (ISBF). She serves on the editorial board for Biofabrication and Advanced Healthcare Materials. In 2019 she was elected as Fellow to the European Alliance for Medical & Biological Engineering and Science (EAMBES).

**Schedule Wednesday, 8 September, 2021**

- **9:30 AM**: GW AW02 - George Winter Award 2021
- **10:00 AM**: KdG AW02 - Klaas de Groot Award 2021
- **11:00 AM**: COFFEEBREAK
- **11:30 AM**: K06 - Biomimetic Nanomaterials and Biosensing Devices
  - S09: Role of Biomaterial Properties on Cell-Scaffold Interplay
  - S10: Advances in Functionalisation and Fabrication of Gelatin Hydrogels for Biomedical Applications
  - S11: Nanostructure-based Biomaterials Design and Biological Interactions
- **12:00 PM**: ESB-SIBB S02 - Iberian Society for Biomechanics and Biomaterials Joint Session II: Biomaterials for cancer models and treatment
- **12:30 PM**: ESB-BM5 Joint Session: Biomaterials Science Journal Lectureship Symposium
- **1:00 PM**: N12 - Biomaterials for Cardiovascular Applications and Angiogenesis
- **2:00 PM**: YSF NC - YSF National Chapter Meeting
- **2:30 PM**: Social 5 - Yoga
- **4:00 PM**: PS 2 - Poster Sessions 2
- **4:30 PM**: BREAK
- **5:00 PM**: K07 - Biomaterials for Cardiac Tissue Engineering and Regenerative Medicine
  - K08 - Mechanomodulatory Biomaterials and its Impact on Cell Behaviour
  - S12 - Biocompatibility Testing According to ISO 10993: What are the Changes and What can the Biomaterials Community Learn from it?
  - S13 - Biocompatibility Testing and Data-Driven Biomaterials
- **6:00 PM**: ESB-SFB S - Society for Biomaterials Joint Symposium: Immunomodulatory Biomaterials
- **6:30 PM**: N13 - Advances in Additive Manufacturing and Biofabrication
- **7:00 PM**: Int AW - International Award 2021
- **8:00 PM**: Social 6 - Music Evening - Performance by a University of Porto "Tuna"

*In this workshop, we will briefly explain the YSF’s “Green Lab sustainability” Initiative, and Pedro Alves (Instituto de Investigação e Inovação em Saúde - U. Porto (i3s), Portugal) will explain and share his “Greenlab experience”. Afterwards, the session on “Communication skills” will include insights on how to “Boost your Communication skills & How to do a good pitch” by Jane Bennett-Powell (freelance journalist and science communication trainer), followed by the important advices on “Pitching to Investors” from Sonia Hallen (LSP connecting investors to inventors, The Netherlands). During the same session, Jasper Van Hoorick (Ghent University & Xpect-INX, Belgium) will share his experience on the steps “From Academic research to spin-off company: the story of XPECT INX”. This session will end with an interactive round table with the audience.*

Design of biomaterials/cells structures for bottom-up tissue engineering strategies – less is more

João F. Mano

University of Aveiro, CICECO - Aveiro Institute of Materials, Department of Chemistry, Aveiro, PT

The control of cell microenvironment is of crucial importance for the ability to direct cell behavior in 3-dimensional tissue engineering structures. Bioinspired engineered microenvironments provide cells with a holistic “instructive niche” that harbors signals for cellular control both in both space and time. We explore this problem using reductionistic approaches, in which cells are exposed to substrates exhibiting controlled geometries, surface, (bio)chemical compositions and mechanical properties. Miniaturized supports can be then assembled into larger constructs using bottom-up tissue engineering tools. Examples from our group are presented covering alternative approaches of assembly cells with precise spatial arrangement, including cell encapsulation in (i) microgels or in (ii) liquified capsules, (iii) 1D/2D cell-rich objects, and (iv) combinations of cell and biodegradable polymeric microparticles. Non-bulk properties of biomaterials are highlighted towards minimalistic strategies involving low amounts of biomaterials.

**Cell fate controlling micromaterials for the engineering of multiscale tissues**

**Jeroen Leijten**

*University Twente, Developmental BioEngineering, Enschede, NL*

The modular design of tissues is of indispensable importance for proper organ function. Yet, most tissue engineering strategies are based on creating homogeneous tissues, which has limited are capacity to create viable and functional tissues. We have developed several novel micromaterials that allow for the facile creation of tissues with modular designs, which allow for unprecedented control over cell fate and drive the engineering of functional multiscale tissues. Specifically, we used microfluidic droplet generation to fabricate 3D single microgels with on-demand tunable biophysical and biochemical properties to controllably program stem cell differentiation along chosen lineages. These microgels were combined with distinct biomaterials to create modular bioinks that offer uncoupled control over the engineered tissues pericellular and extracellular environments. Similarly, we have used our microtechnology to create hollow microgels that create, protect, and instruct organoids, which was explored for various biomedical applications including production of cardioids and immunoprotected islet-mimics. In addition, we have used microfluidic technology to produce oxygen generating micromaterials to enable the engineering of viable clinically sized tissues. Lastly, to endow our tissues with macroscale properties such as tissue shape, we have used our modular bioinks in combination with various biofabrication techniques such as injection molding, photolithography, and 3D printing to engineered multiscale hierarchical living implants with unprecedented design and function. In short, I will here present several of our microfluidic micromaterial-based concepts that are focused on advancing the engineering of multiscale hierarchical tissues constructs.

TRS-S01 | Translation Research Symposia

Chairs
**Fabrizio Barberis**
Universita' degli Studi di Genova, Department of Civil Chemical and Environmental Engineering, Genova, IT
**Yves Bayon**
Medtronic, Trévoux, FR

The session will share an overview on the Medical Device Regulation (MDR), starting to be fully in force in May 2021. It will illustrate the importance of the regulation throughout the life cycle of medical devices from their development to their market approval in Europe. A focus will be made on implants and biomaterials.

Lectures will be given by speakers with different background, representatives of start-up companies, large corporate companies and MedTech Europe, the European trade association of MedTech companies.

Hybrid nanoparticles and hydrogels for biomedical applications

Luisa De Cola

University of Milano, Department DISFARM and Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Milano, IT

Advancements in the use of nanoparticles for biomedical applications have clearly shown their potential for the preparation of improved imaging and drug-delivery systems. However, only a few successfully translate into clinical practice, because, a common “barrier” preventing nanoparticles from delivering efficiently their payload to the target site after administration, is related to the nanoparticle uptake by macrophages. We have recently reported disulfide-bridged organosilica nanoparticles with cage-like morphology, and assessed in detail their bioaccumulation in vivo. [1] The fate of intravenously injected 20 nm nanocages was investigated in both healthy and tumor bearing mice. Interestingly, the nanoparticles exclusively co-localize with hepatic sinusoidal endothelial cells (LSECs), while avoiding Kupffer-cell uptake (less than 6%), in both physiological and pathological condition. Our findings suggest that organosilica nanocages hold the potential to be used as nanotools for LSECs modulation, potentially impacting key biological processes such as tumor cell extravasation and hepatic immunity to invading metastatic cells or a tolerogenic state in intrahepatic immune cells in autoimmune diseases.

Recently we have also shown that nanoparticles can be an interesting component for hybrid hydrogels. [2] We have shown that injectable nanocomposite hydrogel able to form in situ a tissue mimicking matrix as an innovative material can be employed for the treatment of esophageal fistulas. [3] The hydrogel is based on hyaluronic acid (HA), the cross-linking process occurs at physiological conditions leading to a hydrogel made of >96% by water and with a large-pore microarchitecture. The material, easily injectable with an endoscopic needle, is formed in a time compatible with the surgical procedure and has final mechanical properties suitable for cell proliferation. The in vivo experiments (porcine model) on esophageal-cutaneous fistulas, showed improved healing in the animals treated with the hydrogel compared with the control group.

Introduction

Nowadays there is an increasing need for engineered biomaterials in the field of bone tissue regeneration due to some limitations presented by the current pharmacological and surgical strategies. Especially in pathological conditions such as osteoporosis, constructs able to guide and rebalance cell activities are highly demanded [1]. In this context, three dimensional (3D) nanofibrous scaffolds fabricated by means of electrospinning represent promising tools for bone tissue engineering, mimicking the chemical and morphological features of the native tissue [2]. Moreover, the use of superparamagnetic iron oxide nanoparticles (SPIONs) have demonstrated their potential in the design of responsive biomaterials for different tissue engineering applications, exploiting the well-known healing effect of the magnetic field on different tissues, including bone [3].

In this study, SPIONs were produced by a thermal decomposition process. Subsequently, type I collagen, which is the main organic phase of bone, was combined with SPIONs to design magnetically responsive nanofibrous composite scaffolds by means of electrospinning. The resulting mats were characterized in terms of physicochemical, magnetic, and biological properties to explore their potential for bone tissue regeneration applications.

Experimental Methods

SPIONs were synthesized by thermal decomposition of iron (III) oleate in octadecene at 315 °C. The particles were further processed exploiting a ligand exchange of the oleic acid surface layer with dimercaptosuccinic acid to obtain a stable suspension in water. The nanoparticles were characterized by Transmission Electron Microscopy (TEM), X-ray diffraction (XRD), Dynamic Light Scattering (DLS) and Fourier Transform Infrared measurements (FT-IR). Concentration in Fe2O3 was determined by Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES). Magnetic characterization was carried out in a vibrating sample magnetometer (VSM). A novel hybrid formulation containing about 0.4 wt% SPIONs was obtained by adding the calculated volume of a stable aqueous suspension of magnetic particles into a 20 wt% type I collagen solution, prepared by dissolving lyophilized rat tail collagen in 40% acetic acid. After the rheological characterization of the suspensions, 3D fibrous scaffolds were fabricated using a Fluidnatek LE-50 electrospinning machine (Bioinicia, Spain) equipped with a plate collector, at a distance of 10 cm with voltage and flow rate of 20 kV and 1 mL/h, respectively. The morphological features of the scaffolds were investigated by Scanning Electron Microscopy (SEM) and TEM. The magnetization of the composite electrospun matrix was studied as function of the applied magnetic field, while their biocompatibility was preliminary evaluated in vitro by using mesenchymal stem cells derived from human bone marrow.

Results and Discussion
SPIONs measuring 12 nm in diameter have been successfully synthetized and subsequently coated to obtain a stable colloidal suspension in water over time. The SPION suspension was subsequently combined with a type I collagen solution, obtaining a final homogeneous hybrid suspension containing 0.4 wt% of magnetic particles. After optimization of the process parameters, magnetically responsive composite scaffolds were obtained by means of electrospinning, where morphological analyses confirmed the formation of fibers in the range of 100-500 nm as well as the uniform distribution and embedding of SPIONs (Figure). Finally, a preliminary biological assessment was exploited to confirm the biocompatibility of the developed constructs and their potential as bone regenerative scaffolds.

**Conclusion**

Magnetically responsive nanostructured scaffolds were successfully obtained combining type I collagen and superparamagnetic iron oxide nanoparticles (SPIONs) after the optimization of new synthesis strategies. The comprehensive characterization of the resulting scaffolds demonstrated their potential for bone tissue regeneration applications.

Peptide conjugated light-responsive NPs to target blood-brain barrier

Akhilesh Rai¹,², Rafaela Ferrão¹,²

¹ University of Coimbra, Faculty of Medicine, and Center for Neuroscience and Cell Biology, Coimbra, PT; ² Center for Neuroscience and Cell Biology, Center for Neuroscience and Cell Biology, Coimbra, PT

Introduction

No therapies are currently available to completely reboot the brain function after stroke [1]. One major drawback for the treatment of these diseases is the incapacity of drugs/carriers to cross efficiently the blood-brain barrier (BBB) [2]. BBB is a bottleneck in the development of drugs or drug carriers for the treatment of brain diseases. Studies have demonstrated that nanoparticles (NPs), upon an intracerebroventricular administration, can deliver active molecules at the SVZ region, triggering the neurogenic process [3]. Nevertheless, this type of administration is very invasive and requires specific medical facilities. Here, we report that near-infrared (NIR) light-responsive polydopamine (PDA) NPs can transiently open the BBB and facilitate their crossing across in vitro BBB model. Moreover, we demonstrate the paracrine effect (cytokines secreted by macrophages after the exposure of PDA NPs and NIR light) on the integrity of the BBB model.

Experimental Methods

PDA NPs (100 nm) were synthesized using dopamine as a precursor under the alkaline condition. Different densities of transferrin (Tf) peptides were covalently conjugated on PDA NPs using amine-PEG-maleimide (5kDa) linker. In vitro Mouse BBB model was used to analyze the permeability of Tf conjugated PDA NPs. Mouse brain endothelial cells (bEND.3) was used to prepare monoculture BBB model. ICP-MS measurement was done to quantify the amount of NPs, which transcytosed across in vitro BBB model. Moreover, the integrity of BBB after exposure of NPs and NIR light was evaluated by analysis of permeability of Lucifer yellow and electrical resistance (TEER) measurement. To study the paracrine effect, the conditional media (CM) were collected after the incubation of PDA-Tf NPs with mouse macrophages and the exposure of NIR light. CM was added in the mouse BBB model for 24 h and the integrity of BBB was evaluated by permeability and TEER measurement.

Results and Discussion

NIR light-responsive PDA NPs are synthesized using dopamine as a precursor under the alkaline condition. TEM measurement indicates the size of PDA NPs is 100 nm. We have prepared PDA-Tf₅₀/₁₀₀ NPs by conjugating 50 and 100 Tf-maleimide complexes per PDA NP. TEM measurement indicates that there is no significant increase in the size of PDA NPs after conjugation with Tf peptide. Zeta potential measurement shows that PDA-Tf₅₀/₁₀₀ NPs are positively charged as compared to PDA NPs. Importantly, PDA-Tf₅₀/₁₀₀ NPs are stable in EGM2 media for 24 h while NPs aggregates in EBM (without FBS) media. Photothermal measurement shows that 10 and 50 μg/mL of PDA NPs increase the temperature of solution to 2 and 6°C respectively after the exposure of NIR light (wavelength 785 nm, power density 2W/cm²) for 5 min. Results obtained from in vitro BBB model showed that 50 μg/mL of PDA-Tf₁₀₀ NPs crossed the BBB more efficiently than 50 μg/mL of PDA-Tf₅₀ NPs and the bare PDA NPs after the exposure of NIR light for 5 min. 50 μg/mL of PDA-Tf₁₀₀ NPs and bare PDA NPs do not affect the integrity of the BBB after the exposure of NIR light. The transcytosis of PDA-Tf₅₀ NPs and PDA-Tf₁₀₀ NPs through the BBB depend on their avidity to Tf receptors of bEND.3 cells. Importantly, 50 and 100 μg/mL PDA-Tf₁₀₀ NPs and the bare PDA NPs do not induce cytotoxicity to bEND.3 cells with or without exposure of NIR light. We further show that there is no significant change in the integrity of in vitro BBB model after incubation with the conditional media (cytokines secreted by mouse macrophages after incubation of 50 μg/mL of PDA-Tf₁₀₀ NPs and the exposure of NIR light).
Conclusion
We show that light-responsive PDA-Tf NPs can transiently open the BBB upon the exposure of NIR light and thereby promoting greater crossing of NPs. There is no harmful effect of cytokines secreted by macrophages after the NIR light exposure on the integrity of in vitro BBB model. Overall, our results open the possibility of targeting effectively the brain by modulating the physicochemical property of NPs.

[Ru(η⁵-C₅H₅)(PPh₃)₂]-PAMAM metalloendrimers as anticancer candidates able of triggering the "stress-induced premature senescence" pathway

Nádia Sofia H. Nunes¹, Helena Tomás¹, João Rodrigues¹²

¹ CQM – Centro de Química da Madeira, MMRG, Universidade da Madeira, Funchal, PT; ² School of Materials Science and Engineering/Center for Nano Energy Materials, Northwestern Polytechnical University, Xi’an, CN

Introduction
The research interest in metallodrugs was promoted by the successful clinical application of platinum anticancer drugs; nevertheless, the side effects and drug resistance constitute a severe problem. As a result, ruthenium complexes have emerged as a promising alternative because, i.e., of their possibility to kill cancer cells with different mechanisms of action, their ability to bind to albumin and transferrin, which facilitate their uptake into tumor cells, and related lower toxicity towards normal tissues[1]. Furthermore, their therapeutic activity, solubility, and selectivity can be enhanced when incorporated onto dendritic scaffolds, producing metalloendrimers[2]. These macromolecules have attractive three-dimensional and hyperbranched globular nanopolymeric architectures with a variable number of tailor-made terminal groups. They can incorporate metal-based drugs on their periphery, be scattered all over the framework, or encapsulated in their internal cavities[2]. Specifically, PAMAM dendrimers have an ethylenediamine core, polyamide branches, and tertiary amines as branching points[3].

Experimental Methods
Based on our knowledge of the field of dendrimers as anticancer drugs[4], we herein present the synthesis and characterization (by NMR, FTIR, EA, MS, and DLS techniques) of a new family of G0 to G3-ruthenium(II)-metalloendrimers with 4 to 32 Ru-moieties, respectively, based on polynitrile PAMAM dendrimers quantitatively coordinated to the metallofragment [Ru(η⁵-C₅H₅)(PPh₃)₂]⁺ (RuCp). Its in vitro cytotoxicity, hemolytic activity, DNA binding, and mechanism of action were also studied.

Results and Discussion
Our results have shown that the acquired IC₅₀ values for the selected set of human cancer cell lines (A2780, A2780cisR, and MCF-7) were generation dependent and comprised within a nanomolar range when compared with RuCp and cisplatin, which suggests the superior anticancer activity of the ruthenium(II)-based metalloendrimers vs. platinum-based systems. They were also less toxic towards human primary fibroblasts (BJ cell line); they exhibit nontoxicity for the human red blood cells and strong interactions with calf thymus DNA. The mechanism of action of the G3-metalloendrimer (G3-RuCp), when compared to RuCp and cisplatin, was investigated in the breast cancer cell line MCF-7 revealing that the cancer cell death stimulated by this metalloendrimer could be caused by "stress-induced premature senescence" triggered by high ROS levels and cell cycle arrest in the G0/G1 phase. This compound does not trigger cancer cell death by apoptosis, necrosis, or autophagy (fig. 1). Such mechanism of action is totally different from the one developed after the treatment of cisplatin (DNA damage response that involves cell cycle arrest in the G2/M phase and induced apoptosis[5], which tells us that the G3-RuCp could overcome the cisplatin resistance phenomena.

Conclusion
To conclude, the abovementioned results validate that these novel metalloendrimers are quite promising for anticancer research. In this sense, in vivo studies are ongoing.

Core-shell PLA nanofibers@SPIONs nanocomposites with enhanced properties for biomedical imaging and magnetic applications

Benjamin Nottelet¹, Hussein Awada¹-², Danielle Laurencin², Ryan Gilbert³, Jessica Funnell², Florence Franconi⁴, Joulia Larionov², Gautier Félix², Laurent Lemaire⁴, Yannick Guari²

¹ University of Montpellier, Department of Polymer for Health and Biomaterials - IBMM, Montpellier, FR; ² University of Montpellier, Ingénierie Moléculaire et Nano Objets - ICGM, Montpellier, FR; ³ Rensselaer Polytechnic Institute, The Gilbert Lab: Biomaterials for Spinal Cord Injury, Troy, US; ⁴ University of Angers, Micro et Nanomédecines Biomimétiques, Angers, FR

Introduction

Composites combining superparamagnetic iron oxide nanoparticles (SPIONs) and polymers are largely present in modern (bio)materials [1,2]. However, while SPIONs embedded in polymer matrices are classically reported, this approach fails in the case of electrospun nanocomposites where the incorporation of SPIONs results not only in beaded defects and a larger distribution in the diameter of the fibers, but also strongly impacts their mechanical and degradation properties, as well as the magnetic properties. Therefore, the controlled anchoring of SPIONs on polymer surfaces is still a major challenge. Herein, we propose an efficient strategy for the direct and uniform anchoring of SPIONs on the surface of functionalized-poly(l-lactide) (PLA) nanofibers via a simple free ligand exchange procedure to design PLA@SPIONs core@shell nanocomposites to be used as multifunctional scaffolds with magnetic and imaging properties [3]. A long term in vivo evaluation of the magnetic nanocomposites in terms of MRI visualization and tissue integration is discussed.

Experimental Methods

Electrospun PLA nanofibers are chemically modified to generate alkyne surface groups [4]. Bifunctional thiol-phosphonic ligand is covalently bound to the surface by thiol-yne photoaddition. Finally, SPIONs are anchored on the PLA fibers via a free ligand exchange procedure. PLA@SPIONs hybrid biomaterials are characterized by electron microscopy (SEM and TEM) and EDXS analysis, to probe the morphology and detect elements present at the organic/inorganic interface, respectively. Magnetic properties are assessed in vitro by using a Quantum Design MPMS-XL SQUID magnetometer working in the 1.8–350 K temperature range with the applied magnetic field up to 7 T. MR imaging was performed on a Bruker Biospec 70/20 system operating at a magnetic field of 7T (Bruker, Wissembourg, France) using a 72-mm diameter birdcage resonator and a respiratory triggered RARE sequence (effective repetition time TR ~ 2000 ms; rat breathing rate 40-50/min; effective echo time TEeff = 23 ms; RARE factor = 8; FOV = 55mm x 55mm; matrix 256 x 256, slice thickness= 1 mm and 8 accumulations). Host-tissue morphologic response to the presence of the scaffolds was assessed by histopathology with hematoxylin-eosin-suffran (HES) and Perls staining.

Results and Discussion

The morphology and core-shell structure of the PLA@SPIONs nanocomposites were fully characterized by electron microscopy (SEM and TEM) and EDXS, revealing the homogeneous coverage of the nanofiber surface by a quasi-monolayer of SPIONs corresponding to 8 wt% of SPIONs. In contrast to classic magnetic composites, magnetization experiments proved that the magnetic properties of the SPIONs are well-preserved after their anchoring on the PLA fibers and that no aggregation occurred. Following an initial cytotoxicity study showing no toxicity of the PLA@SPIONs nanocomposites, their implantation in rats was performed to confirm the high sensitivity of detection obtained in vitro using standard T2-weighted spin echo sequence. PLA@SPIONs were easily detected using the same sequence in a pre-clinical MR scanner with a clear hyposignal due to the SPIONs anchored at the surface of
the PLA fibers and acting as superparamagnetic contrast agents. Even at 6 months post-implantation, the PLA@SPIONs were easily detected and were still clearly distinct from the surrounding tissues. Histological data highlighted a moderate chronic inflammatory reaction that was similar for both PLA and PLA@SPIONs nanofibers. Thanks to Perls staining, the role of macrophages in the degradation of the scaffolds and in the elimination of the SPIONs was clarified. Finally, it also showed similar degradation/integration behavior for the PLA@SPIONs nanofibers compared to PLA fibers thus confirming our initial hypothesis that the herein proposed strategy allows obtaining magnetic nanocomposites without alteration of the degradation properties of the nanofibers.

**Conclusion**

This set of data confirms the soundness of the proposed strategy that, through an efficient anchoring of SPIONs at the surface of PLA nanofibers, yields magnetic core-shell nanocomposites with i) maintained magnetic properties compared to free SPIONs, ii) that allow a clear and long-term MRI visualization despite low SPIONs content, iii) whose tissue integration and degradation are similar to the ones of pure PLA. Overall it confirms the potential of this new class of core-shell magnetic nanocomposites that opens new opportunities in the field of magneto-scaffolds.

An in-depth analysis of the effect of polydopamine nanoparticle size on their interaction with glioblastoma multiforme cells and their photo-thermal conversion abilities

Matteo Battaglini¹, Alessio Carmignani¹,², Gianni Ciofani¹

¹ Italian institute of technology, Smart Bio-Interfaces, Pontedera, IT; ² Scuola Superiore Sant'Anna, The Biorobotics Institute, Pontedera, IT

Introduction
Polydopamine nanoparticles (PDNPs) have drawn the attention of the scientific community thanks to their properties, in particular, owing to their antioxidant capacities and their near-infrared (NIR) photo-thermal conversion abilities.¹⁻³ PDNPs have been exploited as a mean to promote the thermal ablation of various forms of cancers ranging from cervix tumor to brain cancer.⁴⁻⁵ PDNPs have one key advantage over inorganic materials due to their organic nature that grants them the ability to be degraded avoiding potential accumulation inside tissues with potentially adverse effects.² However, how the characteristics of the PDNPs, in particular their size, affect their photothermal conversion abilities and their interaction with cancer cells is still largely unknown. In this work, we tried to fill this knowledge gap by investigating how PDNPs of 8 different sizes respond to NIR stimulation in terms of heat generation and interaction with glioblastoma multiforme cells.

Experimental Methods
PDNPs were prepared using a Stöber reaction protocol with different ratios between reagents to obtain particles at different sizes. Obtained PDNPs were characterized in terms of size (dynamic light scattering measurements), surface charge (Z-potential analysis), morphology (scanning electron microscopy –SEM–), and NIR absorption. Then the photo-thermal conversion ability of the 8 different batches of PDNPs was tested both in water and after injection inside an explant of cow brain tissue. Lastly, the interaction of the 8 different batches of PDNPs with U87 glioblastoma multiforme cells (both wild type and transfected for GFP expression) was assessed in terms of internalization (confocal, flow cytometry, and SEM), and ability to elicit cellular thermal ablation.

Results and Discussion
Characterization of the PDNP dispersions demonstrates the presence of well-dispersed and homogeneous structures at 8 different sizes (ranging from 145±13 nm to 710±57 nm). We demonstrated how the increment of PDNPs size caused an increment in NIR (808 nm) absorption and a decrement in U87 cellular uptake. Photo-thermal conversion abilities were affected by the size of PDNPs bigger PDNPs were able to stimulate a greater heat generation upon NIR stimulation (figure 1). PDNPs also showed the ability to induce cellular apoptosis on U87 cells when combined with NIR irradiation.

Conclusion
Size is a key element in PDNP properties. Our work showed how PDNP size can affect both cellular uptake and photo-thermal conversion properties of the nanoparticles. Smaller particles are internalized by cells at a higher extent but have poorer photo-thermal conversion abilities compared to bigger nanostructures. These data were confirmed both in water dispersions and on an explant of cow brain tissue. Obtained data could be used as a guide to optimize PDNP size to obtain the optimal efficiency in terms of cellular uptake, heat generation upon NIR irradiation, and subsequent thermal ablation of cancer cells.

Figure 1
From top to bottom, representative thermal images of Wilko Petri dishes filled with 100 µg/ml of PDNPs of 145 nm average diameter, and with 100 µg/ml of 710 nm average diameter. The water dispersions are shown at three different time points during NIR irradiation (0, 60, and 120 s). As shown by the images, bigger PDNPs were able to elicit a greater increment in temperature compared to smaller PDNPs after NIR irradiation.

Biofabrication, including bioinks development and bioprinting technologies, can emulate living organs with a high complexity level. OoCs have a tremendous potential in spatiotemporally recreating physical forces and (bio-)chemical concentrations present in the human body. Integrating such technologies rationally would lead to highly physiologically relevant organs and diseases in vitro models.

Integrating biofabrication with organ-on-chip technologies: marrying micro with macro for improved 3D in vitro models.

Lorenzo Moroni\textsuperscript{1,2}

\textsuperscript{1} Maastricht University, Complex Tissue Regeneration/MERLN, Maastricht, NL; \textsuperscript{2} CNR Nanotec, Lecce, IT

Organ-on-a-chips (OoCs) are being developed as highly innovative, predictive tools with limitless potential for organ function modelling, drug discovery and testing. OoCs are miniaturized \textit{in vitro} systems that can recapitulate the microenvironment and key functions of different organs with a high degree of fidelity, facilitating the study of complex cell-cell interaction and regulation. They integrate relevant cell types, physical forces, (bio-)chemical concentration and gradients with unprecedented confidence, spatiotemporally recreating physical, biological and chemical features of the target microenvironment. By mimicking human key organ functions \textit{in vitro}, they are proposed as models for studying physiological processes as well as disease-related mechanisms to elucidate pathological pathways and test the safety and efficacy of potential drug candidates. Despite numerous efforts to integrate different OoC platforms into a multi-organ system, current set-ups are still limited by recapitulating only a specific function of targeted tissues and organs in a two-dimensional configuration.

On the other hand, an increasing level of emulation of living organ architectures has been recently grasped by exploiting the latest achievements in the field of biofabrication, especially considering bioinks development and bioprinting technologies. The fabrication of biomimetic 3D organ structures, displaying highly defined deposition and assembly of several materials and cell types, is more and more widespread, allowing accurate spatiotemporal control over cell–cell and cell–extracellular matrix interactions, but their combination in OoC is still in its infancy. Integrating such technologies rationally, exploiting their individual advantages in an orchestrated manner, would lead to \textit{in vitro} models of organs and diseases with a high degree of fidelity to the real \textit{in vivo} counterpart in terms of cell positioning, cell-cell and cell-matrix communication, taking into account physical and chemical properties of the microenvironment at the cell scale in an unprecedented manner.

In this direction, here I will be presenting some of the recent advances in the field aiming at developing 3D in vitro microphysiological models integrating OoC and biofabrication principles, with a particular focus on neurodegenerative disease models.

Freestanding magnetic microtissues for tissue engineering applications

Lúcia F. Santos, Sónia G. Patrício, Ana S. Silva, João F. Mano

University of Aveiro, CICECO - Aveiro Institute of Materials, Aveiro, PT

Introduction
The major challenge of tissue engineering (TE) remains in the fabrication of functional tissue-like constructs able to recapitulate the well-organized and hierarchical architecture of native tissues composed by well-defined microscale subunits [1]. Regarding “bottom-up” principles, microscale tissue building blocks have been engineered with diverse architectures and then assembled in larger tissue constructs. Cell sheet (CS) engineering has been showing great potential for the construction of such building blocks. In fact, Magnetic-based force TE (Mag-TE) has been explored for the fabrication of complex-shaped and robust tissues [2]. The magnetically controlled strategy has the unique ability to manipulate multiple cell types to form complex tissue-like constructs. In this sense, we herein propose the fabrication of freestanding complex-microtissues by Mag-TE that could act as building blocks for the construction of complex and hierarchical tissue-like constructs.

Experimental Methods
Firstly, Fe$_3$O$_4$ nanoparticles were synthetized and incubated with human adipose-derived stromal cells (hASCs). Then, the magnetically-labelled cells were used to create magnetic microtissues with defined sizes and shapes using superhydrophobic surfaces patterned with wettable superhydrophilic domains [3]. Briefly, the cells were seeded on the superhydrophilic domains, cultured for pre-determined periods and then detached with the aid of a magnet. After 7 days, the cell viability and proliferation of the magnetic microtissues was accessed. Moreover, the cell-cell interactions and the presence of a collagenous matrix was also investigated. Finally, the ability of the microtissues to invade neighbouring tissue models were evaluated along the time using methacrylated platelet lysates and methacylated laminarin hydrogels. To recreate the dynamic environment of native tissues, both static and dynamic conditions were explored. As hypothesized, rapidly sprouting of microtissues in hydrogel was visualized, losing their shape and providing trophic and immunomodulatory factors crucial to proper regeneration of tissues.

Results and Discussion
We herein report a simple, one-pot and high-throughput strategy to obtain microtissues with geometrically controlled shapes by using superhydrophobic surfaces patterned with wettable superhydrophilic domains with specific designs. For the first time, such platform was exploited to produce cell-based tissue constructs, mimicking the structure of native tissues. Microtissues with round, square and fiber-like shapes were successfully engineered, showing great robustness and cell-cell interactions within the construct. Freestanding microtissues showed the remarkable ability to preserve the geometry without the presence of a subtract or a magnetic field with great cell survival, overcoming the current issues of scaffold-free approaches. The ability of such constructs to integrate in vitro tissue models was herein accessed using methacylated platelet lysates and methacylated laminarin hydrogels. To recreate the dynamic environment of native tissues, both static and dynamic conditions were explored. As hypothesized, rapidly sprouting of microtissues in hydrogel was visualized, losing their shape and providing trophic and immunomodulatory factors crucial to proper regeneration of tissues.

Conclusion
Such microtissues can be employed to fill defects with particular architecture and high complexity, addressing the challenge of TE in fabricating functional tissue-like constructs able to recapitulate the well-organized and hierarchical architecture of native tissues. We hypothesise that such structures could be also used as high-retention cell delivery vehicles for regenerative therapies by providing cells and adequate trophic factor to the targeted tissue.

Cell-Assembled extracellular Matrix (CAM): an effective biopaper for the biofabrication of human pre-vascularized and perfusable tissues

Hugo Oliveira, Chantal Medina, Nathalie Dusserre, Charles Handschin, Marie-Laure Stachowicz, Jean-Christophe Fricain, Nicolas L’Heureux

Inserm U1026 BioTis: Bioingénierie Tissulaire, Université Bordeaux, Bordeaux, FR

Introduction
The vascular system plays an essential role in maintaining the homeostasis and function of the great majority of tissues in the human body. When considering regenerative approaches, the efficient formation of a functional vasculature that can support the metabolic needs of bioengineered tissues is essential for their survival after implantation. However, it is widely recognized that the post-implantation microenvironment of the engineered tissues is often hypoxic due to insufficient vascularization, resulting in ischemia injury and necrosis. This is one of the main limitations of current tissue engineering applications aiming at replacing significant tissue volumes.

Here, we hypothesize that fabricated tissue constructs containing pre-organized and more mature vasculature structures can lead to improved graft integration. We have previously shown that cell-assembled extracellular matrix (CAM), synthesized by normal human skin fibroblasts in vitro, could be assembled in a completely biological vascular graft, with sufficient mechanical properties to warrant its testing in a clinic setting. Physiological mechanical strength could be achieved without the need for synthetic materials avoiding the release of the inflammatory response associated with foreign body reaction to permanent synthetic scaffolds, or the harmful degradation products of resorbable polymers. Here, we exploit the inherent qualities of this human biomaterial for the creation of a pre-vascularized network, by using CAM sheets as a biopaper, combined with 3D bioprinting for the controlled deposition of endothelial cells.

Experimental Methods
For the production of cell-assembled extracellular matrix (CAM) sheets, human skin fibroblast (HSFs) were seeded in standard 6-well plates and cultured for 8 weeks with DMEM/F-12 supplemented with 20% FBS. Laser microdissection (30 µm diameter round perforations, spaced every 300 µm, to a final 1.5 x 1.5 cm square, with 50 by 50 perforations) was used to make precise and reproducible perforations within the sheets to enable passive perfusion of the culture medium and oxygen necessary to sustain cell viability and proliferation. Then, HSF were seeded on the surface before bioprinting RFP+ human umbilical vein endothelial cells (HUVECs) in 1.5 cm long lines, spaced by 4 mm, using the microvalve bioprinting function of the 3D Discovery platform (RegenHU, Switzerland). The bioprinted sheets were assembled and cultured in a transwell® system for a total of 26 days.

HUVEC organization was evaluated using confocal imaging. To test the inflammatory response and the capacity of the bioprinted constructs to integrate in an animal host, materials were implanted into a dorsal subcutaneous site of 9 weeks old male NOD Scid Gamma (NSG) mice for 3 weeks. Following in vitro maturation or/and subcutaneous implantation, tissue samples were harvested, fixed, processed for paraffin sectioning and immunostained for CD31, VWF, alpha-SM actin, COL4A, Human Nucleolar and Ulex Europaeus: agglutinin I, and analyzed by microscopy.

Results and Discussion
We demonstrated, for the first time, the use of this unique human biomaterial based on unprocessed ECM, as a microperforated biopaper. Using microvalve dispensing bioprinting, concentrated human endothelial cells (30 million/ml) were deposited in a controlled geometry and cocultured with human skin fibroblasts. Following multilayer assembly, HSF enabled the fusion of the different layers, generating a thick ECM-based construct that supported the survival and maturation of capillary-like structures for up to 26 days of culture. After 3 weeks in the subcutaneous

Page 92 of 2028
space of an immunocompromised mice model, this construct triggered no inflammatory/ degradative response and the pre-formed vasculature successfully connected with the host circulatory system to establish active perfusion.

Conclusion
Here, by combining cellular assembly, laser microdissection and bioprinting, we biofabricated a completely human 3D model of capillary networks and demonstrated its capacity to integrate subcutaneously in an immunodeficient mice model. This mechanically resilient tissue-equivalent has great potential as a base scaffold for the creation of more complex implantable tissues, where rapid anastomosis is sine qua non for cell survival and efficient tissue integration.

ECM-microfiber laden bioinks enable spatial control of capillary formation in 3D bioprinted constructs

Margo L. Terpstra1, Jinyu Li2, Anneloes Mensinga3, Mylène de Ruijter1, Michiya Matsusaki2, Jos Malda1,3, Riccardo Levato1,3

1 University Medical Center Utrecht, Department of Orthopaedics, Utrecht, NL; 2 Osaka University, Division of Applied Chemistry, Graduate School of Engineering, Osaka, JP; 3 Utrecht University, Department of Clinical Sciences, Faculty of Veterinary Medicine, Utrecht, NL

Introduction
Most tissues in our body are fully vascularized, to facilitate gas and nutrient exchange from the blood circulation. Menisci, however, consist of a vascularized and non-vascularized region. In tissue engineering, mimicking the spatial distribution of vascular components is paramount. In fact, capillary ingrowth into non-vascularized tissues can lead to tissue matrix alterations and subsequent pathology. Three-dimensional (3D) bioprinting has the potential to reproduce tissues with anisotropic features. Nevertheless, recreating a construct with stable vascularized and non-vascularized regions has not been achieved to date. In the current study we present the development of two 3D printable bioinks, that can be used and co-printed to recapitulate distinct vascular and avascular zones of the meniscus.

Experimental Methods
Extrusion based bioprinting was performed using two fibrin-gelatin-based bioinks (figure 1). The bioink for the vascularized red meniscal zone was supplemented with type I collagen microfibers (length of 212 ± 72 µm, and diameter of 27 ± 8 µm)(1), HUVECs and MSCs. The bioink for the white avascular meniscal zone were supplemented with cartilage decellularized extracellular matrix microfibers, developed for this study, and meniscus cells. An anatomical meniscus-like construct was 3D bioprinted into a sacrificial suspension bath composed of gellan gum microgels (average maximum diameter of 21 ± 9 µm), using a microCT scan as blueprint.

Results and Discussion
Previously, it was shown that fibrin bioinks with type I collagen microfibers facilitate capillary and lumen formation of HUVECs (1). We developed microfibers derived from cartilage extracellular matrix extracts, bearing components normally involved in preserving the avascular nature of cartilage (2,3). We demonstrate that such microfibers successfully inhibited HUVEC capillary formation (figure 2A), compared to type I collagen microfibers (figure 2B). Through supplementation of the two fibrin-based bioinks with type I collagen or cartilage matrix microfibers, we 3D bioprinted complex structures with distinct regions that facilitate or inhibit vascularization. Within the bath, filament had a thickness of 350 µm (figure 2D), and construct maintained their shape and geometry upon removal of the supporting gellan gum microgels. Four days after printing, the HUVECs showed confined capillary network formation, in the bioink regions printed with collagen microfiber-supplemented bioinks.

Conclusion
This study demonstrates the spatial-specific formation of capillaries in a 3D bioprinted construct. With this, we contribute to the development of biomimetic meniscal grafts. Moreover, this setup can serve as a platform for generating tissue constructs with vascularized and non-vascularized regions. These bioinks could be utilized for in vitro models for studying effects of new drugs, or mechanisms related to localized and anisotropic vascularization.

system. This project received funding from the European Research Council (3D-JOINT, 647426), European Union’s Horizon 2020 research and innovation programme (MEFISTO, 814444) and ReumaNederland (LLP-12, 22).

Figure 1: Bioprinting of a zonal meniscus construct

A meniscus construct was three-dimensional (3D) bioprinted with two fibrin-based bioinks, using a g-code generated from an equine meniscus CT scan. The bioink representing the red zone, normally vascular, included GFP-HUVECs, MSCs, and type I collagen micro-bers. The bioink representing the white zone, normally avascular, included meniscus cells, and cartilage matrix derived micro-bers. Bioprinting was done into a gellan gum microparticle support bath.

Figure 2: Cartilage matrix microfibers inhibit HUVEC network formation

GFP-HUVECs formed a network, supported by MSC-derived pericytes (α-SMA) (C) in presence of type I collagen micro-bers (B), yet this effect was reduced in presence of cartilage matrix derived micro-bers (A). Constructs 3D-printed in a gellan gum microparticle-based suspension bath showed a -filament thickness of 350 micron (D).

Introduction
Developing complex biological structures of clinically relevant sizes that can guide cell behavior remains a major challenge in tissue engineering. 3D bioprinting is a promising approach that allows for precise patterning of cell-laden biomaterials into tissue-mimetic constructs. Widely used bioprinting techniques like extrusion-based bioprinting (EBB) and digital light processing (DLP) employ a layer-by-layer fabrication strategy, which results in extended printing times for large structures and can detrimentally affect printed cells.[1] Moreover, bottom-up approaches cannot fully capture the convoluted porosity typical of many native tissues and certain complex anatomical features necessary for patient-specific grafts. Overcoming these challenges, a novel optical tomography-inspired printing approach in which spatially controlled visible light projections of a 3D object are used to rapidly fabricate large-scale structures in a single step has been developed.[2] Herein, the concept of volumetric bioprinting (VBP) is introduced alongside a hydrogel bio-resin, demonstrating the fabrication of complex, cell-laden biological structures within seconds.

Experimental Methods
A cell-laden, photosensitive gelatin methacryloyl formulation supplemented with the visible-light photoinitiator lithium phenyl-2,4,6-trimethylbenzoyl-phosphinate (LAP) was developed as bio-resin for VBP. Printing time of centimeter-scale constructs was compared to conventional bioprinting strategies (EBB and DLP). Viability (LIVE/DEAD assay) and metabolic activity (resazurin assay) of bioprinted mesenchymal stromal cells (MSCs) and articular cartilage-derived progenitor cells (ACPCs) was assessed. Mid- and long-term cell functionality post-printing was assessed through the fabrication of an MSC-laden trabecular bone model subsequently seeded with endothelial cells to assess neo-vascularization in vitro and an ACPC-laden meniscus model to evaluate biochemical and mechanical development over 28 days.[3]

Results and Discussion
The gelatin-based bio-resin was printed into human auricle constructs from anatomical scans in 22.7s with high volume accuracy (5.71±2.31%). Printing time remained constant for printing samples scaled to 1.23 and 4.14 cm³ through light dose increments. The same designs resulted in extended printing times for EBB (~30-90min) and DLP (~20-30min). Cells printed via VBP maintained high viability (>80%) and showed increasing metabolic activity over short- and long-term culture, as did EBB and DLP prints and cast control samples. The MSC-laden trabecular bone model presented the smallest resolved feature measuring 144.69±13.55 μm and exhibited a complex, interconnected porous network. After endothelial cell seeding in these pores, constructs exhibited enhanced neo-vessel formation compared to cast controls, as well as capillary infiltration into the printed hydrogel. Finally, meniscus constructs cultured for 28 days produced significant amounts of fibrocartilage-like matrix components and consequently exhibited increasing compressive properties over time, approaching values comparable to native meniscal fibrocartilage (~300kPa).[4] (Figure 1).

Conclusion
Page 96 of 2028
This study established a novel bioprinting approach for shaping hydrogels into complex, tissue-like architectures within seconds. Short printing times and freedom of design shown by VBP compared to conventional bioprinting methods make the technique appealing for biomedical applications, including creating patient-specific grafts and developing more complex in vitro models for disease modelling and drug screening. The use of this technique with a cell-laden, photosensitive hydrogel did not affect cell viability and behavior. Complex biological structures were successfully printed and cells in these printed constructs exhibited salient features post-printing and long-term biochemical and mechanical maturation. These findings open new avenues for designing the next generation of biomaterial-based bioprinted constructs of clinically-relevant size, a necessary step towards future clinical applications.

Ultra-High Throughput Production of Perfusable Microporous Annealed Particle Scaffolds

Maik R. Schot, Malin L. Becker, Carlo A. Paggi, Jeroen Leijten

University of Twente, Developmental Bioengineering, ENSCHEDE, NL

Introduction
Microporous annealed particle scaffolds (MAPs) offer numerous advantages owing to their microporous nature, which associates with improved perfusability, cell migration, implant survival, and tissue integration. However, the low throughputs of current microfluidic strategies has limited the translation of this technology into a clinical setting. We hypothesized that in-air microfluidics (IAMF), which was recently invented by our lab, would allow for the ultra-high throughput production of monodisperse cell-laden microgels to enable the fabrication of clinically sized MAPs. To allow the formation of inter-particle bonds, we produced microgels composed of a dual-crosslinking biomaterial based on tyramine-conjugated alginate (ATA). We here combined this material with IAMF to, for the first time, enable ultra-high throughput production of MAPs.

Experimental Methods
Alginate (80-120cP) was modified with tyramine moieties using DMTMM-based coupling. The degree of substitution was quantified using UV-Vis spectroscopy and vial-tilting was used to verify the sol-gel phase transition of the material following ionic crosslinking using calcium chloride and/or covalent crosslinking using Ruthenium/Sodium Persulfate (Ru/SPS). To generate microgels, a piezo-actuated microjet composed of 0.5% (w/v) ATA was collided with a continuous microjet of 0.1mM CaCl$_2$. Upon impact, calcium chloride solution was wrapped around the alginate drops via Marangoni flow, and microgels are formed via outside-in diffusion of calcium ions (Figure 1A). Cell encapsulation in microgels was achieved by dissolving cells in ATA at cell concentrations ranging from 1x10$^6$ cells/mL to 10x10$^6$ cells/mL. Microgel size, sphericity, monodispersity and cell encapsulation were characterized using fluorescent and phase contrast microscopy. MAPs were created by packing microgels using suction-assisted filtration and spiking the packed constructs with Ru/SPS solutions before applying visible light for three minutes. Construct stability was validated via agitation analysis. Construct perfusability was verified by a hydraulic conductivity assay and by performing micro-particle image velocimetry in a MAP on chip.

Results and Discussion
ATA was successfully functionalized with a degree of substitution of ~4% as determined with UV-Vis spectroscopy. ATA samples were able to form crosslinks using ionic as well as enzymatic and light-based covalent crosslinking strategies. Using IAMF, microparticles of controlled sizes ranging from 50 µm to 350 µm with a CV below 5% could be produced with flow rates ranging from 0.9 mL/min to 3.5 mL/min depending on nozzle size offering microgel production rates of up to 4.57 kHz (Figure 1B/C). Cells could be successfully encapsulated at varying amounts (Figure 1D) and with >80% viability for a wide variety of cell types including hepatocytes, stellate cells and endothelial cells (Figure 1E). After particle packing using injection molding, MAP formation was achieved by forming inter-particle crosslinks using visible light in the presence of Ru/SPS (Figure 2A). Upon exposure to hydrodynamic stress, the packed microgel construct without inter-particle crosslinks (blue) dissolved rapidly, whereas the dual-crosslinked construct (orange) remained fully intact even when vigorously agitated, which indicated successful MAP formation (Figure 2A). Confocal microscopy was used to visualize the internal structure of the MAP (Figure 2B) and to quantify the internal architecture of its integrated interconnected microporous network. Figure 2C and 2D show a MAP on chip and a 3D visualization of a MAP on chip perfused with fluorescent particles, showing the interconnected pore network in the MAP and demonstrating its functionality.
Conclusion
Using IAMF and ATA, we are able to produce microgels of controlled sizes which allows for the production of voluminous MAPs using a second, visible light based crosslinking system resulting in a highly porous, interconnected and perfusable matrix of connected microgels. Additionally, cells show high viability upon encapsulation inside microgels.

Introduction

Bioprinting technology is radically changing regenerative medicine, allowing the manufacturing of tissue-engineered constructs with appropriate control over spatial variations and the capability of precise deposition of biomaterials, cells and biological molecules.1 A great challenge is the identification of bioinks able to fulfill the requirements for reproducible additive manufacturing and biological properties for the type of tissue required.2 Hydrogel-based bioinks are the main formulations used for articular cartilage (AC) biofabrication, due to their similarity to the chondral tissue in terms of morphological and mechanical properties. In this work, we proposed an innovative photocurable gellan gum methacrylated (GGMA) based bioink suitable for extrusion-based bioprinting technology to obtain bioprinted AC-like constructs of clinically relevant sizes. In particular, we exploited a nature-inspired strategy, adding Manuka Honey (MH) to the GGMA composition (GGMA-MH).3

Experimental Methods

H-NMR, XPS and FTIR were performed to assess the methacrylation efficiency. Then, the bioinks formulations composed of GGMA or GGMA-MH and mesenchymal stem cells differentiated in chondrocytes (Y201-Cs) were extruded to obtain a grid-shaped construct with Rokit INVIVO bioprinter (Figure 1). SEM analysis was performed on both compositions without cells to assess the porosity and with cells (at day 1 and day 21 of culture) to evaluate their morphology and organisation. Physical properties as water uptake capability and mechanical properties via a compression test and rheological analyses were assessed. Cells viability was monitored straight after the printing process (3h), and during 7 days of culture via Live/Dead, Immunostaining of Nuclei (DAPI) and Cytoskeleton (Phalloidin Rhodamine) and ATP production (MTS). Gene expression analysis (ACAN, COL2A1 and SOX9), mucopolysaccharides quantification and histological analyses (H&E, Picrosirius Red, Alcian Blue) were performed to evaluate the chondrogenic potential of the bioinks formulation (Figure 2).

Results and Discussion

The methacrylation efficiency of GGMA was chemically assessed by means of H-NMR, XPS and FTIR. GGMA/Y201-C and GGMA-MH/Y201-C bioinks printability, defined by the shapes of the bioprinted fibers, were satisfying, as we obtained bioinks extruded to continuous smooth and homogeneous strands, achieving a 5-layers grid (6 mm x 6 mm x 2 mm) via a multilayered deposition process. The chemical crosslinking process occurred via UV irradiation, while the filament was being deposited on the printing bed. Furthermore, the presence of DMEM/F12 onto the printing bed helped the gelation process, via physical crosslinking (Figure 1). SEM investigation demonstrated that both compositions (GGMA and GGMA-MH) showed porous interconnected structure, with pore size in the range 50-250 μm, optimal for nutrition supply and diffusion (Figure 1). GGMA and GGMA-MH hydrogels showed high hydrophilicity as demonstrated by water uptake analysis and suitable mechanical properties (26.3 ± 3.0 kPa for the GGMA and 23.6 ± 5.0 kPa for the GGMA-MH) for AC regeneration. The beneficial effect of Manuka Honey incorporation on
printability and cell viability and fate was evaluated through cell viability assays (Live and Dead, Nuclei and Cytoskeleton staining (Figure 2) and metabolic activity). The chondrogenic potential of the cells laden GGMA-based bioinks was confirmed over 21 days of culture with collagen and proteoglycans histological analyses, gene expression assessment of main chondrogenic genes (SOX9, ACAN and COL2A1) and glycosaminoglycans quantification. Overall Manuka-honey enriched bioink was found to induce a higher expression of COL2A1 and ACAN in Y201-Cs encapsulated cells at 21 days.

Conclusion

Both GGMA and GGMA-MH, represent potential biomaterials for bioink formulations loaded with mesenchymal stem cells differentiated in chondrocytes to obtain a cartilage-like construct. The bioprinting process, with the proper choice of parameters, enabled us to print these bioinks with spatial and microscale resolution in a rapid and continuous manner, without affecting cell viability. Importantly, the addition of MH led to the obtainment of an antimicrobial environment, more viscous formulation, and an optimal cells distribution pattern, inducing the Y201-C to exhibit maximum biosynthetic ability. Finally, these structurally biomimetic cartilage-like bioprinted constructs, with a cell density of ~ 7 million/mL and Young's module of ~25 kPa could be suitable platforms for future investigations on AC disease modelling and therapy.

Nature has inspired the rational design and development of supramolecular biomaterials exhibiting sophisticated structures, properties and functions at the nanoscale by controlling the self-assembly of its basic molecular components. This symposium will highlight several examples on the supramolecular design of peptide-based biomaterials displaying tunable features and multifunctionalities for regenerative medicine.
Exploiting β-sheet peptides self-assembly to design hydrogels for biomedical applications

Alberto Saiani

University of Manchester, Department of Materials & Manchester Institute of Biotechnology, Manchester, GB

The use of non-covalent self-assembly has become a prominent strategy in material science offering practical routes for the construction of increasingly functional materials for a variety of applications ranging from electronic to biotechnology. A variety of molecular building blocks can be used for this purpose, one such block that has attracted considerable attention in the last 20 years is de-novo designed peptides. Our group work focusses on the development of a technological platform for the design of novel biofunctional hydrogels exploiting the self-assembly of so-called b-sheet forming peptides. These hydrogels can be easily functionalised using specific biological signals and can also be made responsive through the use of enzymatic catalysis and/or conjugation with responsive polymers. Through the fundamental understanding of the self-assembly and gelation processes of these peptides across length scales we have been able to design hydrogels with tailored properties for a range of applications from tissue engineering, cell culture and drug delivery to 3D bioprinting and biosensing [1-5].

Molecular Biomaterials for Regenerative Medicine

Helena S. Azevedo

Queen Mary University of London, School of Engineering & Materials Science, London, GB

The extracellular matrix of tissues contains specialized fibrous proteins and polysaccharides that provide much more than mechanical support for cells. Mimicking this intricate and dynamic protein/polymer network has been a major goal in biomaterials engineering. Using self-assembly as fabrication method, biomaterials can be made with nanoscale precision and inbuilt biophysical and chemical cues. In this bottom-up framework, peptides are obvious supramolecular building blocks as they can be designed to self-assemble into nanostructures with defined shape (e.g. nanofibers) and display desired functionality to control cell functions (e.g. cell adhesion, proliferation, differentiation). Our group has been exploiting the peptide and polymer landscape (polymer composition, architecture, molecular weight, viscosity; peptide sequence, charge, conformation) to develop new self-assembling peptide/polymer biomaterials with properties suitable for applications in drug delivery and regenerative medicine. Through careful selection of the building blocks, and their optimal combinations (peptide/polymer ratio, mixing order), we have realised the formation of self-assembling membranes and hydrogels with diverse and tuneable properties. This talk will cover our work on applying relatively simple (macro)molecular engineering approaches to unveil new features in self-assembling biomaterials.

Acknowledgement

Our work has received support through funds from the European Union, Wellcome Trust and Royal Society.

Introduction

Spinal cord injury (SCI) is a severe neurological disorder arising from traumatic damages inflicted on the spinal cord structure. It represents one of the leading causes of disability worldwide [1], inducing sensory and motor dysfunctions owing to the complex lesion environment and limited ability of the central nervous system (CNS) to self-regenerate [2]. Despite the increasing knowledge in understanding the mechanisms and addressing the lesion pathophysiology, there is still not an effective therapy to promote functional recovery following SCI.

Recently, the advances in supramolecular chemistry, tissue engineering and regenerative medicine, have opened up new avenues in the molecular design and development of functional biomaterial architectures aimed at building up a pro-regenerative microenvironment at the lesion site [3]. To achieve an efficient therapeutic solution, multiple aspects of the spinal lesion environment should be addressed by pursuing a multicomponent biomaterial approach [4]. However, to date, the incorporation of multiple signals in the same system is far from being accomplished, which limits its effectiveness in recreating the complexity, fibrous architecture, functionality and dynamic nature of the neural extracellular matrix (ECM). In this regard, the development of ECM-mimetic biofunctional scaffolds that recreate the native neural ECM and modulate cell functions at the nano/microscale level are of utmost importance. Herein, we spotlight the supramolecular design and development of soft biomimetic multitactical patches endowed with topographical, biomechanical and biochemical cues to recapitulate the diversity of signals in the CNS environment, improve cell-biomaterial interaction and control axonal growth (Figure 1).

Experimental Methods

The patches encompass biocompatible polymers ubiquitous in neural ECM (i.e., hyaluronic acid (HA)), poly(L-lysine), widely used for engineering bioinstructive matrices to support neural cell functions, and laminin-mimetic self-assembling peptide (SAP) recreating the neural ECM and promoting neurite outgrowth [5]. Firstly, the secondary structure of the individual and co-assembled systems was assessed by circular dichroism, ATR-FTIR spectroscopy, wide-angle X-ray scattering, and scanning electron microscopy (SEM). Then, the build-up of soft bioactive supramolecular multilayered thin films in a Layer-by-Layer (LbL) fashion was monitored in situ by quartz crystal microbalance with dissipation monitoring. The multilayered thin films were translated into robust free-standing multilayered patches assembled on templates exhibiting distinct nanotopographies (i.e., flat and nanopatterned substrates) to study their influence on cell functions. The developed patches were further crosslinked via carbodiimide chemistry to enhance their mechanical properties. The physicochemical, morphological and mechanical properties were studied by water contact angle measurements, SEM and Universal Mechanical Testing Machine, respectively. The in vitro biological performance of the native and crosslinked patches was assessed using primary neuronal cortical cells.

Results and Discussion
Secondary structure analysis revealed the ability of HA to trigger the self-assembling capability of peptides, leading to the formation of β-sheet structures with a high degree of supramolecular order. Robust free-standing multilayered patches displaying flat and nanopatterned topographical features were successfully produced and characterized. The presence of a nanopatterned topography enhanced the surface hydrophobicity of the patches when compared with the flat ones. The presence of self-assembling peptides improved hydrophilicity when compared to the biopolymer ending-layers.

The influence of the multilayered patches’ crosslinking and nanopatterned features on the behavior of primary neuronal cortical cells was investigated. At 4 days of culture in vitro, we could see obvious differences between the developed multilayered patches. Crosslinked nanopatterned multilayered patches stimulated the outgrowth of neurites, in all conditions, contrarily to uncrosslinked ones. The incorporation of the SAP, as the outermost layer, revealed the formation of aligned neurites along the nanopatterned direction.

Overall, we confirm the synergistic effects of stiffness, induced by the chemical crosslinking, the presence of the bioactive peptide and the aligned nanopattern, in the orientation of neurite outgrowth of neuronal cortical cells.

**Conclusion**

Robust bioactive flat and nanopatterned free-standing multilayered patches were successfully produced by combining molecular self-assembly with the LbL assembly technology, revealing their ability to tune primary neuronal cortical cells behavior. The gathered results highlight the relevance of the synergistic action of topographical, mechanical and biochemical cues in building complex pro-regenerative environments to instruct neuronal cell functions and be effectively used in spinal cord regeneration.

Accelerating drug development with human protein based platforms for in vitro 3D cell culture and disease modelling

Catarina A. Custódio, Sara C. Santos, Cátia F. Monteiro, Inês A. Deus, João F. Mano

Universidade de Aveiro, Departamento de Química/ CICECO- Aveiro Institute of Materials, Aveiro, PT

Introduction

Data from Humane Society International reveal that every year more than 115 million animals are used in laboratories throughout the world, moreover the National Institute of Health (NIH) has noted that 90% of all drugs tested on animals fail in humans. Beyond the ethical concerns, the use of animal models results in an inefficient, long and expensive drug discovery process. Regarding in vitro tests, 2D cell cultures are a practical option for screening assays, still they do not adequately mimic the complex and 3D organized cell native microenvironment. For that reason 3D models are being adopted as platforms for cell culture and in the drug discovery process.

We have developed a technology to synthesize human based cell culture platforms that overcome major issues in drug development and tissue engineering by using ethically sourced human proteins. The proposed materials have tunable mechanical properties, being versatile platforms for cell culture and microtissue development that will increase the accuracy of in vitro studies by providing realistic microenvironments to cells. These novel materials are easily processed in multiple geometries and in microarrays amenable to ‘organ-on-a-chip’ systems and for instrumentation used in high-throughput (HTS) that are a need for pharma companies. They can find also applications as bioinks for bioprinting and tissue engineering applications.

Experimental Methods

The human based materials were produced from human proteins with origin in the extra cellular matrix (ECM) from amniotic membrane (AM) and platelet lysates (PL) from blood plasma. Placenta was manually dissected and separated in the amnion and the chorion membrane. The peeled membranes were decellularized and solubilized, lyophilized, and processed in a cryogenic grinder. Platelet lysates (PLs) were prepared by exposing pooled PRP to a series of freeze-thaw cycles. The obtained ECM proteins and PLs were chemically modified using a methacrylation protocol well established in our group resulting in methacrylated PL (PLMA) and amniotic membrane (AMMA). Degree and local of modification were evaluated by mass spectrometry. The methacrylated proteins were processed in the form of a hydrogel upon irradiation with UV light. Their structural and mechanical properties were evaluated. Total protein content and the release of specific bioactive molecules was done using Micro BCA and ELISA assay respectively. Cell culture was performed using endothelial cells, stem cells and multiple cancer cell lines either dispersed or in the form of spheroids. The biological performance of the humanized hydrogels was assessed by measuring cell viability and proliferation. At pre-determined time points samples were fixed and immuno-stained.

Results and Discussion

The mechanical properties of the developed hydrogel networks, with Young’s modulus values between 2.5 and 25 kPa, showed to be easily adjusted by tuning degree of methacrylation and concentration of proteins in solution. Protein release profile of shows an overall sustained release. It is also important to refer that the hydrogels maintain their shape during the time release tests were performed. The synthesized gels have proven to support distinct human derived cell cultures (Fig 1).

We have demonstrated the superior bioperformance of such hydrogels compared to classical materials, and their versatility for spheroid invasion, endothelial cell alignment and stem cell culture. Cells could perform important biological processes such as growth, sprouting and migration, displaying a good cell-matrix interaction. Moreover patterned hydrogels were able to provide a support for aligned cell growth. These hydrogels demonstrated to support...
cellular proliferation and formation of a necrotic core in spheroids of stem cells and distinct tumor cell lines. The innovation potential of our materials is based on the fact that contain human biochemical cues, is a complete xenofree solution for human cell culture and easy to manipulate. Preliminary results also suggest the ability of the human derived platforms to support cell culture in the absence of animal derived serum.

Conclusion
This is a novel platform technology that is easy to manipulate, cost effective, reproducible and robust that will accelerate research and drug discovery by providing more realistic results. The benefits of using this next-generation of cell culture materials are both, economic and social, being mainly related to the 1) achievement of more accurate and clinical translatable results, 2) faster drug screening and development processes, 3) reduction in animal-model using and costs associated to late stage drug failures.

Porous yet dense, shaping biomimetic materials for 3D cell culture applications using ice

Francisco M. Fernandes, Cleo Parisi, Isabelle Martinier, Léa Trichet
Sorbonne Université, LCMCP, Paris, FR

Introduction
Three dimensional cell culture scaffolds are expected to bridge the gap between traditional in vitro cell culture and in vivo animal models. The impact of minimizing in vivo experiments is expected to be outstanding, with consequences both in the ethical and economical aspects in numerous fields. But, despite the promise of increased physiological relevance, 3D cell culture systems are still far from being the norm. In particular, the extensive set of requirements necessary to fabricate effective 3D cell culture materials is far from trivial and few sound solutions are available. Conditions such as non-cytotoxicity, adequate elastic moduli and suitable macroporosity are often difficult to match into a single material. Here, we report recent results in the development of new 3D cell culture systems based on ice templating of highly concentrated type I collagen solutions that are later transformed into macroporous fibrillar collagen gels. Ice templating relies on the use of controlled ice crystal growth to create porosity. The process is easy to implement, cost effective and applicable to a wide range of materials. Since it relies on the use of low temperatures to shape materials, ice templating has sparked growing interest to shape biological matter which is particularly prone to thermal denaturation, ranging from biomolecules up to living cells.

Experimental Methods
Collagen solutions were initially analyzed using DSC to establish the water-collagen phase diagram in the cold 'regime' and define the optimal ice templating conditions. Macroporous fibrillar materials were prepared using a home-built ice templating device. Upon freezing the 40 mg.mL⁻¹ acid soluble type I collagen matrices with controlled unidirectional macroporosity were fibrillated via topotactic stabilization. Obtained matrices were thoroughly characterized using SEM, TEM, PLOM, confocal microscopy (Second Harmonic Generation) as well as tensile testing. Macroporous collagen materials were used as 3D cell culture matrices up to 28 days in presence of human fibroblasts (NHDF) and C2C12 murine myoblasts. During cell culture materials were systematically analyzed (1, 7, 14, 21 and 28 days) by confocal microscopy to extract the morphological response of cultured cells, the colonization dynamics as well as the expression of hypoxic markers. Control experiments using equally concentrated matrices without macroporosity were performed to specifically assess the role of macroporosity in the cellular local environment.

Results and Discussion
We demonstrate that ice templating can be modulated to induce the supramolecular assembly of type I collagen—exhibiting the textural and mechanical features of the extracellular matrix (ECM)—while imposing a controlled macroporous structure that favors cell colonization, as well as nutrient and gas diffusion. Locally, the materials walls present collagen concentration superior to 200 mg.mL⁻¹, due to the concentration effect induced by the freezing front progression. In parallel, the collagen materials display a global elastic modulus in traction superior to 30 kPa. We will discuss how the motifs developed during freezing enable successful migration and colonization of NHDF and C2C12 across the 3D biomimetic collagen scaffolds. Moreover we will discuss recent results showing how these porous matrices compare with equivalent non-porous collagen matrices in terms of kinetics and extent of colonization, opens an exciting pathway to achieve new biomimetic 3D cell culture materials systems with enhanced physiological relevance.

Conclusion
Page 110 of 2028
The new collagen-based materials discussed here combine macroporosity, that enables cell migration as well as gas and nutrient diffusion, and local high concentration developed during ice templating, which leads to a biomimetic model recapitulating the architectural features of the ECM. These characteristics constitute a long sought-after compromise that gathers the advantages of dense collagen matrices without presenting their common limitations such as hypoxic zones due to limited gas diffusion. Porous, yet dense!

This symposium focuses on a major topic of research for the biomaterials community, which will attract interest from young and experienced researchers alike. It aims to provide a comprehensive overview of the most advanced trends in the development of bioinspired antimicrobial materials.

We plan to cover a wide range of advanced strategies to design novel bioinspired antimicrobial materials, with a special focus on antimicrobial peptides (AMPs), but including also bactericidal topographies, dual-action coatings (combining antibacterial and cell instructive potential), smart stimuli-responsive materials, and strategies to fight antibiotic-resistant bacteria, among others.
Bioinspired strategies to combat multi-drug resistant biomaterial-associated infection

Sebastian A. Zaat

Amsterdam UMC, Medical Microbiology and Infection Prevention, Amsterdam, NL

Biomaterial-associated infections are a main cause of failure of inserted or implanted medical devices, and multidrug resistant bacteria are increasingly prevalent, making treatment complicated (1). Therefore, there is an urgent need for novel antimicrobial solutions capable of also neutralising multi drug resistant pathogens. For such solutions, bioinspired strategies are a promising and expanding field of research. Inserted or implanted biomaterials predispose to infection because they provide pathogens a surface to adhere and to grow out to form biofilms. Moreover, their presence provokes a “Foreign body response”, a cascade of host inflammatory and tissue regenerative responses which, although aimed at proper integration of the foreign material, may increase susceptibility to infection of the tissue surrounding the biomaterial. Due to local immune suppressive effects this may even result in intracellular survival of bacteria within professional phagocytes (2).

We have used biology as an inspiration to develop novel antimicrobials. Thrombocidins, the microbicidal proteins from our own blood platelets (3) have been the design template for our TC-peptides. These peptides have potent microbicidal and anti-biofilm activity, and low toxicity, and are active in animal models of biomaterial-associated infection (4). LL-37, the human cathelicidin with antimicrobial activity produced by human neutrophils and epithelial cells, was the design template for a second family of AMPs, called “SAAPs”, for Synthetic Antimicrobial and Antibiofilm Peptides (5). The most promising SAAPs have been incorporated in PLEX Polymer Lipid Encapsulation Matrix systems for orthopedic implants, allowing their controlled release. A PLEX coating releasing the SAAP OP-145 prevented infection of an implant-associated S. aureus infection in rabbits (5).

We are incorporating these peptides in novel antimicrobial materials for additive manufacturing to construct personalized implants, meeting patient-specific needs and designs. One strategy is to couple the antimicrobial peptides to self-assembling polymers, which may be utilized to coat materials but also for use in electrospinning to construct safe, antimicrobial matrices for in situ tissue engineering, e.g. for prosthetic heart valves or surgical implants (6).

In order to protect the tissue around biomaterials from colonization, it is important to maintain a proper immune condition despite the presence of the implant. To this aim, we study the host immune responses to biomaterials without and with infection, to identify possible pathways associated with increase in susceptibility to infection (7). This research aims to identify to host response-inspired targets to optimize response to biomaterials, and conversely to design materials capable of inducing “the right response”. Moreover, in order to treat infection, antimicrobials need to reach intracellular bacteria. Many antibiotics fail to enter host cells. We therefore have utilized photosensitizers to achieve intracellular delivery of antibiotics, and eradication of intracellular S. aureus infection (8).

Thus, in the triangle of biomaterial – pathogen – biomaterial, bio-inspired solutions are a promising approach to provide new ways to prevent and treat biomaterial-associated infections, even by multidrug resistant bacteria, and to manufacture better and safer biomaterials.

Introduction

Skin chronic wounds arise when a wound gets arrested in a state of persistent inflammation. Chronic wounds are characterized by an intense inflammatory state that precludes the transition to the proliferative and remodeling stages of wound healing [1], [2]. As the wound bed is often unable to properly close and, therefore, remains exposed to the external environment, microorganisms are able to colonize the wound and frequently establish an infection that further impairs healing [3]. Bioactive molecules are often compromised by the highly proteolytic environment in the wound, if applied freely in solution [4]. Conversely, covalent conjugation onto biomaterials may protect them from such enzymatic degradation, prolonging their therapeutic effect. The use of AMPs is a promising alternative to traditional antimicrobial agents, as the former possess a reduced likelihood of inducing bacterial resistance [5]. Thus, herein, the covalent conjugation of an antimicrobial peptide (AMP), Dhvar5, onto chitosan was explored as an efficient strategy to develop a novel biomaterial that can be used, in the future, to produce improved wound dressings with sustained action against bacterial infection.

Experimental Methods

Conjugation of Dhvar5 onto chitosan was carried out through thiol-norbornene photoclick chemistry (TNPC; Figure 1). To this end, Dhvar5 (LLLFLKLRKKRKY) was modified with a flexible spacer plus a cysteine and the chitosan backbone was modified with norbornene groups in a co-solvent (aqueous/organic) system. Then, upon exposure to UV light in the presence of a photoinitiator, the thiol group of the peptide's cysteine readily reacted with the carbon-carbon double bond in norbornene groups, resulting in the covalent conjugation of Dhvar5 onto chitosan.

Results and Discussion

Despite the high molecular weight chitosan (355 ± 22 kDa) used in the present work, which may difficult the access of the AMP to the norbornene groups, up to 18.5% of initial AMP were present in the chitosan-norbornene-Dhvar5 (NorChit-Dhvar5) conjugate, which corresponds to nearly 34 μmol of AMP per gram of NorChit-Dhvar5. Subsequently, thin films of this conjugate were produced by spin-coating to assess their antimicrobial potential against S. epidermidis (ATCC 35984). A significant reduction in the number of total adhered bacteria (~40%) and of viable adhered bacteria (~15%), relatively to chitosan, was observed for NorChit-Dhvar5 conjugates, when AMP conjugation occurred through the N-terminus (Figure 2). Of note, the exposure of the AMP to UV radiation during TNPC reaction led to no adverse effect on the antimicrobial effect of the AMP, as minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) values were not altered (1 and 2 μg/mL, respectively).

Conclusion

Overall, the results obtained in the present study suggest that covalent conjugation of Dhvar5 onto chitosan by TNPC enhances chitosan’s antimicrobial effect. Moreover, we believe NorChit-Dhvar5 may be a promising biomaterial for the future development of wound dressings. The protective effect of the covalent conjugation of Dhvar5 onto chitosan...
will be evaluated, as it is expected to prolong the residence time and, possibly, the half-life of the AMP in the highly proteolytic environment of chronic infected skin wounds.

Introduction
In Europe, more than 200 million women (69%) and 187 million men (61%) suffer from cold sores, a widespread and annoying disease caused by the Herpes Simplex Virus type 1 (HSV-1). Cold sore (Herpes labialis) is very contagious and spreads from person to person through close contact. Taking action at the early stage is the most effective way to contain the virus and promote fast healing. Transparent patches are a widespread remedy as they make cold sores less visible and also act as an antivirus shield, reducing the risk of infection. The HelixComplex® snail mucus is a set of molecules with bioactive properties: anti-microbial, protective, regenerative, antioxidant and moisturizing [1-2]. The anti-viral efficacy against HSV-1 of the snail slime extracted from Helix Aspersa has not been demonstrated before. In this work, biopolymer-based patches enriched with snail slime have been developed and characterized in terms of mechanical, structural and biological properties and proposed for the treatment of cold sores.

Experimental Methods
Sodium carboxymethylcellulose (Mw=250 kDa, ACEF, Italy) and sodium hyaluronate were selected for patches formulation. Patches were prepared by the solvent casting technique by dissolving different relative amounts of these natural polymers directly into the snail slime (HelixComplex®). In particular, a 2% w/V of cellulose and two different amounts of hyaluronate (0.5 and 1 % w/V) were tested. Glycerol (Fagron, Italy) was added to the formulations as a humectant, in two different amounts, 5 and 10% w/V. Tensile tests were performed on films immediately after drying using a 4465 Instron dynamometer equipped with a 100N load cell and the Series IX software package. Stress-strain curves were collected and the Young’s modulus, the stress at break and the strain at break were evaluated. The test was performed at a crosshead speed of 5 mm/min on strip-shaped samples (40 mm long and 4 mm width) on at least 10 specimens for each composition. All films have been subjected to structural investigation: FTIR spectra were recorded in ATR mode while X-ray diffraction patterns were recorded in the 2θ range from 4° to 40° by means of a Philips X’Celerator diffractometer. Water vapor permeability (WVP) studies, were performed using the ASTM E96-93 method, slightly modified as reported in literature [3]. The patches morphology was investigated by scanning electron microscopy (SEM), covering the samples with a layer of gold before analysis. The films bioadhesion was evaluated by means of AntonPaar modular compact rheometer MCR102 and the RheoCompass Software using pig ear skin, as reported in literature [4]. The biocompatibility has been evaluated via MTT assay on human fibroblasts cells (MRC-5). Then, the effectiveness of patches enriched with the snail mucus was tested on in vitro experimental models of Herpes Simplex 1 virus (HSV-1) infections (0.01 PFU/cell) on keratinocytes (HaCaT) cell lines.

Results and Discussion
All the obtained films were transparent and easy to handle (Fig.1a). From SEM images they all appeared smooth and without superficial defects. Moreover, all the obtained films showed good adhesion to the skin: once adhered to the skin, they remained attached for hours without drying out or detaching from the edges. These features are of primary importance for a labial patch as they ensure discretion and good compliance of the patient, as it can be inferred from Fig.1b. All the films showed suitable mechanical properties, as they behave flexible, elastic and with...
maximum deformation values reaching even 200%. The ability of the films to provide a humid environment capable of preventing crusts and letting the wound breathe has been verified by WVP tests. In vitro cytotoxicity assay was performed on all the films compositions and the results expressed as cells viability (%). All the samples displayed a promising safety profile. All samples were then tested against HSV-1, evaluating their efficacy pre-infection, post infection and both pre and post infection. Only the labial patches enriched with HelixComplex® were able to reduce the infection, as reported in Fig.2, suggesting that its use could be very effective in the prevention and in the reduction of the disease, avoiding the infection of neighboring cells.

Conclusion
In conclusion, these films represent a sustainable alternative to the commercial plastic patches. Thanks to their adhesiveness and biocompatibility, films enriched with snail mucus extract demonstrated to be very good candidates to act as a labial patch for the treatment of Herpes labialis.

Acknowledgement
Thanks to the HelixPharma Company which gently provided the HelixComplex® snail mucus.

Using Lattices to Control the Release of Antibiotics and Growth Factors from a Spinal Cage

Sophie E. Louth\textsuperscript{1}, Luke N. Carter\textsuperscript{1}, Kenneth Nai\textsuperscript{3}, Moataz M. Attallah\textsuperscript{2}, Liam M. Grover\textsuperscript{1}, Sophie C. Cox\textsuperscript{1}

\textsuperscript{1} University of Birmingham, School of Chemical Engineering, Birmingham, GB; \textsuperscript{2} University of Birmingham, School of Metallurgy and Materials, Birmingham, GB; \textsuperscript{3} Renishaw PLC, Stroud, GB

Introduction
Spinal cages are implanted between vertebrae to fuse a section of the spine. This procedure carries an infection rate of around 1% which is higher than infection rates for spinal procedures which do not involve hardware [1,2]. Both early infections, within months of surgery, and late infections can occur [3].

The current treatment for infection includes oral and intravenous antibiotics, debridement of the infected tissues, and irrigation of the site. Most commonly hardware is removed, with new hardware implanted if needed. Antibiotic loaded cement beads can be packed into the region to deliver local antibiotics to increase the chance of hardware retention, this requires a subsequent surgery for removal [4].

Temporary antibiotic loaded cement spacers, that are common in orthopaedic infection treatment, are not currently used in spinal infections. This study aims to investigate whether additive manufacture of Ti-6Al-4V can be used to create a new spinal cage which can be loaded with antibiotics and growth factors in order to clear infection and promote bone growth. A lattice structure will be used to provide mechanical support and control the release of the actives. A polycaprolactone coating loaded with growth factors will cover the lattice, and the voids will be filled with an antibiotic loaded brushite cement (Figure 1).

Experimental Methods
Lattice designs were generated using nTopology Platform (nTopology Inc., USA), and printed on a Ren AM 500M (Renishaw PLC., UK) from gas atomised Ti-6Al-4V powder using optimised in-house parameters. Cylindrical samples (6mm radius, 15mm height) were produced for compression testing, with testing performed in accordance with ISO 13314:2011. Cylindrical samples (10mm radius, 20mm height) with porosity ranges of 20-60% for elution studies were produced in the same way. To test antibiotic release these samples were filled with brushite cement containing 2.5\% w/w gentamicin sulphate (Figure 2A). Release into Phosphate Buffered Saline solution was fluoroscopically measured over eight weeks using o-phthalaldehyde derivatizing agent and a Spark Platereader (Tecan, Switzerland).

Bacterial inhibition was investigated for \textit{Staphylococcus Aureus} and \textit{Pseudomonas Aeruginosa} using zones of inhibition. For growth factor release studies a polycaprolactone coating was loaded with 5\%w/w Albumin as an analogue molecule for growth factors. The released Albumin was fluoroscopically measured using an Albumin protein assay kit and a Spark Platereader (Tecan, Switzerland).

Results and Discussion
Compressions testing showed that a number of lattice designs had compressive yield strengths higher than that of bone making them suitable for this application. Different lattice designs could be used to alter the release profiles of the actives by changing the lattice surface area, cement volume, exposed cement surface area and the loading of the actives (Figure 2B). Bacterial testing found sufficient gentamicin sulphate could be released to kill both \textit{Pseudomonas Aeruginosa} and \textit{Staphylococcus Aureus} (Figure 2C and D).

Conclusion
This work has shown that additive manufacturing can be used to create novel medical devices, and exploited for functions beyond anatomical customisation. More specifically the design freedoms of the technique allow the manufacture of lattices which can provide mechanical support, and control the release of actives in a spinal cage.
device. By controlling the release of the antibiotic the infection can be optimally treated minimising the drug loading which reduces the risk of creating antibiotic resistance.

Future work will investigate whether the presence of the biomaterials will chemically effect the lattice structure. The mechanical properties of the composite of the lattice, polymer and cement will also be investigated both as cylindrical samples, and in the full spinal cage.

Multifunctional bioinspired melanin-CeO₂ hybrid nanozymes for regenerative medicine

Giulio Pota¹, Anna Cuna¹, Giuseppe Vitiello¹,⁴, Anna Zanfardino³, Michela Di Napoli³, Alessandro Pezzella²,⁵,⁶, Giuseppina Luciani¹

¹ University of Naples Federico II, Department of Chemical, Materials and Production Engineering, Naples, IT; ² University of Naples Federico II, Department of Physics, Naples, IT; ³ University of Naples Federico II, Department of Biology, Naples, IT; ⁴ Center for Colloid and Surface Science (CGSI), Florence, IT; ⁵ National Research Council (CNR), Institute for Polymers Composites and Biomaterials (IPCB), Napoli, IT; ⁶ National Interuniversity Consortium of Materials Science and Technology (INSTM), Florence, IT

Introduction

Chemical designed nanozymes has emerged as a next-generation nanomedicine, due to their ability to combine enzyme-like features with high catalytic stability, multiple functions, low cost as well as great design versatility [1]. Moreover, surface modification of nanozymes, appears as an effective strategy to achieve superior catalytic activity, high selectivity and controllable performance for biomedical applications. In particular, nanosized CeO₂ has been rising great interest for its biocompatibility and biological activity, related to the presence of a dual surface oxidation state (Ce³⁺/Ce⁴⁺) caused by oxygen vacancies in the fluorite lattice [2]. This feature makes it a red-ox active material, able to quench or generate ROS, exerting antioxidant and antimicrobial activity. Similar properties are shown by melanin, a class of hydrophobic natural pigments with intrinsic multifunctional properties such as free radical homeostasis as well as anti-inflammatory, antioxidant action and potent antimicrobial activity [3,4]. In this study, CeO₂ and melanin are combined at the molecular scale into a core-shell architecture. To this purpose, CeO₂ nanoparticles were produced by hydrothermal route and subsequently coated with melanin, which was obtained by in-situ 5,6-dihydroxyindole-2-carboxylic acid (DHICA) oxidative polymerization, mediated by Ce⁴⁺ species. Hybrid nanozymes were submitted to physico-chemical characterization to investigate the nanoparticle-biomolecule interactions. Finally, antioxidant and antimicrobial assays were carried out to prove the efficacy of the proposed strategy in boosting intrinsic biocide and antioxidant properties of organic and inorganic components.

Experimental Methods

CeO₂ nanoparticles were produced following a one-step hydrothermal synthesis, starting from Ce(NO₃)₂·6H₂O and NaOH as precursor and morphologic agent, respectively [2]. Melanin coatings were produced by dropwise addition of DHICA-in-ethanol solutions, at different concentrations, to a CeO₂ water suspension. The coated samples were named as CeO₂-DHICA, CeO₂-DHICA 2, CeO₂-DHICA 10. The interactions between the inorganic core and the organic shell were investigated through Fourier Transform Infrared Spectroscopy (FTIR), UV-vis, Electron Paramagnetic Resonance (EPR) spectroscopy. The antioxidant properties of all the samples were tested through DPPH assay. Finally, the antimicrobial power of the nanosystems was assessed towards two bacterial strains, Escherichia Coli (Gram (-)) and Stafilococcus Aureus (Gram (+)).

Results and Discussion

The hydrothermal synthesis produced polyhedral nanoparticles with average size in the range 10-25 nm (Fig. 1a). The adsorption of DHICA onto nanoceria was achieved thanks to a Ce(IV)-catechol complex in the form of a bidentate bridge, as unveiled by FTIR and UV-Vis spectra. The coated sample at the highest DHICA content exhibit higher absorbance in the visible region than bare CeO₂ as well as red-shifted spectrum, suggesting melanin formation. The presence of a melanin shell in CeO₂-DHICA 10 was confirmed by EPR spectroscopy, showing one asymmetric peak (Fig. 1b), with a g-factor of 2.0032 ± 0.0002 and a ΔB of 4.4 ± 0.2, typical values of carbon-centred radicals of melanin.
chains generated through polymerization via ligand-to-metal charge transfer mechanism [5] between DHICA and CeO2. Bare CeO2 nanoparticles exhibited mild antimicrobial activity (Fig. 2a) limited to Gram (+) bacteria probably due to a mechanical damage of the bacterial cell wall, while melanin-coated CeO2 nanozymes experienced a remarkable boost in the biocide power which was more evident against Gram (-) strains and could be determined by a peculiar mechanism of action based on melanin-promoted ROS production and membrane destabilization [4]. Finally, all the nanosystems exhibited DPPH radical scavenging activity, which was higher than bare CeO2 and markedly increased with DHICA content (Fig. 2c). Among all the samples, melanin-coated CeO2-DHICA 10 sample exhibited the best performance. Indeed, DHICA melanin is composed of poly hydroxyindole planar structure with extended resonance which must help stabilize the catechol phenoxy radicals generated during the DPPH radical quenching through a Hydrogen Atom Transfer (HAT) mechanism. Moreover, the sinergistic CeO2-melanin interplay enhanced the antioxidant power exhibited by the bare pigment, stressing the efficiency of the surface combination.

Conclusion

Melanin coating onto CeO2 nanoparticles was successfully obtained exploiting DHICA interaction with Ce4+ ions and its polymerization via ligand-to-metal charge transfer mechanism. Moreover, the conjugation on the molecular scale between the redox-active organic and inorganic moieties resulted in a significant boost of intrinsic antimicrobial and antioxidant activity, related to ROS buffering behaviour, involving both scavenging and production. Obtained nanozymes hold huge promise in regenerative medicine.

Cetylpyridinium chloride loaded MBGNs coating on ZrO2 dental abutment for the prevention of peri-implantitis

Zeqian Xu¹,², Kai Zheng³, Sebastian Spintzyk², Stefanie Krajewski², Aldo R. Boccaccini³, Xinquan Jiang¹, Frank Rupp²

¹ Shanghai Jiao Tong University, Department of Prosthodontics, Shanghai Ninth People’s Hospital, Shanghai, CN; ² University Hospital Tübingen, Section Medical Materials Science and Technology, Tübingen, DE; ³ University of Erlangen-Nuremberg, Institute of Biomaterials, Erlangen, DE

Introduction
Dental implants have been widely applied in supporting the dental prosthesis for the patients. Dental abutments, which connect dental implants and dental prosthesis, are partly exposed to the oral cavity. ZrO₂ is widely used as an abutment material due to its mechanical properties and esthetic characteristics. However, peri-implantitis, the destructive inflammatory process around dental implants contributing to supporting bone loss, has become an important issue for implant failure. Bacterial colonization and subsequent biofilm (plaque) formation on the dental abutment and implant surface is one of the essential cause and effect factors for peri-implantitis. Plaque control and tissue regeneration have become the main target in preventing peri-implantitis. Numerous studies have been carried out focusing on antibacterial coatings on the implant surface. However, most effective bactericidal or antibacterial coatings are accompanied by influenced biocompatibility and limited antibacterial duration. Cetylpyridinium chloride (CPC), as a cationic quaternary ammonium compound, is clinically widely used as an antibacterial agent in mouthwash to prevent dental plaque formation. Bioglass exhibits great osteoconductive and osteoinductive function, showing excellent capability of binding to bone tissue as well as to soft tissue through forming a carbonated hydroxyapatite layer (HCA) when exposed to biological fluid. Additionally, mesoporous bioactive glass nanoparticles (MBGNs) developed by the Sol-Gel technology exhibited great drug loading and drug-releasing capability, functional duration, and satisfying biological outcomes. This study aims at applying MBGNs nanoparticles loaded with CPC as an antibacterial coating on ZrO₂ surface and investigating the antibacterial capability and biocompatibility of the coatings, in order to prepare a kind of novel antibacterial coating for ZrO₂ dental abutment to minimize the risk of peri-implantitis.

Experimental Methods
The ZrO₂ blanks (Ivoclar Vivadent) were CAD-CAM into round disks through the dry milling machine K5+ (VHF) and sintered by VITA ZYrcomat sintering oven. After being ultrasonically cleaned with ethanol (99%) and dried with N₂, ZrO₂ round disks (diameter 13 mm, thickness 2 mm) were coated with PDA in a stirring system overnight (19 h) and ultrasonically cleaned with ddH₂O. Meanwhile, the MBGNs were loaded with 0.01%, 0.0.25%, 0.05% CPC for 24 h hours, washed with ddH₂O for 3 times, and harvested through centrifugation (CPC-MBGNs). Afterward, 1 mg/ml CPC-MBGNs loaded with different concentrations were dissolved in PDA and coated under stirring for 4 h. The disks were harvested and dry in 60°C incubator. The ZrO₂ disks (n=3/group, 0.01CPC-MBGNs, 0.025CPC-MBGNs, 0.05CPC-MBGNs, MBGNs, PDA) with and without coating are incubated with Streptococcus gordonii (S. gordonii ) in Schaedler medium (start OD₆ₓ= 0.54) for 6 h, 24 h, 72 h respectively. The OD value of the medium was measured and the samples were harvested for LIVE/DEAD staining. After 3d pre-treatment, 24 h extraction medium in McCoy’s medium were harvested and incubated with L929, HGF, and Saos-2, respectively, the cytotoxicity was evaluated by CCK-8. One-way ANOVA was used for the statistical analysis.

Results and Discussion
CPC-MBGNs nanoparticles were observed on the surface of ZrO₂ disks after the coating process. The ZrO₂ disks coated with CPC-MBGNs have shown significant contact killing effects towards the adhered S. gordonii after 6 h incubation (Fig. 1A). A lower amount of S. gordonii adhesion on the CPC-MBGNs coated ZrO₂ disks was found compared with the control group, which means CPC-MBGNs coating played a role in contact killing and inhibiting primary colonization towards the primary colonizer of oral biofilm formation (S. gordonii). When comparing with the uncoated group, a significant lower OD value was observed after 6 h, 24 h, 72 h incubation with S. gordonii (Fig. 1B), which indicates that the antibacterial coating could inhibit the proliferation of the planktonic bacteria. No significant cytotoxicity was observed towards L929, HGF, Saos-2 (Fig. 1C), which indicates low toxicity towards the soft and hard tissue surrounding the antibacterial coating.

**Conclusion**

The CPC-MBGNs drug-loaded nanoparticle coating could significantly inhibit the oral biofilm formation on the ZrO₂ abutment through contact killing, inhibiting bacterial primary colonization and the proliferation of the planktonic bacteria, without causing significant cytotoxicity towards the surrounding soft and hard tissue. Therefore, the coating has been proven antibacterial. This might offer the possibility for the peri-implant soft tissue to form a tight epithelial seal and to prevent bacterial infiltration. Therefore, the CPC-MBGNs antibacterial coatings on ZrO₂ abutment surfaces showed great potential for preventing bacterial-caused infections, such as peri-implantitis.

Development of Multifunctional Antimicrobial Supramolecular Biomaterials

Martijn Riool1,2, Moniek G. Schmitz2,3, Leonie de Boer1, Patricia Y. Dankers3, Sebastian A. Zaat1

1 Amsterdam UMC (location AMC), Medical Microbiology and Infection Prevention, Amsterdam, NL; 2 Dutch Polymer Institute (DPI), Eindhoven, NL; 3 Eindhoven University of Technology, Department of Biomedical Engineering, Eindhoven, NL

Introduction
The use of biomaterials inside the body always entails the risk of infection. This risk might even be higher in *in situ* tissue engineering applications. Since the porous scaffold materials can form a niche for invading bacteria, the intended *in situ* production of novel tissue may be severely compromised by infection. Therefore, we aim to develop a new polymeric supramolecular scaffold material, exerting two important functions: preventing microbial adhesion and thereby preventing biofilm formation, and inducing endogenous (eukaryotic) cells to regenerate the body.

Experimental Methods
In our research, supramolecular contact-killing materials based on antimicrobial peptides (AMP) are developed. A special class of supramolecular biomaterials are based on fourfold hydrogen bonding 2-ureido-4(1H)-pyrimidinone (UPy) moieties. The supramolecular base material consists of an UPy end-functionalization polycaprolactone (*i.e.* PCLdiUPy). These UPy-materials can be functionalized with bioactive compounds, either via a modular approach in which the UPy-base material is mixed with UPy-modified additives1, or via a post-modification strategy to specifically functionalize the surface of the biomaterial using click chemistry2. The antimicrobial activity is introduced via UPy-functionalized AMPs, using SAAP-148 or TC84, synthetic derivatives of LL-373 and thrombocidin-14, respectively. The regenerative activity is introduced via an UPy-functionalized heparin binding peptide (UPy-HBP). The peptides were synthesized by manual Fmoc-based solid phase peptide synthesis. Solid polymer films were prepared by drop-casting PCLdiUPy with UPy-SAAP-148 or UPy-TC84 on glass coverslips. The antimicrobial activity of the UPy-AMPs in solution and when incorporated in the drop-casted samples was evaluated against *Escherichia coli* ESBL and *Staphylococcus aureus* JAR060131 and LUH14616 (MRSA) and *Acinetobacter baumannii* RUH875 using the LC99.9 (*i.e.* the lowest concentration killing at least 99.9% of the inoculum) and the JISZ2801 surface antimicrobial assay, respectively. Moreover, the cytotoxicity of these AMPs was tested against human dermal fibroblasts.

Results and Discussion
Coupling of the UPy-linker to SAAP-148 did not influence its antimicrobial activity in solution. For the solid drop-casted materials, incorporation of 5 mol% UPy-SAAP-148 is sufficient for killing all 4 bacterial strains tested. This indicates that the peptide remains active after immobilization in the materials. Unfortunately, TC84 loses its antimicrobial activity upon UPy-coupling, both in solution and as a solid. QCM-D adsorption studies revealed that heparin adsorbed to spin coated material films of PCLdiUPy with 5 mol% UPy-HBP mixed via the modular strategy. Current studies focus on characterization of the UPy-SAAP-148/TC84 and multifunctional biomaterial with XPS, AFM, WCA, zeta potential and leakage experiments to investigate the material properties. Moreover, we assess the *in vivo* efficacy of dip-coated titanium implants with 5% UPy-SAAP-148 in the experimental biomaterial-associated infection mouse model.

Conclusion
In conclusion, this modular approach will enable a stable but dynamic incorporation of AMPs, and control of cell adhesion by using cell-adhesive peptides. Ultimately, we aim to use such materials for *in situ* infection-free tissue engineering.

Tuning the Biomolecular Content of Biosynthetic Hydrogels for 3D Neural Tissue Interfaces

Martina Genta, Catalina Vallejo-Giraldo, Roberto Portillo Lara, Josef Goding, Rylie Green

Imperial College London, Bioengineering, London, GB

Introduction
Material designs and approaches have been explored to mimic native tissues and improve the device-tissue interface of bionic devices. While conductive coatings and biomimetic hydrogels have been used to improve the electrochemical properties and reduce the mechanical mismatch, neural interfaces are still affected by foreign body responses that hinder their performance over time [1]. Current research in this space aims to create a platform able to support neural tissue growth and foster the formation of natural synaptic connections between the device and the host tissues. To reach this objective it is critical to understand the interplay between mechano-biological cues and spatial constraints in 3D environments. In this study, the material design relies on tailoring the hydrogel biomolecular content to generate spatial cues and create a permissive hydrogel for encapsulated cells. In particular, the incorporation of gelatin into poly(vinyl alcohol)-norbornene hydrogels (PVA-Gel-NB) was evaluated to engineer constructs that provide biochemical cues and a supportive environment for encapsulated cells. It was hypothesised that RGD motifs in gelatin chains enhance cell adhesion to the polymer network, while matrix metalloproteinase 2 (MMP-2)-sensitive domains distinctive of gelatin enable enzymatic remodelling of the hydrogels by migratory developing cells.

Experimental Methods
PVA-NB was synthesised as described by Qin et al [2] and Gel-NB synthesis was adapted from Koshy et al [3]. Hydrogels with different polymer ratios, namely 100:0, 50:50, 25:75, and 0:100 (PVA:Gel), were fabricated by visible light photopolymerisation using Eosin Y as initiator and DTT as crosslinker. Compression testing was performed to assess the mechanical properties of the hydrogels, while mass swelling ratio and mass loss were monitored over time to evaluate the physical characteristics of the hydrogels and their hydrolytic degradation behaviour. Cytocompatibility of PVA-Gel-NB hydrogels was evaluated by encapsulating primary P4 Sprague-Dawley rat hippocampus astrocytes. The growth and migratory ability of astrocytes were assessed using an Alamar Blue assay and immunostaining against GFAP to evaluate astrocytes development, MMP-2 to identify gelatinase localisation, as well as paxillin to target focal adhesions.

Results and Discussion
PVA-Gel-NB hydrogels were successfully polymerised with the exception of pure gelatin hydrogels (0:100 PVA:Gel) that did not form a hydrogel but rather remained a viscous liquid (Fig. 1A). This first observation underlined the importance of having a synthetic component as structural support when designing biomimetic hydrogels. The addition of gelatin to the PVA hydrogel network affected the mass swelling behaviour and the mass loss trend, especially in 25:75 (PVA:Gel) hydrogels (Fig. 1B-C). Young’s moduli ranged between 30 to 0.3 kPa over a period of 28 days. Despite the changes caused by the incorporation of gelatin, mechanical and physical properties were in line with common hydrogel systems used for neural tissue engineering [4]. Cytocompatibility was evaluated by assessing the development of primary astrocytes after seven days in culture. Immunostaining with GFAP showed limited development of astrocytes encapsulated in pure synthetic PVA-NB hydrogels (100:0 PVA:Gel), while increasing the gelatin percentage led to a higher cytoplasmic development (Fig. 2B). This behaviour was also confirmed by an increase in metabolic activity (Fig. 1D). In addition to cell spreading, hydrogels with the highest amount of gelatin (25:75 PVA:Gel) supported cell adhesion and the development of mature focal adhesions (Fig. 2C-F). The ability of
cells to spread and anchor to the polymer network indicated that 25:75 (PVA:Gel) hydrogels were able to provide a 3D supportive environment removing any spatial constraints. This was further supported by the translocation of MMP-2 to the cytoplasm, confirmation of the active state of astrocytes, as opposed to nuclear localization indicative of pathological or apoptotic states (Fig. 2D-G) [5].

**Conclusion**

The incorporation of gelatin to PVA hydrogel networks supported cell development by providing both biological and spatial cues necessary for cell interaction and growth. While this is normally achieved by the addition of MMP-degradable crosslinkers and adhesion motifs to the polymer network, the combination of synthetic and natural polymers enabled a simple and scalable fabrication method towards biomimetic bionic interfaces. Moreover, this study showed that primary astrocytes were able to spread and establish mature focal adhesions, which was indicative of their active involvement in network remodelling. These results emphasised the importance of understanding cell-material interactions when designing hydrogels for tissue engineering. Future work will focus on establishing primary co-cultures of astrocytes and neurons in PVA-Gel-NB hydrogels to assess their ability to support the formation of functional neural networks.

Polyphenol Rich Extracts-Loaded Liposomes against Neurodegenerative Diseases

Attilio Marino¹, Matteo Battaglini¹, Andrea Desii¹, Gianni Ciofani¹

¹ Istituto italiano di tecnologia, Smart Bio-Interfaces / Center for Materials Interfaces, Pontedera, IT; ² Istituto Giannina Gaslini, Core Facilities-Proteomics Laboratory, Genova, IT

Introduction
Parkinson’s, Alzheimer’s and Huntington’s disease represent devastating neurodegenerative conditions with no satisfactory therapy options. Robust evidence of the role of the reactive oxygen species in inducing the pathogenesis and in sustaining the neurodegenerative processes has been shown in the literature [1], and many preclinical studies and clinical trials involved the use of organic antioxidants, such as polyphenols, for the treatment of these diseases [2]. Results are quite promising but the limited blood-brain barrier (BBB) crossing of these molecules limits their application in vivo. The realization of efficient and safe nano-formulations for brain delivery, such as liposomes, promises to improve brain delivery and treatment efficacy. In this work, selected polyphenol-rich vegetal extracts were used for the fabrication of therapeutic liposomes with elevated BBB crossing capabilities and remarkable protective effects on a drug-induced in vitro model of Parkinson’s disease.

Experimental Methods
Pomaces from white and black grape varieties cultured in the Cinque Terre territories (La Spezia, Liguria, Italy) were used as a natural source of polyphenols. Hydroalcoholic extraction has been performed as indicated elsewhere [3]. Characterization of the extracts was carried out by performing total antioxidant capacity (TAC), Folin-Ciocalteu phenol quantification, and high-performance liquid chromatography (HPLC). Extracts displaying higher antioxidant activity were selected for liposome preparation. Liposomes were prepared by using an Avanti® Mini-Extruder (from Avanti Polar Lipids Inc.) with 100 nm pore membrane and then functionalized with the anti-transferrin receptor (TfR) antibody for improving BBB crossing efficiency [4]. Transmission electron microscopy (TEM) imaging and dynamic light scattering (DLS) measurements have been performed to characterize liposome morphology, size, and z-potential. Biocompatibility studies were performed on brain endothelial cells (HCMEC/D3) and SH-SY5Y-derived neurons by using the WST-1 viability assay at 72 h of liposome incubation. Results were compared to empty liposome-treated cultures and non-treated controls. The protective effects of the extract-loaded liposomes were then investigated in rotenone-treated cells by flow cytometry after FITC-annexin / propidium iodide double staining. BBB crossing was assessed on in vitro static 2D multicellular models by measuring the concentrations of the extract-loaded liposomes in the abluminal compartment at different time points (8, 24, 48, and 72 h).

Results and Discussion
Higher total antioxidant capacity (TAC) was found in extracts from white grape (WG) compared to black grape (BG) pomace varieties. The higher TAC was associated with higher polyphenol content. Specifically, an increased amount of catechines (16% increase) and epicatechines (42% increase) were found in WG compared to BG pomace extracts. Unilamellar liposomes showed a spheroidal shape and a 118 ± 24 nm diameter size with a z-potential of -25 ± 4 mV. A schematic representation of the extract-loaded liposomes and the TEM imaging are shown in Figure 1a and 1b, respectively. The liposomes (both empty and loaded) showed high biocompatibility. Significant toxicity was found only for relatively high concentrations (≥ 800 µg/ml in both neurons and endothelial cells). Interestingly, 400 µg/ml extract-loaded liposomes were able to significantly reduce rotenone-induced cell death in neurons (58% decreased necrosis, 73% decreased early apoptosis, and 73% decreased late apoptosis; Figure 2). The incubation with extract-loaded liposomes in rotenone-treated cells was able to rescue the physiologic cell death levels observed in non-
treated controls (corresponding to ~15% in differentiated SH-SY5Y neurons). Finally, extract-loaded liposomes were able to efficiently cross the BBB, with abluminal concentrations reaching ~50% µg/ml at 72h of incubation.

**Conclusion**
We report on the successful development of a safe and efficient antioxidant nano-formulation able to rescue the apoptotic and necrotic conditions in the rotenone-based Parkinson model. The excellent BBB crossing capability of the proposed nanoformulation paves the way for future preclinical investigations on relevant in vivo models. The potential exploitation of extract-loaded liposomes for the treatment of different neurodegenerative conditions characterized by high ROS levels will be investigated. Finally, antioxidants were extracted from grape pomaces (i.e., a byproduct of wine production) following a “green” sustainable approach. A reduced environmental impact for nanomaterial preparation is therefore guaranteed.

Novel hybrid nanoparticles for Alzheimer’s disease theranostic: efficient overcoming of nanomaterials across the blood-brain-barrier

Catarina I.P. Chaparro1,2, Vera L.S. Neves2, João P. Borges1, Paula I.P. Soares1

1 NOVA School of Science and Technology (FCT-NOVA), CENIMAT/i3N (Centro de Investigação em Matérias), Almada, PT; 2 Faculdade de Medicina da Universidade de Lisboa, Instituto de Medicina Molecular, Lisboa, PT

Introduction
Alzheimer’s disease (AD) is a chronic and progressive brain disease that leads to deterioration of cognitive function [1]. The distinguishing pathological hallmark of AD is the build-up of cortical and cerebrovascular deposits of amyloid-β (Aβ) peptide. The development of novel nanomaterials as imaging contrast agents and drug delivery systems for early detection and treatment of AD is a recent and promising strategy [2]. Nanotechnology-based approaches such as nanoparticles (NPs) have provided enormous hope by overcoming issues regarding poor blood-brain-barrier BBB permeability and drug delivery applications. Magnetic nanoparticles (MNPs) have become an appealing strategy for AD theranostic since they can act as a multifunctional platform. Superparamagnetic iron oxide nanoparticles (SPIONs) are particularly used as contrast agents for magnetic resonance image (MRI), as cell labeling agents for cell tracking and to induce magnetic hyperthermia (MH) [3]. Polymer’s biodegradability facilitates clearance of the nanocarrier and can be exploited to trigger drug release. Poly(lactic-co-glycolic) acid (PLGA) nanoparticles enhance drug pharmacodynamic and bioavailability and, in the present work they are used to incorporate magnetic cores within their nanostructure. The present study aims to develop a nanoparticulate system that translocates the BBB and actively targets Aβ peptides to promote their disaggregation. The work comprises the conjugation of a peptide that reversibly crosses the BBB (PepH3) [4], with a tailored antibody fragment for Aβ (VL2), which allows clearance of the toxic Aβ deposits from the brain to the blood.

Experimental Methods
In this work, SPIONs were synthesized by thermal decomposition technique and PLGA-NPs were prepared with those previously stabilized SPIONs through simple-emulsion solvent evaporation according to a modified procedure reported by Kandasamy et al. [5]. Different parameters such as SPIONs content, polymer weight, and surfactant concentration were varied to optimize the size and encapsulation efficiency of SPIONs. The size of the nanoparticulate system was confirmed by DLS, TEM, and SEM techniques, while the iron content of SPIONs encapsulated in PLGA-NPs was determined using 1,10-phenanthroline colorimetric method through UV/VIS spectrometry. Magnetic hyperthermia was performed to evaluate the temperature variation of all formulations. At last, the functionalization of nanoparticles’ formulations with the construct VL2-PepH3 is being tested for further in vitro assays which comprises translocation across a BBB model and its integrity assessment.

Results and Discussion
SPIONs highly monodispersed with an average core diameter of 6 nm were encapsulated in PLGA-NPs and after the encapsulation process, the formulations tested were within the size range of 212–340 nm (Figure 1 and 2). The encapsulation efficiency (EE) was calculated through the iron content of SPIONs. These values fluctuate between 30 and 60% and are directly related to SPIONs concentration, PLGA mass, and surfactant agents’ concentration. The sizes of nanoparticles are as well dependent on these features. Smaller nanoparticle sizes and higher EE values are achieved when using the following conditions in the preparation of the nanoparticles: 5 mg of SPIONs; 10 mg of PLGA and 0.5% of poly(vinyl alcohol) (PVA) as a surfactant agent. Magnetic hyperthermia studies suggest that both formulations with higher SPIONs EE values are capable of increasing their temperature of up to 7°C.

Conclusion
Page 133 of 2028
We have initially synthesized hydrophobic SPIONs, which are successfully encapsulated inside the PLGA-NPs. Herein, the above-described parameters are varied during the encapsulation process to obtain the most suitable PLGA-NPs for in vitro evaluation. We are studying the BBB interaction with the developed nanosystem with the purpose of supporting those novel hybrid nanoparticles as a new theranostic strategy to overcome the challenges in current therapies of AD.

Introduction
The skeletal muscle has limited capacity to regenerate even small defects. Surgical implantation of biomanufactured skeletal muscle constructs has recently emerged as a promising strategy to treat volumetric muscle defects [1]. However, timely innervation of the implanted constructs with the host peripheral nerves remains an unresolved challenge. The objective of this study was to build a 3D bioprinted skeletal muscle construct with a neurotrophic factor (NF) delivery system to accelerate peripheral nerve regeneration and construct innervation.

Experimental Methods
Ciliary neurotrophic factor (CNTF) and glial cell line-derived neurotrophic factor (GDNF) were encapsulated within Poly (lactic-co-glycolic acid) (PLGA) microspheres. The influence of the microspheres on the viscoelastic properties of the bioink was assessed as well as their compatibility with the bioprinting process and viability of human muscle progenitor cells (hMPCs). The release kinetic of the encapsulated factors from 3D bioprinted construct was evaluated with ELISA. The bioactivity and the effect of the sustained release of CNTF and GDNF were evaluated by their ability to enhance neurite outgrowth in an \textit{in vitro} assay with embryonic chick dorsal root ganglia (DRGs).

Results and Discussion
The developed CNTF/GDNF-loaded microspheres have been efficiently and homogeneously incorporated into a fibrin-based bioink without interfering with bioprinting process nor with the viability of hMPCs. Furthermore, we showed that the encapsulated CNTF and GDNF retain their biological activity over at least 14 days and that their sustained release significantly enhanced the neurite growth at the later time points.

Conclusion
In conclusion, we showed the feasibility of PLGA microspheres as a vehicle for the delivery and sustained release of NFs in biomanufactured skeletal muscle constructs demonstrating their potential for further \textit{in vivo} applications.

Hydrogel Mediated Delivery of Cerebral Dopamine Neurotrophic Factor Modulates N-glycosylation and Improves Motor Function in a Pre-Clinical Model of Parkinson's Disease

Ana L. Rebelo¹, Sunny Abbah¹, Sergio M. Saldaña¹, Stefan Kirnbauer³, Alexandre Trotier¹, Manus Biggs¹, Richard Drake², Martina Marchetti-Deschmann³, Abhay Pandit¹

¹ National University of Ireland Galway, CÚRAM Research Centre for Medical Devices, Galway, IE; ² Medical University of South Carolina, Department of Cell and Molecular Pharmacology and Experimental Therapeutics, Charleston, US; ³ Technical University of Vienna, Institute of Chemical Technologies and Analytics, Vienna, AT

Introduction
Parkinson's Disease (PD) is a neurodegenerative disorder mainly characterised by the death of dopaminergic neurons in the substantia nigra pars compacta¹, related to different motor symptoms. Currently in the clinic there are only symptomatic therapies available, which fail to address the specific pathophysiology of the disease². However, as an attempt to prolong the remaining neurons' survival, the administration of neurotrophic factors (NTF) has also been heavily investigated. Cerebral dopaminergic neurotrophic factor (CDNF) is an NTF selective for dopaminergic neurons that acts on the endoplasmic reticulum (ER), improving the unfolded protein response (UPR)³,⁴. As ER stress is present in PD pathophysiology and CDNF targets the ER in dopaminergic neurons, its use becomes attractive in this scenario. Additionally, ER stress is intimately associated with dysregulation of N-glycosylation (which is seen in PD), so the improvement of ER homeostasis is likely to regulate N-glycosylation, recovering the healthy brain glycome. With that aim, we have explored the effect of CDNF on the brain N-glycome. Furthermore, as bolus-delivery has some disadvantages, encapsulating CDNF in a hydrogel system for sustained delivery in the target-site to prevent its rapid elimination is of interest. Therefore, this project aims to optimise a collagen-based hydrogel to deliver CDNF into a PD model's brain and assess its effect in modulating the animals' behaviour and the brain's intrinsic N-glycome.

Experimental Methods
In this study, collagen hydrogels with different concentrations of collagen and 4S-StarPEG (crosslinker) were fabricated, and their mechanical and chemical properties studied through stability/degradation assays and rheology. The optimised hydrogel was then used for an in vivo study with 66 male Sprague-Dawley rats. A PD model was created by unilateral stereotactic injection of 6-hydroxydopamine (6OHDA, a neurotoxin that targets dopaminergic neurons) on the medial forebrain bundle. Two weeks post 6OHDA injection, rats were randomly assigned to different groups, including different doses of CDNF (1, 5 and 10 ug), delivered either as a bolus or encapsulated in collagen hydrogels; negative controls injected with collagen hydrogels only or saline were also included. Animals were sacrificed at one and eight weeks post-injection, and tissue collected for immunohistochemistry (against glial and dopaminergic neuronal markers) and N-glycomic analysis (through matrix-assisted laser/desorption ionisation-mass spectrometry imaging (MALDI-MSI)). Throughout the study, every two weeks, the animals' behaviour was assessed through the cylinder test and apomorphine-induced rotations.

Results and Discussion
Upon optimisation, 2mg/ml collagen with 0.4mM 4S-StarPEG hydrogels were found to be the most suitable for intracerebral injection, since these had the storage modulus of 234.08 ± 9.67 Pa, and loss modulus of 21.96 ± 2.27 Pa, and a reduction of free amines to 65%, displaying an excellent crosslinking efficiency. Once injected into the brain, the hydrogels loaded with CDNF improved significantly the behaviour of the 6OHDA injected animals (reduction in the number of apomorphine-induced rotations and enhanced use of both limbs on cylinder test). The animals'
brains were also taken for N-glycomic profiling, where healthy brains revealed a high spatial expression of oligomannose and core-fucosylated glycans (Figure 1), as was previously reported by ultra-performance liquid chromatography\(^5\). These were also modulated upon biomaterial-injection.

**Conclusion**

This study showed the potential of delivering CDNF to the brain using a biomaterial system and its impact on modulating the N-glycomic signature seen upon disease.

Exploring a biodegradable dendrimer as carrier of neuroprotective mRNA to reach the ischemic brain

Marília Torrado¹,², Victoria Leiro¹, Pedro Mota¹, Sara C. Silva-Reis¹, Ana Jesus¹, Sofia D. Santos¹, Ana P. Pêgo¹,²,³

¹ i3S/INEB - Institute for Research and Innovation in Health/Institute of Biomedical Engineering, University of Porto, Porto, PT; ² ICBAS - Abel Salazar Biomedical Sciences Institute, University of Porto, Porto, PT; ³ FEUP - Faculty of Engineering, University of Porto, Porto, PT

Introduction

According to the World Health Organization, Stroke is the 2nd cause of death worldwide and the 1st in Europe. 15 million people suffer a stroke per year, of which 5 million are left permanently disabled. Besides the evident social impact, this high morbidity represents an annual economic burden of over $72 billion (US).

Ischemic stroke, accounting for 82-92% of stroke cases, occurs when blood supply to the brain is occluded, resulting in a cascade of events that leads to neuronal death. Yet, the only FDA approved therapy (tissue plasminogen activator) is not applicable to most patients (<10% of cases) [1,2]. Also, this therapy only mitigates the effects of occlusion by restoring the blood flow, lacking neuroprotective and/or neuroregenerative properties.

Along the years, brain-derived neurotrophic factor (BDNF) has been put forward as a promising neuroprotective approach. However, its reduced plasma half-life and the poor blood-brain-barrier (BBB) permeation have limited its therapeutic administration. Additionally, the uncontrollable delivery of BDNF can lead to deleterious side effects [3]. Gene therapy has been explored as a solution for effective BDNF expression at the lesion site. Nevertheless, a biocompatible vector, capable of protecting the neuroprotective nucleic acid from endonuclease degradation and of reaching the ischemic brain in an efficient way remains an unmet challenge.

Herein, we propose the use of biodegradable dendrimers as delivery vectors of mRNA encoding for BDNF (BDNFmRNA) as a novel neuroprotective strategy. These cationic dendrimers, recently developed and patented in our group [4], are endowed with the ability to complex mRNA, shielding it after intravenous administration (Figure 1). Also, their nanosize, full-biodegradability, multivalency and the possibility of fine-tuning their properties make them promising candidates to a successful therapy.

Experimental Methods

The explored dendrimers rely on a gallic acid-triethylene glycol-ester (GATGE) repeating unit and a poly(ethylene glycol) (PEG) chain. Dendriplexes with BDNFmRNA were prepared at different N/P ratios (moles of dendrimer amines/moles of mRNA phosphate groups) and characterized in terms of size and polydispersity index (PdI) by dynamic-light scattering, and Zeta-potential by laser doppler electrophoresis. Additionally, transmission electron microscopy was used for morphological analysis. mRNA complexation was evaluated with gel retardation and SYBRGold exclusion assays. Dendriplexes internalization and cytotoxicity were assessed in mice cortical neuronal cultures, using Lipofectamine-2000 (L2k) as control. In order to evaluate safety for intravenous administration, haemolysis and clotting assays were performed, incubating dendriplexes with purified human red blood cells and recalcified human plasma, respectively. Finally, dendritic nanoparticles biodistribution was evaluated in mice, after systemic administration of Cy5.5-labeled dendriplexes or vehicle.

Results and Discussion

Dendriplexes showed appropriate characteristics for the proposed strategy as they present sizes <100 nm, which is essential for BBB permeation, PdI values <0.3, positive net charges, spherical shape and mRNA complexation efficiencies higher than 90%. The internalization studies revealed that our dendriplexes are internalized by virtually
all neuronal cells in culture, with higher accumulation in cytoplasm and perinuclear regions, contrary to L2k, which internalization was reduced. Also, no cytotoxicity was obtained with our nanoparticles at the used N/Ps, whereas only less than 50% of cells were viable with L2k. Also, haemolytic studies revealed that dendriplexes are non-thrombogenic and coagulation assays further confirmed the hemocompatibility of our system. In vivo, the labelled dendriplexes were detected abundantly in the liver and kidneys, without histological changes. We were also able to observe dendriplexes in the brain, and an increased BDNF expression was verified in all the analysed organs of animals injected with dendriplexes. This demonstrates the great ability of the dendrimer to protect and deliver effectively the BDNFmRNA after systemic administration. Further studies will be performed in a mice model of stroke (pMCAO) to evaluate the neuroprotection effect, where it is expected to obtain a significantly increased accumulation of dendriplexes in the brain, due to the stroke-compromised BBB.

Conclusion
Together, these results point to a novel biocompatible and biodegradable tool, able to reach neurons and to transport potential neuroprotective nucleic acids in a safe and controllable way. Also, with the emerging field of mRNA therapeutics, these vectors represent a valuable asset to be explored to further applications.

Tissue engineered brain-machine interfaces fabricated by two-photon induced degradation of photoresponsive hydrogels

Augusto V. Loffredo1, Lana Van Damme2, Jasper Van Hoorick2, Sandra Van Vlierberghe2, Abhay Pandit1, Manus Biggs1

1 National University of Ireland Galway, CÚRAM - SFI Research Centre for Medical Devices, Galway, IE; 2 Ghent University, Polymer Chemistry & Biomaterials Group (PBM-UGent), Ghent, BE

Introduction
The brain-computer interface and neuromodulation devices provide a means to record and stimulate the nervous system to provide a communication platform to drive peripheral devices/prosthetics and/or mitigate neurological deficits. Indeed, future initiatives to treat and correct myriad neurological conditions rely on a precise interface with the nervous system for optimal monitoring and modulation. There has been substantial progress using penetrating, inorganic microelectrode arrays and optically based methods to record and stimulate from the central nervous system (CNS). However, conventional microelectrodes produce a chronic foreign body response with concomitant signal degradation over time. Moreover, electrical stimulation and recording currently lack specificity in targeting specific neuronal subtypes (e.g. excitatory versus inhibitory) and/or compartments (e.g. dendritic/somatic versus axonal)1. As such, there is currently a need for a chronically stable and highly specific modality for input to and output from the CNS. The goal of this work is to develop tissue engineered ‘living electrodes’ to provide high fidelity connectivity (synaptic integration) with endogenous neural networks to allow biologically based neuromodulation while mitigating the chronic foreign body response that currently limits conventional penetrating electrodes. To fabricate encapsulating neuron hydrogels, we have developed a novel system of 3D printing by multiphoton degradation of a photoresponsive gelatine hydrogel. By patterning the hydrogel to possess microscale voids via two-photon (2P) initiation of DAS4, we demonstrate that hierarchical tissue engineered constructs with controlled neural polarity can be fabricated, and integrated with a micro-electrode array to produce a living neural interface.

Experimental Methods
Methacrylamide-functionalised gelatine (GelMA) was synthesised as previously described2. A degree of substitution of 39% was obtained as confirmed by NMR spectroscopy (data not shown). A 5% w/v of GelMA solution was prepared containing a 0.1% w/v lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) photo-initiator in PBS and crosslinked using UV light at 365 nm for 10 minutes to form a hydrogel. To induce the formation of localised microregions of degradation, the hydrogel was processed using a commercially available two-photon lithography system (Nanoscribe® Photonic Professional GT) in the presence of a biocompatible two-photon initiator (DAS), synthesised as described by Tromayer et al3. An array of 10 µm diameter micro-tunnels (Figure 1A) was developed through free-radical-induced degradation of the gelatine hydrogel by two-photon initiation of DAS4. Nanoindentation and RAMAN microscopy were used to evaluate the impact of 2P exposure, under different laser doses, on the scaffolds mechanical and chemical properties respectively.

In vitro analysis of cell viability and the axonal guidance capability of the morphologically modified hydrogels was evaluated using primary cortical neural population isolated from E17 Sprague dawley pups as previously described8. Neuron viability and polarity were assessed via a LIVE/DEAD assay and immunofluorescent imaging respectively.

Results and Discussion
Van Hoorick et al have recently observed photocleavage in gelatine-based hydrogels when using high laser light intensity4. It was hypothesized that this photocleavage is due to the formation of a very high number of radicals generated under 2P initiation that results in cleavage of the amide bonds, resulting in localised degradation.

Page 141 of 2028
phenomenon was further analysed in the present work using Raman microscopy and nanoindentation that confirmed the profile of the localised degradation under the different laser doses tested. Furthermore, LIVE/DEAD assay indicated that cell viability was not significantly reduced when cultured within the photoresponsive hydrogel. Confocal microscopy of cortical neural cultures after 14 days seeded onto the GelMA hydrogels indicated that the cell axons infiltrated the hydrogel matrix only through the degraded micro-tunnel regions, with the soma restricted to the hydrogel periphery (Figure 1B).

**Conclusion**

By creating degradable gelatine 3D interspaces between the cell layer and the substrate, it was possible to induce neural cell guidance by controlling the dimensions of those spaces generated on the hydrogel layer. We hypothesize that the combination of photocrosslinking and two-photon induced degradation in gelatine-based materials can be used to rapid prototype 3D neural constructs with controlled axonal orientation.

Introduction
Neurodegenerative disorders (NDs) constitute one of the most devastating types of chronic diseases and lead to a crucial medical burden on society. Although, many novel pharmaceuticals have been develop to treat neurological diseases such as Parkinson’s disease (PD) and spinal cord injury (SCI). NDs’ pathogenesis of is marked by an initial toxic insult and a resulting secondary chronic pathological damage. Specifically, early and later stages of NDs involve a decreased neurotrasmission, and an overexpression of inflammatory genes related to specific receptors activation including Toll-like receptor-4 (TLR-4) and Transient potential receptor-4 (TRPV-4) [1]. Indeed, recent findings have identified the neuroinflammation as the major cause of neurodegeneration [2]. Current studies have been reported antioxidant, anti-inflammatory, immunomodulatory, and radioprotective properties of natural and synthetic melanins [3]. Here, the inhibition of neurodegenerative processes by 3D substrates based on coated PLA aligned microfibers functionalized with eumelanin and combined with other therapeutic molecules were investigated.

Experimental Methods
3D electrospun substrates were prepared combining electrospinning, spin coating and solid-state polymerization processes [3]. Physico-chemical and morphological investigations (ATR-FTIR and SEM analyses) were performed to study eumelanin coated microfibers orientation and integrity. In order to evaluate neuroregenerative properties of microfibers, a pre-neuronal human derived cell line from neuroblastoma (SHSY5Y) was cultured onto the 3D electrospun substrates with or without TRPV-4 antagonists and later stimulated with 1-Methyl-4-phenylpyridinium iodide (MPP+), in order to reproduce an in vitro PD model. Cell differentiation and neurodegeneration inhibition were detected through cell viability assay and neuronal marker expression (GAP-43 and TRPV-4 expression) by using confocal analysis. Additionally, to investigate antioxidant and antiinflammatory potential of microfibers, microglial cells were stimulated with lipopolysaccharide (LPS), in order to reproduce an in vitro model of neuroinflammation. Hence, cell morphological changes and substrates mechanism of action on neuroinflammation were investigated by measuring nitrite production, reactive oxygen species levels and inflammatory markers expression through quantitative and qualitative methods (q-PCR, confocal and spectrophotometric analyses).

Results and Discussion
The SEM and ATR measurements on 3D electrospun substrates revealed any chemical degradation process ascribable to the polymer matrix over time. Thus, our substrates represent a valid tool for reproducing more realistically 3D in vivo microenvironments thus promoting cell-cell interaction and biological response in terms of viability and differentiation. Indeed, biological results showed that eumelanin microfibers support pre-neuronal cell survival, adhesion and the formation of neuritic processes (GAP-43 expression) over culture time and inhibited neurodegenerative activities on an in vitro model of PD induced by MPP+ (TRPV-4 modulation). Additionally, 3D electrospun substrates were able to decrease neuroinflammatory response in terms of nitrite production, ROS levels, NF-κB expression and IL-6 secretion induced by LPS in microglial cells through the inhibition of TLR-4 signal. Finally,
morphological studies (SEM and confocal microscopy) suggested that substrates were able to counteract LPS induced cell morphological changes.

Conclusion
Our results validate the promising features of 3D electrospun substrates functionalized with eumelanin as new therapeutic tools for promoting neuroregeneration and controlling neuroinflammation in NDs (as shown in Figure 1).

Can 3D graphene oxide scaffolds prompt neural regeneration? Lessons learned *in vivo* at the rat injured spinal cord

**Maria C. Serrano**

*Consejo Superior de Investigaciones Científicas (CSIC), Instituto de Ciencia de Materiales de Madrid, Madrid, ES*

**Introduction**

Since the early 2000's, graphene-based materials (GBMs) have arisen as promising nano- and microplatforms for boosting a plethora of biological phenomena, both *in vitro* and *in vivo*. Within their most remarkable properties with interest in biomedicine, GBMs show customizable nanosized features, mechanical compliance with soft tissues and electrical conductivity. Although their biocompatibility continues to be an open debate for scientists in the field, outstanding efforts are prompting their entrance in the biomedical arena [1]. In neural cultures *in vitro*, GBMs have already proved capacity to modulate neural cell survival, neurite growth, differentiation [2], electrical signaling and ion channel function [3], to cite a few. Nonetheless, progress in preclinical models *in vivo* are still limited. For almost a decade, our group has focused on the exploration of 3D reduced graphene oxide (rGO) biomaterials as supportive platforms for neural repair at the rat injured spinal cord. Specifically, we have explored the capacity of both rGO microfibers [4] and porous foams [5] to boost neural regenerative features at both subacute and chronic stages. More recently, we have incorporated motor training routines mimicking those applied to spinal cord injured patients in the clinic, for who an effective cure remains a therapeutic challenge to date, to prompt their regenerative potential.

**Experimental Methods**

GO slurry was purchased from Graphenea, S.A. Chemical reagents were purchased from Sigma-Aldrich. Adult male Wistar rats were provided by the animal facilities at the Hospital National Hospital for Paraplegics in Spain. 3D porous rGO foams were fabricated by a freeze-casting methodology and rGO microfibers by a hydrothermal process. Results were collected from two different lesion models: a cervical right hemisection at C6 level and a complete transection at T9 level. Additionally, treadmill-based motor training was applied to some of the groups. Animals were sacrificed at 10 (subacute), 30 (early chronic) and 120 (late chronic) days by using a standard perfusion-fixation protocol. Organs were stained with hematoxylin-eosin. Spinal cord samples were examined by immunofluorescence for the presence of neural, glial, inflammatory, and vascular markers. Fluorescence images were collected with a Leica TCS SP5 microscope.

**Results and Discussion**

From the early time points investigated, rGO biomaterials seemed to play a favorable role in the stabilization of the lesion site, evidencing a remarkable infiltration of the totality of their 3D structure by a diversity of cells. In early chronic stages, the formation of vascular structures to nourish the lesion site was supported inside the 3D rGO foams, accompanied by neurites growth and immunomodulatory effects on macrophages. Lesions in late chronic animals receiving 3D rGO foams were largely colonized by excitatory neurites and functional blood vessels. Finally, the combination of these 3D rGO biomaterials with a motor training routine significantly impacted immune, vascular and neural features at the injured spinal cord.

**Conclusion**

Since 2014, our group has provided significant evidences of the beneficial effects that rGO-based 3D biomaterials sustain at the injured spinal cord in rat models. Favorable results in combination with motor training routines bring insights into the prominent field of regenerative rehabilitation. Based on these findings, further work is encouraged to take full advantage of the potential of GBMs in neural tissue engineering applications *in vivo*.

Introduction
The reconstruction of large bone defects (> 5 cm³) remains a challenge for clinicians. Indeed, the gold standard solution to treat such defects is the bone autograft. However, this solution has many disadvantages: it increases the number of surgeries required, thus increasing risks for the patient, it induces pain and morbidity risks at the donor site, and it is only available in a small quantity, making it impossible to repair too large defects [1]. To address this challenge, we developed a new critical-size mandibular bone defect model on mini-pigs (12 cm³), close to human clinical issues, and treated it using a 3D-printed scaffold coated with a 2D bioactive coating (Figure 1).

Experimental Methods
A full-thickness 12 cm³ bone defect, including the periosteum, was created in the mandibular bodies of nine mini-pigs (both sides). Scaffolds made of clinical-grade poly-L-lactic acid (PLLA) were 3D-printed by fused deposition modeling (FDM) and coated with a polyelectrolyte film crosslinked at two different levels (called EDC30 and EDC70, EDC30 films being softer than EDC70 films) delivering an osteogenic bioactive molecule (BMP-2) at different doses (20, 50, and 110 µg/cm³ of scaffold, corresponding to 0.02-0.08 mg/mL) [2]. A preliminary experiment was led on three mini-pigs to optimize bone regeneration and the operating techniques. One animal received two negative controls: an empty defect and a film-coated scaffold at EDC70 without BMP-2; one animal received two film-coated implants, one at EDC30 and one at EDC70, both loaded with BMP-2 at 20 µg/cm³; and one animal received two film-coated implants, one at EDC30 and one at EDC70, both loaded with BMP-2 at 110 µg/cm³. A second main experiment was further led in larger groups to perform statistical analysis. In this experiment, only EDC30 films were used. There was a negative control consisting of a film-coated scaffold without BMP-2, six film-coated scaffolds loaded with BMP-2 at 50 µg/cm³, five film-coated scaffolds loaded with BMP-2 at 110 µg/cm³, and four iliac bone autografts added as a positive control. In both experiments, bone regeneration was assessed qualitatively and quantitatively using CT scans, µCT scans, and histology. CT scans were acquired at days 16, 30, 51, and 91. A CT-scan score was defined by the authors considering four criteria: the percentage of filling of the porous implant (F), the homogeneity of the newly formed bone (H), the ability to distinguish between cortical and cancellous bones (D), and the amount of "ectopic" bone (E). Each criterion was evaluated in a blind manner by four clinicians with a score between 0 and 4. Then, the global score (S) was calculated by each clinician and for each CT-scan:

\[
S = (2F+2H+D-E)/4
\] (1)

µCT scans using a Sanco Medical VivaCT40 scanner were acquired at the endpoint of the study (day 91). Histology was performed by sectioning the samples using a laser microtome (LLS Rowiak) and staining with Sanderson’s rapid stain and Van Gieson’s staining. The histomorphometry provided bone area over total area inside each of the three sections of the implant.

Results and Discussion
Page 148 of 2028
For both experiments, there were no surgical or healing complications. No general or local inflammation occurred during the study. The preliminary experiment allowed optimizing the film coating parameters: no BMP-2 dose-dependence was found for the EDC70 films loaded at two doses while a difference was seen for the EDC30 films, which were selected for the second main experiment. For EDC 30 films, the BMP-2 dose delivered from the scaffold through the polyelectrolyte film significantly influenced the amount of regenerated bone, its mineralization, and the repair kinetics, with a clear BMP-2 dose-dependence (Figure 2). Furthermore, the analysis of µCT scans showed that bone was homogeneously formed inside the scaffolds with little ectopic bone formation, independently of the BMP-2 dose used. Scaffolds loaded with BMP-2 at 110 µg/cm³ showed extensive bone repair, with a fully filled bone defect. In this case, bone repair was as good as for the bone autograft. The BMP-2 doses applied in our study were reduced 20 to 75-fold compared to the commercial collagen sponges currently used in the clinical applications (dose of 1.5 mg/mL), without any adverse effects.

**Conclusion**

3D-printed PLLA scaffolds combined with 2D biomimetic polyelectrolyte films and loaded with reduced doses of BMP-2 thus open perspectives in personalized medicine, since 3D printing allows the customization of the scaffolds shape and the biomimetic film allows the controlled delivery of BMP-2 in space and time.

Surfactants – undervalued calcium phosphate bone cement additives

Ewelina Cichoń¹, Karolina Stępień², Anna Ślósarczyk¹, Joanna Czechowska¹, Aneta Zima¹

¹ AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Krakow, PL; ² Medical University of Warsaw, Department of Pharmaceutical Microbiology, Warszawa, PL

Introduction
Surfactants - surface active agents have been quite poorly studied as additives to calcium phosphate bone cements (CPCs). In general, surfactants stabilise the foam at the water-air interface, reducing the surface energy required to maintain a larger interphase area associated with the formation of bubbles [1]. This property can be used to obtain macroporous CPCs [2]. What is more, the lowering of surface tension by surfactants usually leads to improvement of cement paste injectability. It should be highlighted that surface active agents in bone cement formulations do not only affect their porosity and injectability, but also other physicochemical properties of the final materials such as setting time, compressive strength, microstructure as well as hydrolysis and degradation rates [3]. Moreover, many surfactants additionally possess interesting biological properties (such as antibacterial activity) that can be transferred to the materials in which they are added.

The aim of this study was the evaluation of the highly porous chemically bonded alpha tricalcium phosphate (α-TCP) based cements designed for bone tissue engineering. The influence of three types of surfactants (Tween 20, Tween 80 and Tetronic 90R4) on the physicochemical and biological properties of foamed calcium phosphate cements (fCPCs) has been investigated.

Experimental Methods
Before cements preparation, surfactants critical micelle concentration (CMC) values in the 2% w/v aqueous solution of Na₂HPO₄ were specified by the pendant drop method. Then, the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC) of studied surfactants for Staphylococcus aureus NCTC 4163, Staphylococcus epidermidis wild-type 1457, Escherichia coli ATCC 25922 and Pseudomonas aeruginosa PAO1 were determined. The foamed cements were fabricated by the surfactant-assisted process. Three different materials (fTW20, fTW80 and f90R4) were prepared using different nonionic surfactants. The concentration of each surfactant in the cements liquid phases was 1.25 g·L⁻¹. The liquid to powder ratio was equal to 0.7 g·g⁻¹. The control material (fCTRL) was without the addition of any surfactant. Physicochemical and biological properties in vitro of the prepared foamed cements were investigated.

Results and Discussion
The studies revealed that the amount of a particular surfactant should be precisely determined taking into account its critical micelle concentration in the liquid phase of the cement. Measured CMC for Tween 20, Tween 80 and Tetronic 90R4 were approximately 250 mg·L⁻¹, 50 mg·L⁻¹ and 25 mg·L⁻¹, respectively. The foamability of a surfactant solution is maximum at concentrations around and above its CMC [4], therefore the higher concentration of surfactants in the cements liquid phases was applied to cement foaming. MIC and MBC for surfactant solutions are presented in figure 1.

The diffractograms of all prepared cements revealed the presence of two crystalline phases α-TCP and hydroxyapatite (HAp). After 7 days of setting and hardening in air cements fTW20 and fTW80 revealed approximately twofold lower (13 and 15%) amount of HAp phase than material without any surfactant – fCTRL (32%), meanwhile result for f90R4 cement was comparable to it (27%). The porosity of fCTRL reached 54.8 ± 0.5 vol%. For the f90R4 material, it was slightly higher i.e. 57.5 ± 0.8 vol%. Cements with the polysorbates addition possessed higher porosity 72.9 ± 0.8 and 78.1 ± 2.3 vol%, for fTW20 and fTW80, respectively. Compressive strength of the foamed cements...
was relatively low due to their high porosity (>50 vol%) connected to the high L/P ratio of 0.7 g·g\(^{-1}\) and foaming procedure. For the control material – fCTRL it was equal 2.37 ± 0.50 MPa. The surfactant addition caused a further decrease of compressive strengths, which were 1.13 ± 0.35 MPa, 1.79 ± 0.48 MPa, and 1.43 ± 0.43 MPa for fTW20, fTW80 and f90R4, respectively. Investigated foamed cements were chemically stable in vitro (figure 2). After incubation in SBF, numerous apatite-like forms were visible on the materials' surfaces.

**Conclusion**

To conclude, surfactants should not only be considered as foaming agents or binders but also deserve more attention as modifiers affecting the physicochemical and biological properties of CPCs. What is more, before the use of surfactant in material preparation, in order to reach the best outcomes we should deal with its own properties.

Development of a Personalized 3D Printed Bioactive and Biodegradable Implant for Guided Bone Regeneration

Sergi Rey-Vinolas, Soledad Perez-Amodio, Oscar Castano, Miguel Angel Mateos-Timoneda, Elisabeth Engel

1 Institute for Bioengineering of Catalonia (IBEC), The Barcelona Institute of Science and Technology, Baldiri Reixac 10-12, 08028, Barcelona, ES; 2 CIBER Bioingeniería, Biomateriales y Nanotecnología (CIBER-BBN), Madrid, ES; 3 Department of Materials Science, EEBE, Technical University of Catalonia (UPC), d'Eduard Maristany 16, 08019, Barcelona, ES; 4 Department of Electronics and Biomedical Engineering, University of Barcelona (UB), Martí i Franquès 1, 08028, Barcelona, ES

Introduction
The interest in titanium meshes for guided bone regeneration (GBR) has increased over recent years due to their good stability, volume preservation, and predictable tissue regeneration [1]. However, they also present important drawbacks such as the need for a second surgery to remove the mesh after bone regeneration, and the mesh exposure prevalence [2]. In addition, the combined use with autologous bone graft for larger bone defects is still the gold standard [3]. This technique implies harvesting a healthy bone graft from other anatomic locations, thus can cause side effects such as morbidity, extra pain, and extra surgery to collect the graft. Consequently, this industrial project aims to develop a biodegradable and bioactive patient-specific implant for guided bone regeneration, capable to reproduce complex geometries based on additive manufacturing technologies. As it is based on a resorbable polymer (Polycaprolactone-PCL) and loaded with bioactive microparticles (MPs), the device is a temporal bone substitute able to stimulate angiogenic and osteogenic processes.

Experimental Methods
Different bioactive calcium phosphate-based MPs have been synthesized and dispersed into PCL obtaining thin films. Those films have been used as a raw material to be extruded by 3D Printing (3D Discovery, RegenHU). Apart from a condition with pure PCL, three more conditions with the synthesized MPs have been studied (PCLA, PCLB, and PCLC) in order to enhance the bioactivity of the implant. To assess the stability along the regeneration process, a degradation assay was performed under physiological conditions (HEPES 10mM pH 7.4 at 37ºC) for one year. Scaffolds were evaluated in vitro with human gingival fibroblasts (hGFib) to study the proper gingival attachment to the implant. As well, human mesenchymal stem cells (hMSCs) to evaluate cells’ viability by the quantification of their metabolic activity by Alamar Blue and cytotoxicity by LDH following ISO10993 standards. An angiogenesis protein-related array was performed to identify key proteins present in hMSCs supernatant culture media from seeded scaffolds. Polyamide bone defect models were also kindly provided by AVINENT Implant System.

Results and Discussion
Scaffolds with a parallel patterned design were fabricated by 3D-Printing with a highly interconnected macro-porosity to allow cell migration and blood vessel infiltration. For all conditions with MPs, a good homogeneous dispersion was evidenced according to μCT and FESEM images, facilitating ions release during their degradation process. The degradation assay carried out over one year showed that scaffolds maintained their structure and mechanical properties, with a maximum weight loss of 10% without collapsing.

One of the most frequent clinical complications is meshing exposure, so hGFibs were cultured on scaffolds showing a good biocompatible behavior according to the metabolic activity results, and full colonization of the scaffolds observed by fluorescent confocal images. Furthermore, no cytotoxic effects were detected in all conditions. Vascular endothelial growth factor (VEGF) was quantified among others proteins, showing its highest production levels after
3 days of culture. To support the *in vitro* results achieved, an *in vivo* subcutaneous model in mice is currently in progress.

Finally, complex geometries obtained from clinical cases were 3D printed and compared to polyamide defect models, obtaining a correct fit and, hence, validating patient personalization (fig 1).

**Conclusion**

We have developed a personalized bioactive and biodegradable 3D printed implant for guided bone regeneration, as a promising substitute of current techniques solving their main drawbacks such as a second surgery, extra pain, and morbidity. Although PCL loaded with different bioactive MPs was studied, further experiments are ongoing to select the most efficient condition for the application.

Fabrication of injectable calcium phosphate cements containing PLGA microspheres as drug delivery system for bone regeneration

Carole Barou1,2,3, Habib Belaid1,2, Vincent Cavaillès2, Mikhael Bechelany1

1 Institut Européen des Membranes, Montpellier, FR; 2 Institut de Cancérologie de Montpellier, Montpellier, FR; 3 Biologics 4 Life, Pertuis, FR

Introduction
Bone is a living tissue which undergoes constant remodelling and whose performance could be altered by various diseases such as osteoporosis, fibrous dysplasia, or cancer metastases. In addition to be painful for patients, these diseases lead to pathological fractures, which require multidisciplinary approaches for their treatment. In many cases, a bone substitute material is used to fix the damaged tissue and to provide a mechanical support. The goal of this work is to propose a combined matrix having the potential to improve drug targeting to obtain a selective accumulation in the bone lesion with tunable characteristics. For this purpose, we focus on improvement of rheological properties of the injectable cement and the polymeric loading efficiency of a bisphosphonate.

Experimental Methods
The solid mineral phase was constituted by β- tricalcium phosphate (β-TCP) (50µm) and mono calcium phosphate monohydrate MCPM (150µm) powders at a 45:55 molar ratio, and 1 wt% dihydrogen pyrophosphate. The calcium phosphate cement (CPC) was obtained by addition of a citric acid solution (0.5M) with a powder-to-liquid ratio of 0.4mL per gram of solid content. A second type of cement is currently investigating, with magnesium and calcium phosphates as raw materials (MgCPC). The solid phase and the liquid phase were then respectively loaded into two connected syringes and a push-pull action for 30 seconds allowed to mix the cement. Different percentages of zirconia were added in the solid phase to establish the ideal content for the radio-opacity performance. Subsequently, acid poly-(lactic-co-glycolic) (PLGA) were designed by double-emulsion-solvent-evaporation method. A range of polymeric particles size (from 1µm to 200µm) and sodium alendronate content (0.5 to 5wt%) were investigated. Different formulations (CPC/PLGA5 to CPC/PLGA30) were tested by the addition of PLGA microspheres into the cement (5 to 30 wt%).

Results and Discussion
The initial CPC formulation containing 20 wt% of ZrO2 showed the best radio-opacity, with a compressive strength of 23 MPa and a Young’s modulus of 3.5 GPa. Then, CPC containing PLGA microspheres were characterized by scanning electron microscopy (SEM) to show the incorporation of microspheres. Physicochemical analyses by X-ray diffraction (XRD) and infrared spectroscopy (FTIR) confirmed the final cement phase conversion. The CPC/PLGA30 induced a global diminution of the initial setting time compared to CPC (from 12 to 7 minutes). Although the incorporation of PLGA microspheres increased the force necessary to inject the cement, the CPC/PLGA30 appeared fully injectable after 4 minutes. Additionally, the cohesiveness was improved by addition of the biopolymer. Due to the dissolution-precipitation reaction and the mixing preparation, the CPC has naturally a microporous structure. The addition of PLGA microspheres in the formulation increased drastically the porosity (from 4 to 45%), thus the degradation kinetics of the biomaterials was increased too. In vitro results showed a controlled release of sodium alendronate in the medium from the composite cement. The burst effect was limited compared to the formulation directly incorporating the drug into the cement, without PLGA particles. Finally, biocompatibility of formulations was validated via a viability test using MC3T-3 and hFOB 1.19 cells.
in presence of CPC and CPC/PLGA30. In vivo studies are ongoing in rat caudal vertebrae, to access the bone regeneration ability of the formulations.

**Conclusion**

The results validated this calcium phosphate cement as drug delivery system with PLGA particles as drug carriers. The improvement of the composite is ongoing to increase biologic efficiency of the matrix with magnesium ions, using MgCPC base. This appears as a very promising material for a local release of sodium alendronate to address osteoporosis or metastasis fracture sites, suitable with the clinician needs.

1 Royal College of Surgeons in Ireland, Tissue Engineering Research Group, Dept. Anatomy and Regenerative Medicine, Dublin, IE; 2 University of Nottingham, School of Pharmacy, Nottingham, GB; 3 Advanced Materials and Biomedical Engineering Research Centre (AMBER), Dublin, IE

Introduction

In osteoarthritis (OA), chondrocytes propagate and experience an altered physiochemical microenvironment, which hinders the success of biomaterial guided cell therapies and regenerative strategies. Functionally deficient pathological extracellular matrix (ECM) production and increased catabolism drive abnormal loading and further increase proinflammatory cytokine (e.g., interleukin-1B and tumour necrosis factor-α) production. Gene activated scaffolds targeting the transient attenuation of proinflammatory signalling have the potential to interrupt degenerative positive feedback loops while promoting anabolic processes to restore tissue functionality. In this study, we aimed to functionalise a chondrogenic freeze-dried collagen-hyaluronic acid (Col-Hya) scaffold (developed in the Tissue Engineering Research Group at the RCSI1) to deliver an immunomodulatory small interfering (si)RNA and increase scaffold effectiveness in inflammatory environments. For this, we investigated the targeted knockdown of connexin-43 (Cx43), a membrane channel protein that is significantly increased in OA cartilage (~40-fold) and has increasingly recognised roles regulating gene and protein activity pertinent to OA progression, including the activity of mechanosignalling molecule YAP (yes-associated protein) and proinflammatory transcription factor NFκB1,2,3,4. We developed and characterized a non-viral scaffold mediated Cx43 siRNA delivery system using a cell penetrating peptide with a glycosaminoglycan-binding domain (GET peptide5). Next, we used this siRNA delivery platform to investigate the effects of Cx43 knockdown on human articular chondrocyte (hAC) responses to OA-associated proinflammatory signalling (IL-1B and TNF-α) and the link between Cx43 and the YAP1-NFκB signalling axis in chondrocytes. Finally, we tested the ability of our siRNA-activated scaffolds to promote cartilage ECM production and healthy gene and protein expression in the presence of IL-1B and TNF-α in 3D culture models.

Experimental Methods

To optimise GET-Cx43 siRNA encapsulation and delivery, physiochemical characterisation (size, charge, morphology) and encapsulation efficiency assays were performed. Efficiency of siRNA knockdown in hACs was tested in 2D culture (quantitative reverse-transcription (qRT-)PCR, western blot). Optimised GET-siRNA formulations were then incorporated into Col-Hya scaffolds and controlled complex release profiled and Cx43 knockdown tested (qRT-PCR, western blot). Immunomodulatory effects of scaffold delivered siRNA were investigated through hAC culture with IL1b or TNFa and analysis of gene (qRT-PCR) and protein (western blot, immunohistochemistry, ELISA) expression and ECM production (histology, glycosaminoglycan (GAG) assay). The interactions of Cx43, YAP and NFκB were investigated through co-immunoprecipitation, small molecule inhibitors and promotors (YAP-Verteporfin, VP, 1 mM; Lysophosphatidic Acid, LPA, 20 mM) and immunofluorescent staining. The effect of scaffold-mediated Cx43 knockdown in responses to IL-1B and TNF-α in a 3D model were assessed by qRT-PCR, western blot, histology, GAG assay and ELISA over 28 days culture.

Results and Discussion

GET-siRNA complexes demonstrated favourable physiochemical and encapsulation properties. Complexes achieved successful Cx43 gene and protein knockdown in hACs in 2D culture (up to 90 % until 7 days culture).
Release profile analysis of GET-siRNA in Col-Hya scaffolds demonstrated successful complex incorporation, with Cx43 knockdown observed in scaffold invading hACs (>80% until 7 days) (Figure 1A). Cx43 knockdown reduced hAC responses to cytokine stimulation, increased healthy anabolic chondrocyte gene expression, GAG production and reduced catabolic responses (Figure 1B). In addition to reduced connexon-mediated cell-cell inflammatory signalling, co-immunoprecipitation experiments and immunofluorescent staining identified a protein-level interaction between Cx43 and YAP, a modulator of IL-1B and TNF-a (Figure 1C). In 3D models, IL-1B and TNF-a decreased healthy chondrogenic gene/protein expression and GAG production over 28 days chondrogenic culture. GET-Cx43 functionalisation decreased these catabolic cell responses and increased healthy ECM and GAG production over 28 days culture.

**Conclusion**

This study successfully functionalises a chondrogenic scaffold through incorporation of an immunomodulatory siRNA, allowing transient interruption of degenerative positive feedback loops while tissue functionality is restored. Using this scaffold-mediated non-viral siRNA delivery, we knocked down Cx43 expression in vitro, which decreased cellular responses to IL-1B/ TNF-a and promoted anabolic phenotypes. Further, we also describe a mechanistic link between Cx43 and IL-1N/ TNF-a signalling, identifying Cx43 as a potential therapeutic target in OA. The development of the siRNA-activated scaffold delivery system potentially offers a new paradigm in biomaterials in cartilage repair.

Introduction

Traditional methods to promote bone healing (e.g. autograft) and advanced therapeutics (e.g. recombinant human bone morphogenetic protein-2 [rhBMP-2]) have had a limited impact on easing the burden of a proportion (<20%) of patients with fractures who suffer from delayed healing or non-union. Increasingly, the response of the immune system to a fracture, and during the stages of bone healing, has been identified as a major regulator and, in some cases, as a predictor of healing outcome, shifting research focus towards the development of novel immunomodulatory therapies. Interleukin-1 receptor antagonist (IL-1ra), the natural antagonist of the potent pro-inflammatory cytokine IL-1b, has recently been shown to enhance bone healing in mouse calvaria. However, its therapeutic efficacy in long bone defects alone, or as an adjuvant in rhBMP-2 therapy, remains unknown. This study sought to determine the therapeutic efficacy of IL-1ra (2.5 μg) alone, or in combination with a low dose of rhBMP-2 (1 μg), in long bone defects when delivered using a collagen-hydroxyapatite scaffold (CHA) in a rat model.

Experimental Methods

Therapeutic efficacy was evaluated over 14 weeks using 2 mm segmental femoral defects in skeletally mature (20 – 24 week old) female F344 rats (n=8 per group), internally fixated using a 1.25 mm-thick polyetheretherketone RatFix plate (RISystem, Switzerland). Animals received either no treatment (empty defect), a CHA scaffold, CHA loaded with IL-1ra, or CHA loaded with a combination of IL-1ra + rhBMP-2. New bone formation within and around the defect site was monitored using \textit{in vivo} microCT and radiographs, immediately after surgery, and at 3, 4, 6, 8, 10, and 14 weeks post-op. Lateral and anteroposterior digitally reconstructed radiographs (DRRs) were generated from \textit{in vivo} microCT scans using Amira software to evaluate cortical bridging using a RUST-based scoring system, which is typically used in clinical practice to evaluate tibial fracture healing. The biomechanical resilience of newly formed bone was evaluated using non-destructive 4-point bending, while tissue morphology was evaluated by histopathological analysis, at 14 weeks.

Results and Discussion

Empty defects ultimately failed to bridge after 14 weeks (31±11% defect filled with new bone, 0/4 defects bridged). Treatment with CHA scaffolds led to a limited improvement in new bone formation (46±16%, 1/8 bridged) compared to empty defects, while IL-1ra (2.5 μg) loaded CHA scaffolds led to a similar outcome compared to empty defects (34±20%, 1/8 bridged) (Fig. 1). CHA scaffolds loaded with a combination of IL-1ra (2.5 μg) and rhBMP-2 (1 μg) led to superior bone healing (95±3%, 8/8 bridged) compared to CHA scaffolds loaded with rhBMP-2 (1 μg) (88±7%, 8/8 bridged), comparable to that of a higher 5 μg rhBMP-2 dose (93±4%, 8/8 bridged) (Fig. 1). The combination of IL-1ra (2.5 μg) and rhBMP-2 (1 μg) led to significantly accelerated bone formation at both week 4 and 6 compared to rhBMP-2 alone (1 μg) (Fig. 1). The combination of IL-1ra (2.5 μg) and rhBMP-2 (1 μg) also resulted in stiffer and more resilient new bone formation (16% failed the mechanical test) compared to CHA scaffolds loaded with rhBMP-2 (1 μg) (50% failed the mechanical test).

Conclusion

Page 160 of 2028
Taken together, this study is the first to determine that a single, locally administered, dose of IL-1ra can significantly enhance femoral fracture bone healing when used in combination with low dose rhBMP-2. This finding was observed in a clinically relevant internal plate fixation context, rather than the more widely used ExFix. This study suggests that the immunomodulatory effects of IL-1ra accelerates rhBMP-2-induced early bone formation, ultimately resulting in greater volume and stiffer new bone. This evidence supports the use of IL-1ra as an immunomodulatory strategy to enhance the efficacy of low dose rhBMP-2 therapy in future bone healing approaches.

Microwell-Based Engineering of the Bone Microenvironment through Ionic Calcium and Phosphate Signaling

Steven Vermeulen, Zeinab T. Birgani, Roman Truckenmüller, Pamela Habibovic

Maastricht University, MERLN Institute, Department of Instructive Biomaterials Engineering (IBE), Maastricht, NL

Introduction

Bone fractures or musculoskeletal disorders such as osteoporosis present a significant burden on individuals and the healthcare system [1]. A challenge in regenerative medicine is recapitulating the complex three-dimensional (3D) bone microenvironment in vitro to study these disorders or to develop regenerative therapies. This study applies a microwell-based platform to create aggregates of human mesenchymal stromal cells (hMSCs) and supplement media with inorganic compounds such as calcium (Ca$^{2+}$) and phosphate ions (Pi) to support differentiation. We found that combining a spheroid environment with inorganic signaling allowed rapid mineralization and induced a synergistic effect on osteogenic markers. This opens up possibilities for the generation of complex bone organoid models for regenerative medicine applications.

Experimental Methods

Polycarbonate arrays consisting of 500 µm diameter microwells were generated using film microthermoforming (Fig. 1A-B) [2]. The seeding of hMSCs inside these microwells allowed rapid aggregation into spheroids. 24h after cell seeding in micro-wells and standard polystyrene culture plates, cell culture medium was supplemented with either 4 mM Ca$^{2+}$ or 2 mM sodium phosphate dibasic dihydrate (Pi) with or without dexamethasone (DEX). RNA was extracted at 5, 10, and 20 days, after which osteogenic marker expression was assessed through quantitative PCR (qPCR). Quantification of mineralization was performed using OsteoImage staining.

Results and Discussion

To evaluate the effect of the 3D environment and Ca$^{2+}$ or Pi signaling on osteogenic marker expression, we harvested RNA and subsequently performed qPCR analysis. Targeting the osteogenic marker BMP2 [3], we found that already after 5 days an increase in expression levels occurred when cells were subjected to either Ca$^{2+}$ and Pi signaling on flat tissue culture plastic (Fig. 2A). Interestingly, the 3D spheroid microenvironment was sufficient to elevate BMP2 levels as compared to 2D culture, with Ca$^{2+}$ and Pi signaling not further enhancing expression. Similarly, Osteopontin (OPN) [4] was strongly elevated due to the spheroid environment (Fig. 2B). In contrast with BMP2, OPN demonstrated a further increase in expression levels when treated with the inorganic supplements. Of interest, DEX lowered both BMP2 and OPN expression levels when combined with Ca$^{2+}$ and Pi. Next to enhancing the expression of osteogenic markers, mineralization was induced as early as 10 days in hMSCs spheroids when treated with Ca$^{2+}$ or Pi (Fig. 2C). These findings support the notion that a spheroid environment, together with inorganic signaling, is an efficient way to enhance osteogenic differentiation.

Conclusion

Microwell-based spheroid formation of hMSCs in combination with either Ca$^{2+}$ or Pi supplements allows rapid mineralization and enhances the expression of osteogenic markers.

Introduction
In bone tissue engineering, biomimetic scaffolds comprising calcium phosphate bioceramics, e.g. β-tricalcium phosphate (β-TCP), are aimed to serve as an artificial temporary extracellular matrix (ECM) in order to support cell adhesion and guide new bone tissue formation. The combination of bioceramics with organic materials, such as hydrogels containing hyaluronic acid (HA), naturally occurring polysaccharide that serves as a major component of extracellular matrix in mammalian connective tissues, is highly advantageous to overcome the brittleness of their intrinsic nature. Among the different types of hydrogels, thermosensitive hydrogels based on amphiphilic copolymers, such as Pluronics (polyethylene oxide-polypropylene oxide copolymers, PPO-PEO-PPO), thanks to their ability to undergo thermal gelation as well as low cytotoxicity, have attracted significant attention in biomedical applications and pharmaceutical industries [1,2]. However, infections during or post scaffold transplantation are still challenging which reduce the efficacy of bone healing. After the transplantation, infections may also be distributed to the scaffold from other sources of inflammation through bloodstream. Silver nanoparticles have shown a strong capability to inhibit or decline infections and have been also utilized for bone regeneration applications. Among different methods, biosynthesis of silver NPs, by using plant extracts, has received considerable attention due to the growing need to develop environmentally and non-toxic technologies [3]. On considering the properties of β-TCP, HA, Pluronic, and Ag NPs, our work was aimed to fabricate thermosensitive hydrogel biocomposites for bone tissue repair, which can be injected easily and possess antimicrobial properties to prevent infection.

Experimental Methods
Ag NPs were synthesized within corn silk extract (CSE) by microwave assisted method. The hydrogels were prepared by dissolving different amounts of HA, β-TCP, Pluronics F127 and F68 in CSE with and without AgNPs. The hydrogels composition was optimised by rheological analysis.

Results and Discussion
Fig. 1A shows the schematic illustration for synthesis and stabilization of Ag NPs by CSE. The absorption spectra of samples before and after microwave treatment are presented in Fig. 1B. Fig. 1C shows the results of DLS analysis of silver NPs and it can be seen that the prepared NPs have a narrow size distribution with a mean diameter of 49±2 nm. TEM image (Fig. 1D) shows well-dispersed silver nanoparticles which are spherical in shape with an average size of 13±1 nm. Rheological experiments demonstrated that the thermosensitive hydrogels have good mechanical properties with gelification temperature (Tgel) close to body temperature (Fig. 2A). The systems showed antibacterial activity toward gram-positive (Bacillus Subtilis, Staphylococcus Aureus) and gram-negative (Pseudomonas Aeruginosa, Escherichia Coli) bacteria (Fig. 2B). L929 cells exhibited a noncytotoxic and typical mouse fibroblast-like cellular morphology after 24 h of the incubation with the samples (Fig. 2C and D). Schematic representation of injection of the thermosensitive nanocomposite are presented in Fig. 2E. Thermosensitive hydrogels, which
possess good retention at the application site, have appealed a great deal in biomedical and clinical fields. At room temperatures, the systems are liquid and could be injectable whereas, at the body temperature, they became a gel. This fast sol-to-gel phase transition behavior is beneficial for cell entrapment to give a uniform distribution of cells within the gelled matrix. HA offers many advantages as a tissue scaffold which including biodegradability, biocompatibility, and bioresorbability which have been shown in many studies. Hyaluronic acid could activate cell surface receptors, influencing intracellular signaling cascades for cell growth, migration, proliferation, and differentiation [4]. One of the main reasons of scaffold failures is due to the implant-associated bacterial infections. Hence, using antibacterial scaffolds helps more success for bone tissue formation which are of clinical importance. In this study, we used spherical particles of Ag to impart antibacterial activity to the thermosensitive hydrogels to avoid bacterial contamination [5].

**Conclusion**

In conclusion, silver NPs were biosynthesized in an aqueous medium of corn silk extract without using toxic chemical reagents. The new thermosensitive HA-based nanocomposite hydrogels demonstrated good mechanical properties with \( T_{\text{gel}} \) close to the body temperature. The system revealed desired antibacterial activity against several gram-positive and gram-negative bacterial strains which can prevents bacterial infection. In addition, from the biological point of view, the nanocomposites revealed appropriate biocompatibility in comparison with the control samples.

Targeting macrophages to modulate inflammation in cartilage degeneration: using poly(lactic-co-glycolic acid)-based nanoparticles for ibuprofen delivery

Kaoutar Chattahy1,2, Catarina L. Pereira1,2, Flávia Sousa1,2, Cristiana Couto1,2,4, Meriem Lamghari1,2,4, Mário A. Barbosa1,2,4, Bruno Sarmento1,2,3, Raquel M. Gonçalves1,2,4, Susana G. Santos1,2

Introduction

Osteoarthritis (OA) is the most prevalent chronic joint disorder worldwide, leading to cartilage destruction, pain, loss of function, and disability(1). Controlling inflammation and pain are major challenges in OA therapy, as infiltrating macrophages contribute to the inflammatory joint microenvironment(2). The use of nanocarriers improves drug retention and targeting, providing effective local therapeutic dosages(3). Polylactic acid-glycolic acid (PLGA), has been widely used as a drug carrier. PLGA nanoparticles are degradable, biocompatible, and can be produced to deliver different kinds of drugs(4). Herein, we propose the development of PLGA-based nanoparticles (NPs) loaded with clinically used ibuprofen, as a strategy to control the inflammatory response, thus improving the microenvironment for cartilage repair. The hypothesis underlying this work is that macrophages can be effectively modulated by delivering ibuprofen encapsulated in PLGA NPs.

Experimental Methods

PLGA-based NPs were prepared by the nanoprecipitation method. The organic phase (PLGA + Ibuprofen in acetone) was added to the aqueous phase (Poloxamer 407 in water) under stirring and NPs were purified by subsequent washes. Formulations containing theoretical drug loadings of 5, 10 and 20% were produced to achieve the highest drug loading. Association efficiency and drug loading were quantified by a validated High-Performance Liquid Chromatography (HPLC) method. NPs were characterized for size, Pdl and charge by Dynamic Light Scattering (DLS). NP ibuprofen drug release profile was addressed in PBS (pH 7.4) at different time points (0, 4, 24, 48, 72 and 168h). Samples were collected and centrifuged (20 min at 9600g), and ibuprofen in the supernatant was quantified by HPLC. Human monocytes were obtained from buffy coats (donated by Serviço de Immunohemoterapia, CHUSJ-Centro Hospitalar Universitário de São João), differentiated to macrophages using M-CSF, and stimulated at day 10 towards pro-inflammatory (M1) phenotype with LPS+IFNγ. Ibuprofen-loaded PLGA NPs were added to M1 macrophages, to achieve 15 or 30 μg/ml of ibuprofen. Equivalent amounts of empty PLGA NPs and the same concentrations of free Ibuprofen were used as controls. NP internalization was characterized at day 12, by cell surface labelling (CD14, CD86, HLA-DR, CD163) and conventional or imaging flow cytometry. PGE2 and cytokines (IL-10, IL-1β and TNF-α) secretion were quantified in culture supernatants, using commercial ELISA kits.

Results and Discussion

Ibuprofen loaded PLGA NPs presented an average size by intensity of 206±2.9 nm, a Pdl of 0.06±0.02, and zeta potential was -1.77±0.25mV. Results showed that differences in association efficiency (AE) and effective drug loading were less pronounced in 20% formulation. Thus, the formulation of Ibuprofen loaded PLGA NPs with 20% of
theoretical drug loading and 75% of AE was used for further experiments. Drug release experiments demonstrated an initial burst release (30%) and extended drug release up to 40% after 7 days. PLGA NPs were readily internalized by up to 75% of cells, without significant impact on cell morphology. Low LDH release indicates that NPs are not cytotoxic towards macrophages after 72h of incubation. Upon macrophage M1 polarization, treatment with Ibuprofen loaded PLGA NPs, particularly the 30 μg/ml concentration, reduced cell surface levels of M1 markers CD86 and HLA-DR, when compared with untreated M1 stimulation, and free Ibuprofen treatment. Levels of secreted PGE2, in response to M1 stimulation, were reduced by treatment with Ibuprofen loaded PLGA NPs, using both concentrations, albeit not as significantly as for free Ibuprofen. Cytokine secretion profile for all samples is currently being analyzed to determine the impact of Ibuprofen loaded PLGA NPs on the modulation of macrophage secretory profile.

Conclusion
PLGA NPs are internalized by macrophages without cytotoxicity, and are suitable carriers for Ibuprofen, acting to modulate macrophage pro-inflammatory response, and the production of key mediators of cartilage-associated inflammation and degradation.

Application of Organ-on-a-Chip Systems in Precision Medicine

Peter Ertl

Technische Universität Wien, Technical Chemistry, Wien, AT

Personalized medicine is broadly defined as the use of information from a patient’s genotype to either initiate a preventative measure against the development of a disease or the ability to select the most appropriate therapy that is particularly suited to a patient. Despite the benefits of using DNA based personalized diagnostic approaches, in many cases the underlying genetic risk factors are too many to reliably predict cellular responses to drug treatments. To overcome this challenge, next generation personalized diagnostic tools also need to make use of information obtained from living cell assemblies that resemble the (patho)physiological microenvironment of individual patients to accurately predict disease onset, progression and remission. In course of the presentation current state-of-the-art of personalized diagnostics will be reviewed and three different organ-on-a-chip applications in precision medicine introduced including cancer drug screening, chronic inflammation research and neurodegenerative diseases.

Stereolithography-based 3D-printing of transparent and biocompatible microfluidics for Organs-on-a-Chip applications

Anna Fritschen¹, Alena K. Bell²,³, Lukas Stühn², Robert W. Stark², Andreas Blaeser¹,⁴

¹ Technical University of Darmstadt, Department of Mechanical Engineering, BioMedical Printing Technology, Darmstadt, DE; ² Technical University of Darmstadt, Institute of Materials Science, Physics of Surfaces, Darmstadt, DE; ³ Technical University of Darmstadt, Collaborative Research Center (CRC) 1194 – Interaction between Transport and Wetting Processes, Project A07, Darmstadt, DE; ⁴ Technical University of Darmstadt, Centre for Synthetic Biology, Darmstadt, DE

Introduction

Soft-lithography methods are routinely applied in biomedical research, for instance for the fabrication of microfluidic devices, multichannel bioprinting print heads and Organs-on-a-Chip. While soft-lithography offers excellent resolution, it is a complex process and geometrically limited. Transparent 3D-printing could overcome these challenges by enabling complex 3D-shapes, round features and single step fabrication of closed channel systems. However, to compete 3D-printed microfluidics need to comply with multiple requirements, such as low surface roughness, good optical transparency, highly resolved features and high cytocompatibility. Stereolithography printing has proven to be a suitable method for this purpose, as it offers excellent resolution (down to 30–40 µm) and is generally suited to process transparent and biocompatible materials. However, sufficient transparency for high magnification and fluorescence microscopy, closed channel fabrication and long-term cytocompatibility currently remain a challenge.

Experimental Methods

In order to fabricate 3D-printed components that fulfil the above-mentioned criteria, we established a novel stereolithography strategy based on a modified Asiga Pico ²HD² printer. We investigated a commercial resin (Asiga PlasClear) and two own PEG-DA formulations. To reduce surface roughness and bulk defects, modifications of the build plate and resin vat were realized. The surface quality, optical transparency and chemical composition of the prints were characterized by confocal microscopy, AFM as well as UV/VIS and Raman spectroscopy. Finally, cytocompatibility of the applied materials was fluorescence microscopically assessed using primary endothelial cells and fibroblast cell lines.

Results and Discussion

The confocal microscopy and UV/VIS spectroscopy results revealed a significant advantage of the build plate and resin vat modification compared to a non-modified printer. All prints exhibited low surface roughness of less than 0.3 µm and superior optical transparency of over 90% in the visible light wavelength range (400 – 800 nm). However, during light microscopy, a periodic structure was visible in all printed parts indicating interference patterns caused by the voxel illumination during DLP. Additional AFM microscopy supported this assumption, as the dimensions of the surface features were of the size of the DLP pixels of 27 µm. Interestingly, the height of these periodic features were found to be dependent on the photoinitiator (BAPO) and -sensitizer (ITX) concentration and varied between 40 and 400 nm. Even more, the presence and concentration of photoinitiator and photosensitizer proved crucial for optimum print resolution and defined channel geometries. For this reason, different combinations and concentrations of the photoinitiator and photosensitizer were systematically investigated regarding minimum feature size and general printability. The commercial resin proved to be easy in use and offered a minimum feature size of 200 µm. Open channel structures could be achieved with a diameter of down to 350 µm. For the PEG-DA based resins, prints without photosensitizer exhibited low spatial resolution and low channel quality. The addition of low concentrations
of photosensitizers led to clearly defined prints with minimum feature sizes of 150 µm outperforming the commercial resin. Cytocompatibility tests with primary endothelial cells and established fibroblast cell lines and Raman spectroscopy revealed the need for post-fabrication treatments such as prolonged solvent extraction and UV-exposure to remove toxic photoinitiator and photosensitizer residues. Additionally, resin formulation and photoinitiator concentration were found to further impact post-fabrication cytocompatibility. Finally, high magnification phase contrast and fluorescence microscopy (up to 400 x) could be successfully demonstrated with various fluorescent dyes. Still, the commercial resin was shown not to be compatible with DAPI staining, as the cured parts absorbed most of the light with wavelength below 400 nm, which lies within the excitation wavelength band of DAPI. Finally, the printed microfluidic chips were used in Organ-on-a-Chip models containing cells directly cultured on the surface of parts as well as in a hydrogel matrix. Cell culture under perfusion was feasible for various days with cells showing the expected morphology under perfusion.

**Conclusion**

In summary, our work reveals that DLP printing is a versatile and reliable platform for the fabrication of transparent microfluidic devices that entail high feature resolution, optical clarity and cytocompatibility. Even more, we could prove that printer modification and resin optimization can be advisable to fully exploiting its potential. These qualities make DLP printing a promising technology for rapid prototyping of microfluidic components, customized cell culture dishes and Organ-on-a-Chip devices.

**Introduction**

It is estimated that 10% of the worldwide population suffers from chronic kidney disease (CKD) with a rising tendency. [1] Patients with CKD have limited treatment options, with fibrosis being the pathological endpoint of CKD, where an increase of ECM deposition is normally observed. [2,3] Therefore, novel therapies that could halt or even reverse the progression of CKD are urgently needed. [1] Bioprinting is considered one of the most promising approaches to generate novel 3D *in vitro* models and organ-like constructs [4], which can offer viable alternatives to investigate underlying pathomechanisms and progression of kidney diseases. [5] In this work, we aim to establish a robust protocol for the isolation of primary kidney cells from a transgenic reporter mouse, showing keratin 8 conjugated with a yellow fluorescent protein (K8-YFP), and to test their suitability for bioprinting.

**Experimental Methods**

A method to isolate primary renal cells was established (*Figure 1a*). Primary murine tubular epithelial cells (pmTECs), endothelial and fibroblast (pmFibroblasts) cells were successfully isolated, but further optimization is required for the culture and expansion of primary endothelial cells. These cells were used in a new bioprinting platform laying the foundation for the development of a 3D renal tubulointerstitium model for *in vitro* studies. Polysaccharide biomaterial inks were characterized in terms of viscosity and printability. Endothelial cell line (HUVECs) and pmTECs were combined with polysaccharide biomaterial ink (alginate and pectin) and processed with a microfluidic 3D bioprinter. Cell viability and metabolic activity were evaluated for co-culture conditions. The production of core-shell bioprinted constructs was investigated by including HUVECs in the shell and pmTECs in the core.

**Results and Discussion**

As tubular epithelial cells are the major cell type in the kidney, we primarily isolated these cells. The established method allowed a successful isolation of pmTECs, fibroblast and endothelial cells, but further culturing was only successful for pmTECs and pmFibroblasts. pmTECs and pmFibroblasts were positive for cell-specific markers (*Figure 1b*). Immunofluorescence of keratin expression showed increase expression in fibrotic tissue (*Figure 1c*), as well as a different cell morphology in diseased tissue (*Figure 1d*). The processing parameters to bioprint polysaccharide based biomaterial inks were optimized. We tested the optimized bioprinting protocol with bioinks containing pmTECs and HUVECs, investigating cell survival and metabolic activity of the bioprinted constructs, leading to cell viability above 90% after one week in culture. Finally, bioinks were processed in a core-shell arrangement to mimic the tubulointerstitium, where the peritubular capillaries wrap the renal tubule, showing high accuracy in cell deposition (*Figure 2a*), dimension of the bioprinted constructs and capability to produce hollow filaments (*Figure 2b*).

**Conclusion**

Microfluidic bioprinting strategy was used to build a novel 3D kidney *in vitro* model presenting primary murine tubular epithelial cells bioprinted for the first time. This model will facilitate the investigation of the interstitial fibrosis, whose underlying mechanisms are currently not completely understood. This study lays the basis for an alternative 3D *in vitro* model for the investigation of mechanisms, potential therapies and the development of renal fibrosis.

3D Bioprinting of prevascularized full thickness constructs with an endothelialization of hollow channels

Bastian Böttcher, Karl-Heinz Feller
Ernst-Abbe-Hochschule Jena, IMPT Jena, Jena, DE

Introduction
The 3D printing of cell-laden hydrogels allows the creation of complex three-dimensional structures with ECM similar materials and a spatial arrangement of different cell lines. Consequential in vivo alike 3D cultures with different functional regions can be fabricated. However, a major drawback in current 3D models is the insufficient nutrient supply due to high distance between cells and surrounding medium. To reduce the subsequent concentration gradient, the integration of prevascular structures is helpful. Coaxial extrusion allows printing hollow structures with an on-site delivery of cells around the channel. Herein we investigated the effect of prevascularized structures in small full-thickness constructs made of a gelatin/alginate hydrogel by investigating if it is beneficial for cell survival and if HUVEC can form an endothelium when printed around the channel.

Experimental Methods
3D printing of the prevascularized constructs was achieved using an extrusion-based bioprinter by combining pneumatic cartridge dispensers and coaxial printing tools. The whole cell-laden gelatin/alginate construct was made in a three-step process. Firstly, a base layer was printed that served as a substrate for other gel components. Afterwards a coaxial printed strand was printed while the core consisted of a CaCl$_2$-laden gelatin that crosslinked the surrounding gelatin/alginate gel during printing. These coaxial printed struts were printed in a parallel manner. The space between these layers was filled in the third step with another cell-laden gel. For investigating the effect of prevascularization on cell viability, only HepG2 cells were used in all cell-laden gels, while HUVEC instead of HepG2 were printed in the shell of the coaxial printed strand for determination of a possible endothelialization. A day after printing, the cell-laden constructs were treated with sodium citrate and investigated at different time intervals for cell specific activity.

Results and Discussion
The treatment of the cell-laden constructs with sodium citrate lead to an improvement of cell survival for every cell line used. In general, the cell viability remained higher with greater concentration of sodium citrate used. That might be connected to the removal of bio-inert alginate causing an improved diffusion and a higher porosity. When prevascularized structures were integrated into full thickness constructs, an increase in cell viability compared to non-prevascularized constructs could be observed. However, with prolonged cultivation times this effect was extenuated. When HUVEC were delivered into the shell of the coaxial printed strand an endothelialization occurred, though it took several weeks until the inner channel wall was covered with HUVEC, as can be seen in the figure. Consequential coaxial extrusion allows the creation of hollow channels with an endothelium.

Conclusion
The integration of hollow strands into full thickness constructs using coaxial extrusion is an appropriate method for improving nutrient supply. When HUVEC were delivered around the hollow strand, an endothelia was formed that might be a basis for angiogenesis processes to further improve nutrient supply.

Microfluidic-Driven Hydrogel Biofabrication for Engineering Functional Microtissue Architectures

Carlos F. Guimarães, Luca Gasperini, Alexandra P. Marques, Rui L. Reis

Introduction

The microfluidic manipulation of hydrogels can be a powerful tool for the biofabrication of cell-laden, soft fiber-like structures that can be used as building blocks to engineer live-like tissues by approaching their shape and intricate mechanics [1,2]. In the past decade, a wide range of microfluidic setups, chip designs, and printing nozzle configurations have been employed to fabricate structures with varied shapes and compartment organizations, requiring equivalently complex arrangements to be individually assembled for each structure. Simultaneously, most current microfluidic hydrogel fabrication strategies result in continuous structures with uniform architecture, which fail to approach the complex space-varying shape and mechanics that exist in several biological tissues [2]. We have demonstrated that the microfluidic manipulation of hydrogel flows and controlled laminar mixing can be employed for the sequential, high-throughput fabrication of 3D hydrogel cell-laden gradients. These can integrate broad ranges of mechanical properties and material characteristics, such as adhesiveness, biodegradation, and multiple crosslinking. We further explored how these gradients can be used as libraries for high-content screening cell responses to varying 3D environments (Figure 1), ranging from cell adhesion and proliferation to more complex triggering of adipogenic versus chondrogenic differentiation and mechanotransduction [3].

Experimental Methods

Now, we demonstrate a novel biofabrication technique with unprecedented versatility for the creation and tuning of micro-bioarchitectures within 3D hydrogel fibers. We show how one single 3D hydrodynamic flow-focusing chip can be employed to obtain a continuous flow of hydrogel precursors, which organize themselves based on their viscosity and inlet pressure, crosslinking into fibers with a plethora of multi-compartment shapes (Figure 2) [4]. We outline how the material's viscosity and microfluidic channel configuration can be adjusted in order to continuously spin fibers with over 20 different microarchitectures. We further present how the different materials and flows can be tuned to control compartment and fiber sizes down to full diameters below 50µm. To the best of our knowledge, this size represents the smallest multi-compartment hydrogel fibers so far fabricated, approaching the size magnitude of single cells and small vascular structures while simultaneously maintaining the designed architecture at downsized scales.

Results and Discussion

To prove the potential of our system for the biofabrication of complex, multi-compartment structures, we explored ribbon-like cancer/basement-membrane/stroma models for creating a novel cancer-on-a-fiber platform. The effect of 3D architecture and designed cancer microenvironment components (Stroma and Basement Membrane) significantly affected cancer cell's response to doxorubicin, enabling a more faithful in vitro recapitulation of therapeutic approaches. We also leveraged flow-focused core-shell architectures to continuously fabricate vascular-like structures and assemble them in 3D biological networks, a facile approach for large-length vascularization of engineered tissues that can be used to accelerate construct vascularization in multiple settings. We further combined hydrogels and hydrophobic molecule depots as all-in-one tissue engineering constructs, simultaneously integrating stem cells, biomaterials, and pro-differentiation factors. The gradual release of purely hydrophobic dexamethasone
transported in isolated droplets with tunable distribution was capable of triggering stem cell differentiation upon release, doing so to a higher extent than that of its soluble counterpart, which is commonly dissolved in media.

**Conclusion**

The innovative structures we report open several avenues in the hydrogel biofabrication fields, namely those focusing on creating evermore complex biological architectures and micro-modeling 3D environments of health and disease. Additionally, our discovery’s versatility via the use of one single chip might lead to the widespread application of 3D microfluidic flow-focusing as a new biofabrication technique on its own, with a myriad of possibilities for the fields of clinical and experimental tissue engineering.

3D reactive inkjet printing of peptide based hydrogels for corneal tissue engineering

Georgia L. Duffy¹, He Liang¹, Don Wellings³, Kate Black², Rachel Williams¹

¹ University of Liverpool, Eye and Vision Science, Liverpool, GB; ² University of Liverpool, School of Engineering, Liverpool, GB; ³ Spheritech Ltd., Runcorn, GB

Introduction
The human cornea is the window to the eye, and acts to focus light onto the retina. It is composed of three main layers: a stratified epithelium, the stroma, and a monolayer of endothelial cells. Corneal opacities are the 4th leading cause of blindness worldwide, with the only current solution being a corneal transplant from a cadaveric donor. This treatment method has several limitations, such as the limited availability of tissue; which has prompted research into finding suitable alternatives.

3D reactive inkjet printing is an additive manufacturing method where more than one ink is printed together, reacting to form a solid structure. This is a method which can be utilised for tissue engineering applications due to its high resolution and capability of printing cells into the 3D construct. This work aimed to use reactive inkjet printing of natural polymers poly-ε-lysine (pεK) and gellan gum (GG), to form a porous hydrogel construct based on their electrostatic interaction. The hydrogel formed was analysed for its suitability in corneal tissue engineering.

Experimental Methods

Ink characterisation: 20 wt % pεK and 0.35 wt % GG were made up in DI water and their rheological properties characterised. Viscosity, density, contact angle and surface tension measurements were performed to establish the printability of the inks using the Ohnesorge (Oh) equation.

3D printing: Track optimisations were performed to establish the optimal speed and step spacing for the polymer inks. An ideal waveform was designed for each ink to achieve a stable droplet prior to printing. Using the parameters, hydrogel arrays were printed, and bitmaps were designed to print porous constructs.

Imaging of printed constructs: Hydrogel constructs were imaged using optical microscopy (Nikon Ti-E fluorescent microscope) and scanning electron microscopy (Hitachi S4800 SEM). Square arrays and porous constructs were imaged at 1, 3 and 5 passes of each ink to assess the hydrogel microstructure and quality of the print.

Cell culture on cast pεK/GG constructs: Human corneal epithelial cells (HCE-Ts) and human corneal endothelial cells (HCEC-12s) were seeded onto cast hydrogels made with 20 wt % pεK and 0.35 wt % and 0.75 wt % GG. They were also seeded onto TCP as a positive control. The cells were cultured for 7 days and then fixed and stained with DAPI and Phalloidin to analyse their morphology.

Results and Discussion

Ink characterisation: Both 20 wt % pεK and 0.35 wt % GG showed rheological properties suitable for inkjet printing. The Z numbers (Z= 1/Oh) were equal to 9 and 5 respectively, which places them both in the ‘printable range’ of 1-14 [1,2].

Surface structure: Optical imaging of printed arrays showed a unique pattern formed in the hydrogel surface, where the instantaneous reaction of the polymers causes the formation of craters across the surface, Figure 1. This patterning was seen in all printed constructs, from 1 pass per ink up to 5 passes per ink. SEM imaging was done at high magnification on 1 and 5 passes of ink and the crater-like structure can also be seen here.

Porous structure: Optical microscopy and SEM demonstrated that porous circular structures could be printed based on bitmaps.
Cell culture: HCE-Ts formed a monolayer across the surface of the cast hydrogels with both wt % of GG, demonstrating cyto-compatibility of the hydrogels with corneal epithelial cells, Figure 2. HCEC-12s formed a monolayer across the surface of the lower wt % GG hydrogel but fewer cells attached to the surface of the 0.75 wt % GG variant. This suggests the relatively higher amount of the pεK is important to support the cell attachment.

Conclusion
We have shown that it is possible to print porous hydrogel constructs based on the natural polymers poly-ε-lysine and gellan gum using reactive inkjet printing methods. These hydrogels display a unique surface patterning due to the instantaneous reaction between poly-ε-lysine and gellan gum. Preliminary cell culture data on cast hydrogels with the same chemistry demonstrated that both corneal epithelial and endothelial cell lines formed a monolayer across the hydrogel surface, demonstrating the materials cyto-compatibility. Future work includes further characterisation of the printed construct, including physical and mechanical characterisation and further cyto-compatibility testing with human corneal cells.

3D Bioprinting in Self-Assembled Nanoparticles to Fabricate Microphysiological Systems for Tissue/Organ-On-A Chip Applications

Syeda M. Bakht¹,², Manuel Gomez-Florit¹,², Tara Lamers¹,², Milan Sixt¹,², Bárbara B. Mendes¹,², Rui L. Reis¹,², Rui M. A. Domingues¹,², Manuela E. Gomes¹,²

¹ I3Bs – Research Institute of Biomaterials, Biodegradable and Biomimetics, Guimarães, PT; ² ICVS/3B’s – PT Government Associate Laboratory, Braga/Guimarães, PT

Introduction
Organ/Tissue-on-chip have seen an emerging interest in developing biomimetic systems that emulate relevant physiological micro-environment of cells to understand physiological or pathological mechanisms. However, the majority of these systems are fabricated with polymeric materials lacking the ability to imitate cell-cell and cell-extracellular matrix (ECM) crosstalk prevailing in living organisms. These conventional miniaturized microfluidic devices not only require a cumbersome manufacturing process but also have complicated loading processes for cells and biomaterials, none have yet proven to be sufficiently efficient, feasible, or economical. Here, we present a unique strategy to efficiently produce 3D microfluidic fibrillar devices as a green alternative to conventional polymeric materials. The proposed system combines 3D printing of sacrificial/cell-laden inks with the controlled self-assembly of colloidal suspensions of cellulose nanocrystals (CNC) to form non-degradable and fibrillar hydrogel via ionic crosslinking in biocompatible conditions. This system allows the fabrication of complex and perfusable multicellular constructs with high resolution and can support their long-term culture. The transparent CNC fibrillar hydrogel has the capacity to withhold perfusable complex channels and chambers for dynamic culture, which make them ideal for 3D free-form bioprinting to fabricate microphysiological systems for tissue/organ-on-chip applications.

Experimental Methods
CNC fluid gel properties were optimized for matrix-assisted 3D printing to define the printability window by combining different CNC and crosslinking agent (Ca²⁺) concentrations. Characterization of CNC fluid gel viscoelastic properties were performed by rheometry. BioX 3D bioprinter (Cellink) was used to print cell-laden/sacrificial inks. Post printing, CNC fibrillar self-assembly was induced with excess of Ca²⁺ to create stable constructs with embedded 3D printed freeform structures and perfusable channels. To demonstrate the versatility of CNC as support material for embedded 3D printing/bioprinting, various ink hydrogels based on thermal, ionic, and photo-crosslinking were tested. The biocompatibility and stability of our fibrillar matrix for long-term in vitro maturation was evaluated using different types of cellular bioinks, cultured under static and/or dynamic conditions. Cellulase enzyme was used for CNC digestion and release of the biofabricated tissue models.

Results and Discussion
The ionically crosslinked CNC showed ideal shear-thinning and self-healing properties which lead to 3D printing with high precision and resolution. We were able to prove the potential of the biomimetic platform by efficiently printing the most commonly used bioink hydrogels and perfusable complex structures with distinct designs embedded in the CNC fibrillar hydrogel matrix. The optical transparency of the CNC makes them an ideal candidate for post-printing analysis, which is crucial for microfluidic applications. The fibrillar matrix of CNC allowed for diffusion of nutrients and cross-talk between cells in different compartments, which has been a major limitation of microfluidic chips fabricated with conventional polymeric materials such as poly(dimethylsiloxane) (PDMS). CNC matrix was bioorthogonally digested in culture conditions to successfully release the engineered tissue. The preliminary data highlight potential of the ionically crosslinked CNC for tissue/organ-on-chip applications in a simple and integrated single process which will be further investigated in further studies for disease modeling and drug screening.
Conclusion
The results indicate that controlled self-assembly of CNC combined with 3D printing can be a promising and green alternative to conventional polymeric materials and microfabrication technologies. This strategy enables the fabrication of complex and perfusable 3D channels with micro-scale precision in a fibrillar matrix that allows crosstalk between cultured cells. This biomimetic platform will not only allow biofabrication of perfusable channels and chambers for dynamic 3D cell culture and for physiological studies but also the direct bioprinting of freeform cellularized constructs with relevant clinical size within its own support bioreactor for in vitro tissue maturation.

*The symposium aims at introducing the fundamentals and new breakthroughs in the application of smart biomaterials in medicine. Recent advances of smart polymeric materials responsive to electricity, magnetic field, light, etc. will be approached. A particular attention will be moreover devoted to the exploitation of piezoelectric (nano)materials, for therapeutic and diagnostic purposes, and for tissue regeneration.*
Shape Memory Biomaterials and Their Applications

Jinlian Hu

City University of Hong Kong, Department of Biomedical Engineering, Hong Kong, CN

Shape memory polymers and their composites as biomaterials have received broad attention in various applications due to their unique advantages of stimuli responsive shape, displacement, strain and stress adaptiveness. With the advancement of knowledge, science and technology in materials design, fabrication and characterization, a wide variety of shape memory polymeric materials can be engineered for tissue regeneration, soft robotics, cellular manipulation, 4D printing, smart medical devices and minimally invasive implantation. The talk will first give a brief review on their recent progress in terms of cellular mechanisms, structural design and applications. Then the focus of the lecture will put on an innovative solvent-responsive coiling-expanding stent and their sister laminated structural materials.

Piezoelectric materials for biomedical applications: From tissue engineering to cancer nanomedicine

Gianni Ciofani

Istituto Italiano di Tecnologia, Smart Bio-Interfaces, Pontedera, IT

Electrical stimulation of cells and tissues is an important approach of interaction with living matter, which has been traditionally exploited in the clinical practice for a wide range of pathological conditions; standard methods of stimulation are, however, often invasive, being based on electrodes and wired connections. The possibility to achieve an indirect electrical stimulation, by means of piezoelectric materials, is therefore of outstanding interest for all the biomedical research, and it emerged in the latest decade as a most promising tool in many bioapplications [1].

The generation of small electric charges upon the application of mechanical stimuli to piezoelectric nanomaterials is a unique phenomenon in the context of remote stimulation of cells and tissues. Electrical cues are known to foster specific biological responses, and piezoelectric nanomaterials own the ability to act as real “nanotransducers”, thus allowing obtaining “wireless” and remote electric stimulation thanks to non-invasive excitation through mechanical sources (usually ultrasound or vibrations).

Piezoelectric nanomaterials are usually ceramic or polymeric, with piezoelectric nanoceramics typically showing higher piezoelectric features than polymers. Concerning piezoelectric polymers, poly(vinylidene difluoride) (PVDF) and its copolymers show the best piezoelectric features, and have been widely investigated to promote cell stimulation: some works of our group, for example, reported on PVDF-based nanocomposites for stimulation of neuronal [2] and bone [3] cells.

Finally, it is worth to mention the potentialities of piezoelectric stimulation of cancer cells. It is in fact well-known as low-intensity electric stimulation represents an alternative treatment able to affect cancer cells without the use of any drugs/chemicals, and to significantly enhance the effects of chemotherapy by reducing multidrug resistance. Recently, our group provided the first evidences of the efficacy of this antitumor approach mediated by piezoelectric barium titanate nanoparticles and ultrasound, respectively on breast cancer [4] and on glioblastoma multiforme [5] cells. Efforts are now focused on replacing inorganic and non-biodegradable ceramic materials with piezoelectric polymers (such as the aforementioned PVDF) exploitable in the clinical practice.

Graphene containing hydrogels as biocompatible materials towards self-powered electronic medical devices

Andreia T. Pereira1, Catia R.S. Rodrigues2, Ricardo Vidal1, João O. Ventura2, André M. Pereira2, Inês C. Gonçalves1

1 INEB/3S - Instituto de Engenharia Biomédica, Porto, PT; 2 IFIMUP – Instituto de Física de Materiais Avançados, Nanotecnologias e Fotónicas, Departamento de Física e Astronomia, Faculdade de Ciências, Universidade do Porto, 4169-007 Porto, Portugal, Porto, PT

Introduction
With the rise of the digital era, the Internet of Medical Things (IoMT), which establishes networks that exchange healthcare data between medical devices and people, through the use of biosensors, appears as the edge of the next breakthrough in the biomedical field. Moreover, electronic medical devices (EMD) such as pacemakers, left-ventricular assist devices (LVAD), and brain stimulators have been widely used to treat several diseases. To power supply the biosensors and these EMD, batteries are needed, but have several limitations such as the need for replacement, which frequently involves surgical procedures, their big size/weight, which limits devices miniaturization (specially for biosensors) and the risk of leakage of their content to surrounding tissue, which represents a hazard for patients [1]. Thus, to allow the "boom" of IoMT and improve the performance of electronic medical devices, there is a demand for an endless electrical energy source.

Triboelectric nanogenerators (TENG), reported for the first time in 2012, can convert mechanical energy into electricity by contact-separation or relative sliding between two materials with different triboelectric polarity, allowing scavenging mechanical energy from body movement, muscle contraction/relaxation, and cardiac/lung motions. However, most polymer-based TENG materials are not biocompatible, present limited performance when in the presence of body fluids and are still inefficient to supply EMD.

This work aims to give a step forward on this barrier by proposing as triboelectric nanogenerator an hemo/biocompatible FDA-approved hydrogel, poly(2-hydroxyethyl methacrylate) (pHEMA), which is characterized by its high water content (~60%). To tune the tribopolarity of pHEMA, we envisioned the use of graphene oxide aiming to reach materials with different tribopolarities.

Experimental Methods
GO was produced by modified Hummers’ method [2] and characterized regarding oxidation degree by X-Ray Photo Spectroscopy (XPS), surface topography by Scanning Electron Microscopy (SEM), and lateral size/charge by Zetasizer. pHEMA/GO composites were produced by in situ polymerization of 2-hydroxyethyl methacrylate and tetraethylene glycol dimethacrylate with different amounts of GO (0.6 – 27.5% v/v) [2]. The resulting composites were evaluated regarding their surface topography (SEM) and charge (Electro Kinetic Analyzer). The pHEMA/GO composites’ triboelectric polarity was measured in contact-separation mode towards PTFE (reference material with negative tribopolarity), being evaluated the generated voltage, current, and power density [4]. The storage capacity of produced energy in a capacitor of 1 µF was assessed [4]. Cytocompatibility of pHEMA/GO was evaluated accordingly to ISO 10993-5/12 by assessing the medium extracts’ cytotoxicity towards a human fibroblast cell line (HFF-1) during 24h.

Results and Discussion
The produced GO sheets contain 66% and 34% of carbon and oxygen atoms, respectively. GO has a lateral size of \( \sim 1.9 \mu m \), exhibits a wrinkled structure and presents a surface charge of \(-33.0 \pm 1.3 \text{ mV}\), characteristic of the graphene oxidized forms. When incorporated in pHEMA, GO increased the hydrogel's surface roughness, especially in the...
highest tested concentration (27.5% w/v). Besides this change in surface topography, pHEMA's surface charge increases within the amount of incorporated GO, ranging from -7.3 to 0.5 mV/cm².

Regarding the triboelectric outputs, in an open-circuit under contact-separation mode with PTFE the voltage varies in the range of 50-120 V and the maximum current reaches 1.5-3.0 µA with a maximum power of 0.15-1.38 W/m², even in a hydrated environment. Upon incorporation of 5% v/v GO, a plateau in the triboelectric outputs is achieved. All materials revealed the capacity to charge a capacitor of 1 µF, in 200 s, generating voltage between 0.3-1.5 V. Finally, the in vitro biocompatibility of the polymer composites was confirmed, as pHEMA/GO extracts are not cytotoxic towards human fibroblasts.

**Conclusion**

Incorporation of GO in pHEMA can tailor its tribopolarity, producing materials with different tribopolarity which could be used to assemble a TENG. The electricity generated using biomechanical movements between such materials is suitable to supply diversified implantable devices (~1 µW).

Towards Spatiotemporal Control of Biological Activity via Patterned Magnetic Hydrogels

1 University College Dublin, School of Chemistry, Dublin, IE; 2 Royal College of Surgeons in Ireland, Department of Chemistry, Dublin, IE; 3 University College Dublin, Conway Institute of Biomolecular and Biomedical Research, Dublin, IE; 4 University College Dublin, School of Physics, Dublin, IE

Introduction

Multifunctional nanocomposites which exhibit well-defined physical properties and encode spatio-temporally controlled responses (including changes of shape, microscopic morphology, mechanical strength and permeability) are emerging as components for advanced responsive systems. For instance in the case of biomedical applications magnetic nanocomposite materials have attracted significant attention due to their ability to respond to spatially and temporally varying magnetic fields changing their intrinsic structure, undergoing time-dependent deformations, or releasing cargo on demand.1-4

Experimental Methods

A combination of in-house built multi-head and commercial 3D printers was used to extrude selection of magnetic composite hydrogels. Magnetic nanoparticles were synthesised, stabilized and dispersed homogenously through the gels to optimise their hyperthermic responses. Oscillatory and rotational rheology measurements confirmed the viscoelastic properties providing ideal materials for 3D printing well-defined architectures with high fidelity for both magnetic and non-magnetic components of integrated multi-component builds. The nanocomposite inks showed complete shear- and temperature-recoverability/reversibility to their initial state, confirming that at particle concentrations that enable magnetic responses the necessary printability is not lost. Multiple complex structures were printed with high resolution (~150 mm) with independent magnetic and non-magnetic patterned components and these were shown to be reproducible and robust. Post-printing chemical crosslinking was used to retain long-term fidelity of the printed structures, whilst retaining magnetically responsive hyperthermic responses at low particle concentrations.

Results and Discussion

The combination of MNPs and established 3D printable polymeric hydrogel formulations can provide multifunctional and stimuli-responsive systems with spatial-, temporal- and dosage-controlled release properties. In our recent work towards bio-applications of magnetic hydrogels, we described spatiotemporal hyperthermic heating rules from spatially patterned magnetic hydrogels and demonstrated controllable release of dyes (Fig. 1).4,5 We also fabricated exemplar multi-component magnetically responsive structures and used high resolution in-situ IR thermography to confirm that the incorporated magnetic nanoparticles retain up to 100% of the original hyperthermic efficiency to provide spatial temperature gradients for cell stimulus and for stimulus-responsive timed delivery of biomolecules. Use of thermoresponsive control over hyperthermic release achieved by embedded selection of well-controlled microgels and nanogels made of poly(N-isopropylmethacrylamide) with chemically programmed volume temperature transitions at physiologically relevant range of 32 to 45°C will also be shown. The advantages of spatial patterning of thermally active components will be described in multiple biological scenarios, including timed monitoring of induced disease of kidney and cerebral organoids, chemotherapeutic cancer irradiation, as well as for controlled stem cell
differentiation. Applications of DC-magnetic fields to physical stimulation of patterned magnetic gels will also be presented.

Conclusion
The magnetic responsiveness of conventional magnetic materials and those magnetically manufactured; deformation, hyperthermia and combinations of these are described along with some of our recent developments including timed-automation of interventions into biological processes are briefly discussed.

Introduction
Shape memory polymers (SMPs) are materials capable of programmable shape changes, triggered by the exposure to an external stimulus [1]. Their smart response holds potential for the development of shape-shifting medical devices, e.g. self-expandable stents and dynamically active substrates for tissue engineering. Recently, the possibility to leverage the peculiarities of SMPs also for pharmaceutical applications was envisioned for site-specific delivery of active molecules inside the human body [2,3]. The shape memory effect of a pharmaceutical-grade polymer was proved to be useful for the prototyping of a gastroretentive drug delivery system (DDS), first by programming a temporary shape, which can be fitted inside commercially available capsules, and secondly, by exploiting the recovery of the permanent bulky shape (upon contact with simulated gastric fluid at 37°C) to achieve retention and controlled release of the conveyed drug [4]. The core aim of this work is to propose an experimental strategy, supported by a computational activity, to optimize the performance of this system in terms of the mechanical response and controlled release.

Experimental Methods
Formulations based on pharmaceutical-grade poly(vinyl alcohol) (PVA), glycerol and allopurinol, selected as drug tracer, were processed by fused deposition modeling (FDM) or by hot-melt extrusion. The extruded material was either cut in 50mm long rods or wrapped around specifically developed templates, while still hot, to obtain a permanent shape evaluated as gastroretentive (e.g. cylindrical or conical helix) [4]. Rods were spray coated with an ethanol-based 3:1 solution of Eudragit® RS:RL plasticized with 15% of triethyl citrate, and samples with different coating thickness were collected. Thermo-mechanical characteristics useful for the shape-memory effect were assessed by differential scanning calorimetry and dynamic mechanical analysis. Numerical analyses were performed in a finite element software (Abaqus) by using the generalized Maxwell model whose parameters were fitted from experimental thermo-mechanical data. Mechanical tests were carried out on dry and swollen specimens (i.e. upon immersion in water for 1, 4 and 6h) by using an electromechanical dynamometer under tensile conditions. The release performance was studied in a dissolution apparatus II (900 mL HCl 0.1 N, 37 ± 0.05 °C, 100 rpm), by assaying spectrophotometrically (λ = 251) fluid samples withdrawn at various time points (up to 24 h).

Results and Discussion
Helices and rod-shaped specimens based on a swellable/soluble hydrophilic SMP and containing a drug tracer were successfully obtained by FDM and hot-melt extrusion. Uncoated and coated rods were characterized for mechanical, shape memory and release properties. The coating was found to be fundamental in limiting the polymer swelling and consequently the drug release rate, which was reduced from 98% up to 8% after 6h. Similarly, after 6h of water immersion, the decrease in the mechanical properties was lower than that observed with uncoated ones. Interestingly, shape memory properties were found to be optimal regardless of the presence of the coating. Finally, the modeling activity provided useful guidelines for an efficient and time-saving design of shapes to be potentially...
used for self-expandable DDSs, by well predicting the shape changes occurring during isothermal recovery at body temperature, even in the case of samples with more complex geometries.

Conclusion
The results of this work confirm the possibility to employ PVA as base material for shape-changing DDSs towards 4D printing and propose a modeling approach and technological strategies to optimize their shape, mechanical properties and release performance. In fact, by employing thin coatings (less than 100μm thick) based on insoluble but permeable materials on samples, it was possible to fine-tune the release rate. Furthermore, coatings limit the water uptake and consequently the softening of the core polymer, thus modulating the reduction of mechanical properties over time, without significantly affecting the shape-memory kinetics.

Decoding the materiobiology: multiple roles of biomaterials in participating life activities

Changsheng Liu

China, Frontiers Science Center for Materiobiology and Dynamic Chemistry, Engineering Research Center for Biomedical Materials of the Ministry of Education, East China University of Science and Technology, Shanghai, CN

The repair and reconstruction of defected tissue is a difficult problem that modern medicine tries to resolve. Biomaterials are one of the important elements for tissue regeneration. After implantation, biomaterials will affect the immune response, behaviors of relevant cells and repairing process. Although the biological effects of materials are gradually being discovered, the current studies are still mainly focused on the characterization of the apparent state of materials and the evaluation of the final repair effect. There is a lack of systematic and detailed understanding of how implanted materials participate in the \textit{in vivo} microenvironment \cite{1}. These blind spots directly restrict the design of regenerative materials. Therefore, it is necessary to further decode the correlation between material properties and biological functions, and clarify the rules and relevant mechanisms of how materials influence on the biological functions of cells, tissues / organs and the whole organism at different levels.

Nanoscale control by materials of mesenchymal stem cells for identification of bioactive metabolites.

Matthew J. Dalby

University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB

Metabolites, or biological small molecules, are usually considered in identification of biomarkers. However, they can be used to drive cellular processes, such as stem cell differentiation. Use of complex media recipes to control stem cell differentiation add artefact to metabolomics experiments and so bioengineering approaches are attractive as they can drive different stem cell fates without changing what the cells are ‘fed’. We have developed metabolomics pipelines to identify bioactive metabolites that control mesenchymal stem cell (MSC) self-renewal and differentiation. We started this research avenue using peptide hydrogels with defined stiffnesses that could control MSC chondrogenesis and osteogenesis, identifying GP18:0 and cholesterol sulphate as bioactive metabolites¹. Next, using our nanovibrational bioreactor, the Nanokick², along with synthetic chemistry modification of hit metabolites, we focused on refining our putative osteospecific metabolite candidates to tune potency and specificity identifying fludrocortisone acetate. Finally, we have used nanotopography to control MSC self-renewal³ to identify respiration-link metabolites that drive the immunomodulatory phenotype of MSCs⁴; this is critical if we wish to grow large numbers of high quality MSCs for use as immunosuppressive therapies in transplant procedures.

Self-setting granules for bone repair

Wei Zhu¹, Wei Li², Sheng Cui³, Xisheng Weng¹, Häkan Engqvist⁴, Wei Xia⁴

¹ University of Tsinghua, Department of Orthopedics in Peking Union Medical College Hospital, Beijing, CN; ² South China University of Technology, School of Biology and Biological Engineering, Guangzhou, CN; ³ Nanjing Tech University, College of Materials Science and Engineering, Nanjing, CN; ⁴ Uppsala University, Department of Materials Science and Engineering, Uppsala, SE

Introduction
Bioactive ceramics have been widely studied and used in clinic, mainly for orthopaedics and dental repair. [1-2] Except for the materials from nature and animals, fully synthetic bioactive ceramic materials have shown their good performance, i.e. good biocompatibility, bioactivity, and bone repair and regeneration. [2-3] Among them, bone cements and porous scaffolds are popular choices. [4-5] For bone cement, the advantage is the injectibility, which can be used for minimized operation. However, generally, their porosity is relatively low and the pores are small, which is good for cell migration and bone growth. For porous scaffold, it’s the opposite. They have proper porosity and pores, but not injectable and generally are big. It will be attracting if we can combine the advantages of bone cement and porous scaffold. It is what we are aiming for in this study.

Experimental Methods
α-Calcium sulfate hemihydrate (α-CSH), magnesium oxide (MgO) and fumed silica (SiO2) were used. All materials were used as received without purification. Different ratios between α-CSH and (MgO+SiO2), 0 – 50wt%, were tested. The different powder/liquid ratios were also tested. The mixing paste was placed in a Teflon mould with holes (diameter: 0.5mm and 1mm). The granules were taken out after setting, following by a heat-treatment. The as-obtained granules were injected into the different mould to form porous scaffolds under wet conditions. Both granules and scaffolds were analysed by phase composition (XRD), morphology (SEM), compressive strength, degradation, ion release and changes of pH values of soaking medium. Cell studies were done by the toxicity, RNA extraction and RT-PCR. The in vivo study was done by using a modified femur defect model of New Zealand white rabbits. New bone growth and collagen expression were analysed after implantation for aiming months.

Results and Discussion
Calcium sulfate hemihydrate and amorphous magnesium silicate granules have been prepared. The granules can form porous scaffolds with different shapes. The pore size can be controlled by the size of granules. The formation of the scaffolds was induced by the surface reaction between CSH and water. The content of magnesium silicate in the granules will affect the mechanical strength and degradation. The small granules could be injected through a syringe for bone cement. Cell studies showed good biocompatibility and in vitro osteogenesis. The animal study presented better new bone formation compared with autologous bone chips.

Conclusion
A self-setting ceramic granule has been firstly fabricated with a dual setting system by using a reversible setting reaction of calcium sulfate. The new granules can form varied geometries of porous scaffolds by a simple setting process. The in vitro and in vivo studies show it’s bioactive and has good osteogenesis.

Introduction
Clinical application of injectable bone pastes has been increasing rapidly in recent decades because of their advantages including ease to adaptation into irregular-structured defects (e.g. absence of gaps between the host bone and the implanted filler) and injectability suitable to minimally invasive surgery. These advantages are widely advocated to reduce patient complications and health care costs. Moreover, injectable bone pastes have shown significant bone regeneration potential in many clinical conditions, such as the treatment of maxillofacial deformities and defects, certain indications of spinal fusion and augmentation of osteoporotic fractures. However, significant efforts have been expended towards exploring the optimal formulation of the bone pastes in recent years [1]. In this study, we successfully fabricated injectable bone pastes integrating biphasic calcium phosphate (BCP, HA:β-TCP=2:8) nanoparticles with phosphoserine(PS)-tethered generation 3 poly(ɛ-lysine) dendron (G3-K PS) as osteoinductive component. Furthermore, the incorporation of strontium (Sr) element into the BCP nanocrystals was also considered to minimize bone resorption.

Experimental Methods
The preparation of materials including BCP, SrBCP (with 15 mol% Ca⁺² replaced by Sr²⁺), BCPG3 (BCP in G3-K PS carrier) and SrBCPG3 (SrBCP in G3-K PS carrier) was adapted from previously optimized protocols on SrHA and HA/G3-K PS preparation [2]. G3-K PS semi-dendrimers were synthesized by a solid-phase peptide synthesis (Biotage Initiator) as previously reported [2]. Freeze-dried G3-K PS semi-dendrimers in ethanol solution (5 mg mL⁻¹) was added at 1% (w/w) to the above BCP or SrBCP slurry (Ca+Sr/P in the range of 1.53) under 200 rpm and 37 °C stirring until gelation occurred. The morphology and crystal size of the nanoparticles in the material paste were evaluated by transmission electron microscopy (TEM) analysis, meanwhile the phase composition was analyzed by X-ray diffraction (XRD). The handling properties of the pastes were analyzed on the basis of their injectability and moulding.

In vitro cell tests to assess the osteogenic potential of the synthesized biomaterials were performed using bone marrow stromal cells MSCs isolated from ovariectomized rats and the expression of specific gene markers (Runx2, ALP, Cxcl9, RANKL) at 1, 3 and 7 days of cell culture were analyzed by RT-PCR. Furthermore, to confirm the role of Cxcl9 and Sr ions in material induced osteogenesis, additional Cxcl9 protein (250 ng mL⁻¹) was introduced into the BCPG3 and SrBCP groups in culture medium, and Sr ions (3 mM) were introduced into the BCP and BCPG3 groups in cell culture medium. In vivo studies were performed using ovariectomized female Sprague Dawley rats and paste materials were gently injected into the drilled holes (3.0 mm in diameter and 4.0 mm in depth) by syringe. The rats were euthanized at week 12 post implantation and post-mortem analyses were performed. Several bone metabolic markers including P1NP, CTX-I and Cxcl9 were evaluated using ELISA assay. Moreover, Micro-CT was used to estimate trabecular density and architectural parameters within the defect, including bone mineral density (BMD), structural model index (SMI), trabecular number (Tb.N), trabecular thickness (Tb.Th) and trabecular separation (Tb.Sp). Immunohistochemistry analysis and scanning electron microscopy (SEM) observation were also performed.

Results and Discussion

Page 203 of 2028
In this study, an injectable bone paste material integrating BCP nanoparticles with G3-K PS carrier was successfully synthesized with or without the doping of Sr element into the BCP nanocrystals. Both in vitro and in vivo findings showed that the integration of G3-K PS would downregulate Cxcl9 gene and protein expressions to achieve an enhanced bone regeneration effect, with respect to a higher BMD and BV/TV (Fig.1A-D). Immunohistochemical staining of Cxcl9, Runx2 and RANKL proteins were conducted in the current study. The positive expression of Cxcl9 seemed to be less in BCPG3 and SrBCPG3 groups. Runx2 and RANKL positive expressions were more in BCPG3 group than others. The positive staining signals were further quantified in Fig. 1E. The result was in accordance with in vitro gene and protein expression and in vivo serum biomarker analysis. In this study, it is for the first time reported that the G3-K PS carrier could down-regulate Cxcl9 expression, as characterized by PCR, in vivo serum ELISA and immunohistochemical staining of implanted sample seem to consistently demonstrate. No additional benefit to osteoporotic bone regenerating ability of BCPG3 material was found with Sr incorporation.

Conclusion
The results indicated that the BCPG3 bone paste can become a high-performance bone filler in the treatment of osteoporotic bone defects.

Introduction

The overall aim of this study was to fabricate beads-on-a-string structures in order to make a simple model of the lymphatic system. The developed model could potentially help understanding disease pathologies that can not be investigated in patients suffering from the disease. Furthermore, the fabricated structure could aid in the development of new immunotherapies.

In this study, an alginate hydrogel was proposed for the fabrication of the knotted fibers. As the water-abundant extracellular matrix secreted by the cells can be recognized as a hydrogel, these materials are becoming more and more attractive in the field of tissue engineering [1]. In order to fabricate the specific beads-on-a-string structure (knotted fibers), the Plateau-Rayleigh Instability phenomenon was exploited.

Experimental Methods

In order to fabricate the beads-on-a-string structures, the Plateau-Rayleigh instability theory was explored during co-axial spinning of alginate. First, it was investigated if variations in flow rate and concentrations of the alginate shell had an effect on the created beads-on-a-string structure. Second, the platform was tested in terms of cell encapsulation and culturing. Here, eGFP-expressing mesenchymal stem cells (eGFP-MSC), human peripheral blood mononuclear cells (PBMC), and Jurkat cells were encapsulated in alginate hydrogel environments with varying concentrations (2\textsuperscript{\textdegree}, 3\textsuperscript{\textdegree} and 4\textsuperscript{\textdegree}, w/v). Subsequently, the cytotoxicity was evaluated using live/dead staining and an LDH assay. To study long-term culture, cell-laden beads-on-a-string structures were fabricated and cultured for 13 days. The cells and material structure were evaluated using microscopy. Finally, PBMC activation with and without encapsulation in the alginate material was investigated to assess IL2 secretion from the material. PBMCs isolated from a healthy donor were purified. After purification, the PBMCs were pre-activated using an anti-CD3 antibody (OKT3) followed by encapsulation in the alginate material. The activation was evaluated by IL-2 specific ELISA of culture medium.

Results and Discussion

The results from the structure characterization, show that the diameter of the fabricated beads increases with both flowrate and alginate concentration. From the LDH and live/dead staining, the results show that the material is non-toxic. After long-term culture of the cell-laden beads-on-a-string, the encapsulated cells survived and adapted to the hydrogel environment by spreading out; thereby, suggesting that the system is applicable for cell culturing. The activation study showed that PBMCs successfully secreted IL2 from both non-encapsulated and encapsulated cells, which could be detected in the cell media. These findings show that the PBMCs maintain their functionality after encapsulation, indicating that the system is suitable for immunological studies.

Conclusion

In conclusion, this work brings us one step closer to successfully fabricating artificial lymph vessels. However, further work and optimization are needed to reach the end goal of creating in vitro lymphatic systems.

Alternating Current Electrophoretic Deposition of Anti-infective DNase I Coatings on Polydopamine Activated Titanium Surfaces

Marie Van der Gucht, Rob Lavigne, Annabel Braem, Merve K. Aktan

1 KU Leuven, Department of Materials Engineering, Biomaterials and Tissue Engineering Research Group, Leuven, BE; 2 KU Leuven, Department of Biosystems, Laboratory of Gene Technology, Leuven, BE

Introduction
The difficult-to-treat nature of biofilms encourages researchers to develop strategies that allow preventing the formation of implant-associated biofilms rather than eradicate established biofilms. A promising approach is to inhibit biofilm growth indirectly by the degradation of extracellular DNA (eDNA) present in the matrix using an enzyme, such as deoxyribonuclease (DNase I). Here, we investigate the immobilization of DNase I on titanium (Ti) implant materials for a prolonged protection against biofilm formation at the implant surface. A schematic representation of the coating process is given in Fig. 1. In a first step, Ti surfaces were functionalized using dopamine (DA) chemistry which can enable permanent attachment of the enzyme. Next, PDA substrates are coupled as electrodes during AC-EPD for fast grafting in comparison to a classical diffusion methodology (i.e. simple dipping). After morphological and chemical characterization, the activity, release kinetics, and stability of both types of DNase I coatings were monitored in real-time. Furthermore, the activity of the coatings against Staphylococcus epidermidis (S. epidermidis) biofilm formation was evaluated.

Experimental Methods
Polished Ti substrates were functionalized by immersion in a DA solution (in Tris buffer). The resulting PDA-Ti substrates served as an electrode during AC-EPD or dip coating in a 0.0125 mg/ml DNase I aqueous suspension, a schematic representation of the EPD and dipping setup is shown in Figure 1. An unbalanced triangular AC-EPD signal was adjusted in order to couple the working electrode as an anode during the high-amplitude half cycle. After 10 min of AC-EPD resp. dip coating, samples were rinsed with Milli-Q to remove untethered DNase I followed by drying at room temperature. The coating’s surface morphology was investigated by means of atomic force microscopy (AFM). The thickness of coatings was evaluated using spectroscopic ellipsometry. Wettability and chemical composition of DNase I coatings were performed by contact angle measurements and by Fourier transform infrared spectroscopy (FTIR), respectively. Subsequently, the enzymatic activity of immobilized DNase I on PDA discs was evaluated using the quantitative DNase assay (qDNase assay, Fig. 1), as described previously. Furthermore, the release rate of DNase I molecules from the surface was monitored using qDNase assay. Moreover, the same assessment procedure was used to analyze AC-EPD and dip coatings shelf life (DNase I activity vs. time) at 4°C. Biofilm experiments were performed by adding a S. epidermidis suspension to each substrate followed by incubation at 37°C for 20 h. After gently washing, biofilms were fixed and examined qualitatively and quantitatively using SEM and confocal laser scanning microscopy (CLSM), respectively.

Results and Discussion
According to AFM, the roughness of polished Ti substrates, which initially appeared fairly smooth, increased with further treatment. The highest surface roughness was observed for AC-EPD DNase I in comparison to PDA-Ti and dipped DNase I coated surfaces. Whereas the wettability of pristine Ti increased after PDA activation, incorporation of DNase I resulted in reduced hydrophilicity. Coating thickness was approximately 5-fold higher for AC-EPD DNase I coatings in comparison to dipped DNase I coatings. This was also confirmed by FTIR analysis as the most prominent IR absorption amide I band was observed on AC-EPD coatings. Furthermore, the enzymatic activity of AC-EPD coatings was 3 times higher as compared to dipped coatings. The coating half-life for AC-EPD and dip DNase I coatings was evaluated.
coatings was estimated at 3 days of storage at 4°C, yet a significant activity could still be observed even after 7 days. Release tests, however, revealed that the majority of the AC-EPD coated enzymes were not covalently attached, but rather released from the surface in approximately 24 h. There was no activity observed on dip coating after 24h of release study. Finally, *S. epidermidis* biofilm formation was reduced more on AC-EPD DNase I coatings, as confirmed by SEM (Figure 2) and biofilm thickness observations conducted using CLSM.

**Conclusion**
A proof-of-concept is given for the use of AC-EPD as a fast grafting tool for the immobilization of DNase I on PDA-Ti implant surfaces. When compared to conventional dipping strategies, AC-EPD significantly improved the DNase I deposition yield, while the coating’s enzymatic activity was preserved for at least 7 days. Moreover, AC-EPD DNase I coatings effectively lowered biofilm formation on the Ti surface. Overall, AC-EPD DNase I coatings may hold a great potential to reduce biofilm formation on implant surfaces thereby increasing the success rates of such coated implants.

Development of surface treatment with artificial spider silk polymer nanofilm to improve cell adhesion

Masashi Fujiwara¹, Yutao Zhu³, Tomoyuki Koga⁴, Koji Yamamoto², Yusuke Morita²

¹ Doshisha University, Graduate School of Life and Medical Sciences, Kyoto, JP; ² Doshisha University, Department of Biomedical Engineering, Kyoto, JP; ³ Doshisha University, Graduate School of Science and Engineering, Kyoto, JP; ⁴ Doshisha University, Department of Molecular Chemistry and Biochemistry, Kyoto, JP

Introduction

Since implants such as artificial blood vessels applied for soft tissue are greatly deformed in the living body, flexibility and elasticity are required for the coating materials used for the implants to improve cell adhesion. It is also important not to impair the original surface microstructure of the implants. Spider silk has excellent biocompatibility, and we focused on nanofilm made from spider silk. The nanofilm has high flexibility and excellent self-adsorption property, and is expected to be applied to implants with various surface micro-structures. The purpose of this study was to develop the novel surface treatment method to enhance cell adhesion using an artificial spider silk polymer nanofilm.

Experimental Methods

Preparation of [(F8-PPG)] nanofilm: The peptide-multiblock polymer (F8-PPG) was prepared as an artificial spider silk polymer by the polyaddition of amine-terminated oligophenylalanine with poly(propylene glycol)(PPG) diisocyanate. 0.5, 1.0 and 2.0 wt% [(F8)-(PPG)] polymer solution were prepared by dissolving fluorescently labeled [(F8)-(PPG)] polymer in 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP). A silicon wafer covered with calcium alginate layer was prepared using a spin coater, and then the [(F8)-(PPG)] nanofilms were produced on the silicon wafer from the [(F8)-(PPG)] polymer solution using a spin coater. The [(F8)-(PPG)] nanofilm formed on the calcium alginate layer was removed by immersing it in sodium citrate buffer. The glass slides (20×20×1 mm) were covered with the [(F8)-(PPG)] nanofilm for different polymer concentration. The film thickness of the each [(F8)-(PPG)] nanofilm was measured with a stylus profiler.

Evaluation of self-adsorption of [(F8)-(PPG)] nanofilm: The PDMS plates (Figure 1 (a)) having a micropattern with a height of 20 μm and an interval of 100 μm were prepared as a substrate to evaluate self-adsorptivity of [(F8)-(PPG)] nanofilm to a microstructure. The [(F8)-(PPG)] nanofilms for each solution concentration were put on the PDMS plates. The fluorescence images of the coated surface of PDMS plates were acquired with a fluorescence microscope. Horizontal brightness distribution at the center of the fluorescence images were quantitatively evaluated by an image analysis software.

Evaluation of extension of [(F8)-(PPG)] nanofilm: The PDMS sheets (10×30×1 mm) (Figure 1. (c)) were prepared to evaluate extensibility of the [(F8)-(PPG)] nanofilm with substrate elongation. Central area (10×10 mm) of the PDMS sheets were coated with the [(F8)-(PPG)] nanofilm for each solution concentration. Tensile deformation was applied to each PDMS sheet covered with the [(F8)-(PPG)] nanofilms up to strain of 20% by the tensile device (Figure 1. (d)). The [(F8)-(PPG)] nanofilm on the PDMS sheets were observed with a fluorescence microscope at strains of 5, 10 and 20% to evaluate occurrence of cracks.

Results and Discussion

The film thicknesses of the [(F8)-PPG] nanofilms for solution concentrations of 0.5, 1.0 and 2.0 wt% were 198±48 nm, 243±59 nm and 346±39 nm, respectively. Figure 2 (a)~(c) shows a fluorescence image of a micropattern coated with nanofilm, and Fig.1 (d) shows horizontal brightness distribution at the center of fluorescence images. The [(F8)-(PPG)] nanofilms for all solution concentrations absorbed uniformly on the micropattern. When a strain of 10% was applied to a PDMS sheet coated with the [(F8)-(PPG)] nanofilm, cracks were observed on the [(F8)-(PPG)] nanofilms.
for solution concentrations of 0.5 and 1.0 wt%, but no cracks were observed the nanofilm for solution concentrations of 2.0 wt% up to strain of 20%. These results showed that the [F8]-PPG nanofilm with a solution concentration of 2.0 wt% showed uniform self-adsorption and good extensibility as the coating material. It was expected that [F8]-PPG nanofilm with a solution concentration of 2.0 wt% can be effective surface treatment to enhance cell adhesion without impairing the surface morphology.

Conclusion
We have developed a surface treatment with nanofilms of artificial spider silk polymers that which has excellent self-adsorption and extensibility.

Dual Keratinocyte-attachment and Anti-inflammatory Coatings for Permucosal Sealing of Dental Implants

Sunil K. Boda, Conrado Aparicio

University of Minnesota, Minneapolis, Minneapolis, US

Introduction

Unlike junctional epithelium attachment to teeth, permucosal sealing around dental implants is hindered by inflammation and epidermal down growth [1]. Previous research from our group showed that a combination of keratinocyte-specific and antimicrobial peptide coatings on titanium can promote soft tissue attachment and hinder bacterial colonization, respectively [2]. In the current work, we employ a dual coating on titanium made of a keratinocyte-specific peptide and a fatty acid with anti-inflammatory potential to promote oral epithelial tissue attachment around titanium implants. Taking cue from a previous study, we chose conjugated linoleic acid (CLA) to reduce inflammation triggered epidermal down growth [3]. For soft tissue attachment via the formation of hemidesmosomal structures by oral keratinocytes on dental implants, we tested two peptides; R3G3LamLG3 derived from Laminin 332, the major extracellular matrix component of the basement membrane in skin tissue and Netrin-1 capable of epithelial cell adhesion through α6β4 integrins [4].

In vitro hemidesmosome formation on modified titanium surfaces and modulation of inflammation was assessed using human oral keratinocytes and murine macrophages, respectively.

Experimental Methods

Finely polished titanium (pTi - grade II) discs of 6 mm diameter were either untreated or oxygen plasma (5% O₂, 95% Ar, medium intensity, 5 min) treated. Subsequently, the discs were coated with 1 mM Linoleic acid (LA) followed by coating with cationic peptides - R3G3LamLG3 and Netrin-1 at 1 mg/mL. The different coatings on pTi were characterized by x-ray photoelectron spectroscopy and water contact angle measurements. The proliferation and hemidesmosome formation of human oral keratinocytes (HOKs) were used to assess soft tissue attachment to modified titanium surfaces. Two hemidesmosomal marker proteins, Col XVII (BP180) and Integrin β-4 were evaluated by immunofluorescence microscopy and their expression was quantified by measuring the corrected total cell fluorescence (CTCF) using Image J software. For a favorable immunomodulation, conjugated Linoleic acid (CLA) coating was deployed to induce macrophage polarization from pro-inflammatory M1 to anti-inflammatory M2 phenotype in lipopolysaccharide (LPS) stimulated RAW 264.7 murine macrophages.

Results and Discussion

Consistent with a previous report on tuning the surface reactivity of anatase (TiO₂) on Ti foil to carboxylic acids [5], surface activation of titanium with oxygen plasma promoted the adsorption of LA as divulged by high resolution C1s XPS. Furthermore, XPS survey scan spectra revealed a significantly higher (1.3-1.5 times) recruitment of cationic peptides on plasma pre-treated LA coated surfaces in comparison to corresponding untreated LA coated ones. The proliferation of HOKs was greater on peptide coated pTi in comparison to uncoated or LA coated ones, irrespective of the plasma pre-treatment. This is consistent with earlier findings from own our group [2] and previous reports [5]. Further, both R3G3LamLG3 and Net-1 promoted hemidesmosome formation analyzed in terms of Integrin β-4 and Col XVII expression (CTCF) (Figure 1). Particularly, Integrin β-4 expression in HOKs was commensurate with the relative amounts (N 1s atom %) of peptide detected by XPS (Figure 2). With respect to inflammation, CLA adsorbed on pTi could reduce the induced nitric oxide synthase (iNOS) production; a pro-inflammatory cytokine generated in LPS stimulated murine macrophages, while promoting anti-inflammatory CD-206 expression.

Conclusion

Page 212 of 2028
Oxygen plasma treatment can be a facile approach for tethering small molecules/peptides on polished titanium without modifying surface topography. A dual keratinocyte-specific peptide and anti-inflammatory biomolecule coating on titanium may help promote permucosal sealing around dental implants. Such coatings may also help mitigate titanium allergy or hypersensitivity in patients.

Nanogrooved microdiscs and liquefied-core capsules as platforms for the development of vascularised bone tissue constructs

Isabel M. Bjørge1, Bárbara M. de Sousa2, Sónia G. Patrício1, A. Sofia Silva1, Liebert P. Nogueira3, Lúcia F. Santos1, Sandra I. Vieira2, Håvard J. Haugen3, Clara R. Correia1, João F. Mano1

Introduction

Cell behaviour and stromal cell differentiation into distinct lineages have been shown to be actively influenced by surface topography. Whereas this has been verified in a 2D context, the role of topography in 3D, which better mimics the natural cell environment, needs to be explored. To this end, we developed nanogrooved microdiscs (topodiscs) as substrates for a bottom-up cell-mediated 3D-construct fabrication and combined them with the technology to produce compartmentalised liquefied-core capsules. The liquid core is established upon mild liquefaction, enabling previously formed 3D aggregates of topodiscs and ASCs to serve as living support for freely dispersed HUVECs, via sequential seeding (figure: Project overview). The unique liquid core can be further exploited by employing dynamic culturing within standard spinner flasks, where each individual capsule is transformed into a microbioreactor. While topodiscs are expected to provide topographical cues to direct osteogenic differentiation of previously adhered ASCs, the resultant 3D aggregates will provide living domains for junctional intercellular communication with HUVECs. Our hypothesis is that by combining topographical cues with cell signalling pathways (e.g. connexin 43, a predominant gap junction protein between endothelial and osteogenic cells) and dynamic culturing, bone-like microtissues can be developed by a truly tissue engineering (TE) strategy and without requiring cell culture supplements. Such microtissues would present a close-to-native bone ultrastructure, thus presenting a mineralised and vascularised extracellular matrix.

Experimental Methods

Topodiscs were produced via nanoimprinting of spherical polycaprolactone microparticles between water-soluble polyvinyl alcohol counter-moulds of nanogrooved CD templates. This was performed at an optimised time, temperature, and pressure [1]. Spherical microparticles and smooth surface microdiscs were used as controls, replacing topodiscs in each experimental condition. ASCs-topodisc microaggregates with a controlled size were produced overnight using Aggrewell400 well plates. ASC-topodisc microaggregates and ECs were dispersed within the alginate core of a multilayered membrane encapsulation system, where straightforward core liquefaction enabled a sequential seeding. Each individual macrocapsule was enveloped by a 12-layered polyelectrolyte membrane composed of poly-L-lysine, alginate, and chitosan to both compartmentalise and maintain the liquefied core environment [2]. Encapsulated ASC-topodisc microaggregates were characterised and imaged upon fluorescent live/dead and F-actin/nuclei staining. ASCs and ECs were labelled with lipophilic fluorescent dyes to assess relative cell positioning and alignment. Furthermore, the osteogenic potential of the topodisc-capsule system composed of ASCs alone or ASCs co-cultured with ECs in both static and dynamic conditions was assessed up to 21 days. Construct pre-vascularisation was concurrently evaluated for co-cultures conditions.

Results and Discussion

Topodisc production via nanoimprinting led to a homogeneously nanogrooved surface topography. After 24h in culture, uniform ASC-topodisc microaggregates were formed, which were subsequently encapsulated within liquefied-core capsules, with or without ECs. Merging of several microaggregates into defined 3D constructs within
the liquefied-core capsules was observed for all conditions (figure: Highlighted results). Upon 21 days in culture, osteogenic differentiation was confirmed by the presence of osteopontin and hydroxyapatite for all conditions except for the ASC monoculture with spherical microparticles and smooth surface microdiscs, highlighting the importance of surface nanogrooves. The presence of angiogenesis marker von Willebrand factor and vascular markers laminin and podocalyxin in co-culture systems were indicative of construct pre-vascularisation.

**Conclusion**

Pre-vascularised, mineralised bone-like constructs were effectively achieved within compartmentalised liquefied-core capsules. The nanogrooved surface of topodiscs proved, in part, to be an impacting factor to induce osteogenic differentiation of ASCs. ASC-topodisc aggregates were demonstrated to be optimal supports for EC adhesion. As a next step, proteomic analysis of matrix vesicle content for dynamic co-culture conditions featuring either topodiscs or spherical microparticles will be performed to assess the up- and down-regulation of specific proteins related to osteogenesis, angiogenesis, and mechanotransduction pathways. We envision to propose the developed technology as a patient-specific bone TE strategy for minimally invasive procedures.

High resolution replica molding of naturally inspired surfaces to form polymeric nanostructured biomaterials

Susan Kelleher¹, James MCormack², Lucia Podhorska², Shauna Flynn¹

¹ Dublin City University, Dublin, IE; ² University College Dublin, Dublin, IE

Introduction
Many nanostructured surfaces have shown to display bactericidal properties as a result of surface topography alone. Moreover, the size and distribution of the surface features (on the nano- and micro scale) is known to influence the efficacy of the surface at inhibiting bacterial cell growth. The surface studies to date largely comprise of either natural surfaces e.g. the wings of a number of different species of insects, or of inorganic, hard materials e.g. structured silicon. However, reproducible and controlled production of nanoscale features on the surface of soft, polymeric biomaterials remains a challenge. Herein we present a series of replica molding experiments using a range of templates to produce PEG gels with upright nanopillars on the surface.

Experimental Methods
Our work uses two key templates for replica molding: 1) silicon nanoneedle arrays and 2) natural cicada wings. The silicon nanoneedles were fabricated using block copolymer micelle lithography. PS-b-P2VP was used to fabricate a monolayer of hexagonally arranged spherical micelles on silicon substrates. By controlling the loading of FeCl₃ into these micelles, monolayers of metal nanodots hard masks were deposited onto the silicon surface. These nanodots were then used as hard masks to produced plasma-etched silicon arrays in the nanoscale. Cicada wings were cleaned with acetone, and dried under a stream of nitrogen prior to replication. Replica molding of the templates was carried out using acrylate-terminated polypropylene glycol (PPG) and polyethylene glycol (PEG). Depending on the template, either a UV light/ UV-activated photoinitiator or white light/white light photoinitiator mix were used to cure the materials. A number of different molding method were used for the different templates, including drop casting and capillary-assisted molding. To study the surface nanostructures of the different molds, AFM, SEM, and FESEM were used.

Results and Discussion
Replica molding of the surface of cicada wings and nanostructured silicon in polymeric materials gave excellent results. Highly fluid short-chain prepolymers allowed for full coverage of nanoscale features, even with high aspect ratios. Our 2-step process produced a replica (primary mold) of both the silicon and cicada wing templates. This primary mold was then used to produce a replica (secondary mold). Our wide range of templates shows the diversity of our molding techniques. Using block copolymer patterning techniques, we have produced silicon templates which possess nanoneedles of controlled diameter (30-55 nm), pitch (95-330 nm) and height (45-100 nm). The subsequent replica molding process allowed us to produce these features in PEG with excellent retention of the original structure dimensions. Additionally, we have demonstrated direct molding from the wings of cicadas, which possess sub micron scale pillars (dimension range for different wings = diameter 164-1307 nm and height 182-1003 nm). We ultimately produced polymer replicas of the wings on this scale, which also have excellent retention of the template.

Conclusion
Replica molding is a reliable process for replicating topographical features down to the nanoscale. Polymeric nanoneedle arrays can be produced from silicon templates by combining block copolymer micelle lithography and replica molding techniques. Additionally, direct replica molding of cicada wings is possible using a very
straightforward 2-step process. Our process of replica molding for both natural wings and nanostructured silicon gives excellent replicas of the surface.

Introduction

Direct laser writing through two-photon polymerisation (2PP) can be employed to fabricate solid polymeric masters quickly and accurately from liquid polymer precursors on the nano- to microscale\textsuperscript{[1]}. Generation of reproducible positive moulds from these masters can then be achieved via the more traditional soft lithography technique of replica moulding\textsuperscript{[2]}. A wide variety of biocompatible polymers can be repeatedly moulded from the master negative, such as polyethylene glycol diacrylate (PEG-DA), polypropylene glycol diacrylate (PPG-DA) and polycaprolactone dimethacrylate (PCL-DMA).

Herein, this work specifically focusses on a novel blended polymeric system consisting of varying concentrations of PCL-DMA crosslinked with 1,6-hexanediol diacrylate (HDDA). Much of the focus of this work is on PCL, mainly due to two favourable properties - biodegradability and biocompatibility. The biodegradability characteristic associated with PCL derives from the ester bond found in each monomeric unit which has the capability to degrade in aqueous systems through hydrolysis\textsuperscript{[3]}. By optimising design, moulding and polymerisation protocols, and careful selection of the liquid polymer mixture, a wide variety of controllably degradable microstructures can be reproducibly achieved. In this work, the abbreviation of my university of study, 'UCD', has been incorporated into the polymeric microstructures by smart design of the laser printed master (Fig. 1). As such, this 'UCD' will be degraded in a controlled manner over time upon exposure to an alkaline environment. This degradation can then be monitored via imaging techniques and by mass loss calculations (Fig. 2).

Experimental Methods

Two-Photon Polymerisation of Pore Arrays: A commercial Direct Laser Writing apparatus (Photonic Professional, Nanoscribe Gmbh) was employed for pore fabrication. A single drop of the monomeric photoresist, IP-DIP (Nanoscribe) was deposited onto the centre of one side of the substrate before the holder was placed into the system prior to printing the 2PP array. The stereolithography structure file (stl) of the desired array of pores was loaded onto the software. For pore array fabrication, the laser power and scan speed were set to 15 mW and 6000 μm s\textsuperscript{-1}, respectively.

Replica Moulding: Replica moulding from 2PP master of pore arrays was carried out using PCL-DMA:HDDA blended solutions of varying concentrations. The monomeric cocktail was pipetted beneath a sealed cover glass and between two PDMS spacers until the space was filled. The solution was then cured under white light before being removed and inverted from the 2PP master.

Degradation Study: The degradation of the microstructures was performed in 5 M NaOH and was analysed by SEM. The study was monitored every 5 days for 25 days to try show sufficient degradation of the structures. The 3 polymeric cocktails studied in the process were neat HDDA, 1:9 PCL-DMA:HDDA and 1:4 PCL-DMA:HDDA. The degradation as mass loss was also investigated. Each sample (except 0 days) was immersed into distinct vials of 5 M NaOH (10 mL). After 5 days each sample was removed and rinsed with deionised water. The samples were then dried and weighed. This process of immersing and drying was repeated for 10, 15, 20 and 25 day timepoints. The mass loss percentage was calculated to give a more indicative value of the degradation as a percentage.

Results and Discussion

Page 219 of 2028
Fig. 1 shows the successful replica moulding from the 2PP pore array using 1:9 PCL-DMA:HDDA. Moulding using neat HDDA and 1:4 PCL-DMA:HDDA was also a reproducible success. The results of this work show that the microstructures depicting 'UCD' degrade in a controlled manner depending on the concentration of PCL-DMA used in the polymer cocktail. The greatest structural degradation is seen in the 1:4 (20 % PCL-DMA) samples, the next greatest in the 1:9 (10 % PCL-DMA) and the least in the neat HDDA (0 % PCL-DMA). This is evidence that the degradation that is occurring is due to the hydrolysis of the ester moieties within the polymer backbone of PCL-DMA. This hypothesis is supported by the data in Fig. 2 where the greatest decrease in mass is again seen in the 1:4 sample and the least in the neat HDDA sample. A study is currently underway to show the size-dependent release of fluorescent nanoparticles from the samples as the degradation of the microstructures progresses. Data for this will be obtained prior to the commencement of the conference.

**Conclusion**

This work shows that degradable materials can be accessed and used to fabricate degradable microstructures through the design of micro-scale printing technology in combination with the more conventional technique of replica moulding. This study demonstrates that SEM, mass loss analyses and release studies can be used to monitor the degradation by hydrolysis of the polymeric microstructures incorporated in this work.

Protein-Polyelectrolyte complexes as versatile building blocks for the surface immobilization of proteins in layer-by-layer assemblies

Cédric Vranckx¹, Olivier Cornu², Christine Dupont-Gillain¹

¹ Université catholique de Louvain, Institute of Condensed Matter and Nanosciences (IMCN), Louvain-la-Neuve, BE; ² Université catholique de Louvain, Institut de Recherche Expérimentale et Clinique (IREC), Louvain-la-Neuve, BE

Introduction
After three decades of innovation, layer-by-layer (LbL) assembly is now amongst the most used methods to create nanostructured coatings and materials. With the growing interest in surface biofunctionalization in numerous applications such as biomaterial design, biocatalysis, biosensing, drug delivery or tissue engineering, LbL has been used to immobilize biomacromolecules such as DNA, RNA, peptides and proteins. Actually, controlling protein immobilization at interfaces through electrostatic LbL assembly is largely recognized as challenging due to their polyampholyte nature, conformation-dependent activity, shape and anisotropic charge distribution. vander Straeten et al. demonstrated that it is possible to standardize lysozyme (Lyz) electrical properties through complexation with poly(styrenesulfonate) (PSS) as polyanion, and to incorporate such protein-polyelectrolyte complexes (PPCs) in multilayers by the LbL method using poly(allylamine hydrochloride) (PAH) as polycation. [1,2] However, while PPCs have shown great potential to facilitate protein LbL assembly, this has only been proven for one system and the versatility of the method has only been suggested.

The objective of this work is, firstly, to investigate whether PPCs can be used to immobilize a wide range of proteins, in combination with various polyelectrolytes (PEs) and, thereby, demonstrate the versatility of this method. Secondly, it aims at quantifying the amount of protein in the multilayer.

Experimental Methods
LL-37, Lyz, insulin (Ins) and glucose-oxidase (Gox) were chosen because they are involved in various biomedical and biotechnological applications, and their surface immobilization is topical. These proteins were first complexed with oppositely charged PE, i.e., PSS, alginate (Alg) and heparin (Hep). The resulting PPCs were then assembled with another PE, i.e., chitosan (Chi) and PAH to form [PE-PPCs] multilayers. First, PPCs formation was investigated by optical density measurements. Then, PPCs were integrated into multilayers. As a matter of comparison, the LbL assembly of bare protein with PE, i.e., classical LbL assembly was carried out. In the latter case, the PE used to complex the protein was alternately adsorbed with the bare protein molecule to form a multilayer. The multilayer growth was monitored using quartz-crystal microbalance with dissipation (QCM-D) (Figure 1). Finally, in the case of LL-37, bicinchoninic acid assays (BCA) allowed the quantification of LL-37 in the Chi‒PPCsLL-37‒Hep multilayer.

Results and Discussion
By combining the different proteins and PEs, 32 different self-assemblies were built. In order to better capture the mass difference, i.e., the improved protein adsorption when PPCs are used, the mass increase compared to classical LbL assembly was computed for each protein-PE combination. Results are presented in Figure 2 and show the mass increase in percent for each of the 16 protein-PE couples tested. For instance, the mass increase is 198 % for the Chi–PPCsLL-37–PSS system and up to 509 % for the PAH–PPCsGox–Hep. These results clearly demonstrate that a few hundred percent more protein can be immobilized using PPCs as the building blocks of the LbL assembly. Moreover, the quantification of LL-37 into the Chi–PPCsLL-37–Hep multilayer showed that the adsorbed quantity is linearly proportional to the number of adsorbed layers. For instance, after 25 bilayers, 5.2 µg*cm⁻² of LL-37 were adsorbed. These results are the first to demonstrate the versatility of PPCs for immobilizing proteins on surfaces.
The second parameter that can be extracted from the multilayer growth data is the magnitude of desorption upon PE adsorption. vander Straeten et al. have recently demonstrated that these PAH–PPCs$_{\text{Lys-PSS}}$ multilayers are highly dynamic self-assemblies, leading to the potential release of proteins.[3] However, this has only been demonstrated in one specific case. Our in-depth study determined that a desorption is almost systematically observed upon PAH adsorption and not with Chi. This is a very interesting result because it shows that depending on the PE used, it is possible to control the multilayer reorganization and thus the release of proteins, which has a strong interest in drug release studies.

**Conclusion**

Therefore, with the goal to immobilize proteins at surfaces, PPCs allow a better multilayer growth, ranging from two to four times more, compared to the use of bare proteins.

Very importantly, our approach establishes a way to circumvent the major issues related to LbL assembly of proteins, offering great versatility, in terms of protein and polyelectrolyte nature. It will therefore be beneficial to the many scientific communities willing to modify interfaces with proteins and other challenging biomacromolecules in an efficient manner.
Figure 2
Heat map representing the mass increase when PPCs are used compared to bare proteins. Results with PPCs are expressed in percent of the total mass adsorbed after the adsorption of a two bilayers cushion and five bilayers of PE and bare proteins.

Development of the Evaluation Method for the Material Properties of the Hydration Layer Formed on the Material Surface

Kyosuke Hatayama\textsuperscript{1}, Yusuke Morita\textsuperscript{2}, Koji Yamamoto\textsuperscript{2}

\textsuperscript{1} Doshisha University, Graduate School of Life and Medical Sciences, Kyoto, JP; \textsuperscript{2} Doshisha University, Department of Biomedical Engineering, Kyoto, JP

Introduction
The surface of articular cartilage shows superior lubricating properties owing to the expression of many molecules which possess a hydration function, such as lubricin, hyaluronic acid and highly sulphated proteoglycan. This molecular hydration ability has been applied to the surface modification to reduce the friction between implant device and living body, for instance, an artificial hip joint grafted with MPC polymer\textsuperscript{11}. Although the mechanical properties of these material surfaces are principally evaluated by using atomic force microscopy (AFM), it would be difficult to detect a mechanical characteristic attributed to the fluid-like flow generated in the hydrated layer, such as the Squeeze effect that can affect a decrease of friction in fluid lubrication. Since such effect depends on the size of the contact area and the approach speed of the indenter, we have developed a device that has a larger spherical probe (diameter: 1 mm) than AFM and measured the compressive resistance force generated by the hydrated layer. By applying a viscoelastic calculation model considering changes of the contact area, we estimated the material properties of the hydrated layer originated from its solid and liquid characteristics.

Experimental Methods
Measurement of the compressive resistance force: A slide glass grafted with polyethylene glycol (PEG) was used as a material having a hydration function, and all experiments were performed in PBS. Figure 1 shows a schematic drawing of the spherical stainless probe (diameter: 1 mm) of the indenter and the hydrated layer, and a magnified photo of the major components of the measurement part of the device. The compressive resistance force generated when the tip of the indenter approached to the hydrated layer was detected by measuring the displacement of the leaf spring. The approaching speed of the indenter was controlled by using a piezo-driven fine movement stage. All experiments were conducted under the conditions of approach speeds at 1.8 mm/s and 0.18 mm/s.

Identification of mechanical properties: We assumed that the hydrated layer consisted of PBS and PEG could be described by using multiple Voigt elements, and calculated the compressive resistance force using a calculation model considering changes of the contact area under the approach of the indenter. The viscoelastic property of the hydrated layer was evaluated by identifying the spring stiffness $k$ and the viscous property $c$, which represent material property values independent of the contact area.

Results and Discussion
Figure 2 shows the results of the compressive resistance force as a function of the displacement of the hydrated layer and the numerical calculation values simulated under the conditions of 1.8 mm/s and 0.18 mm/s. Viscous properties due to the difference of approaching speed could be detected in the same deformation of the hydrated layer and those depended on the contact area. From the calculation results considering changes of the contact area, the spring stiffness $k$ and the viscous property $c$ of the hydrated layer were successfully identified as $56.576 \times 10^{-9}$ N/m and $0.4949 \times 10^{-9}$ N·s/m$^2$.

Conclusion
We developed the device that can measure the compressive resistance force generated in the hydrated layer formed on the material surface and constructed the viscoelastic model to numerically calculate the force. It was found that by considering changes of the contact area, the material properties of the hydrated layer could be estimated.

Corneal endothelial tissue engineering using multi-layered polymer sheets

Jasper Delaey¹, Jasper Van Hoorick¹, Bert Van Den Bogerd², Carina Koppen², Peter Dubreuil¹, Sandra Van Vlierberghe¹

¹ Ghent University, Polymer Chemistry & Biomaterials group, Centre of Macromolecular Chemistry (CMAc), Department of Organic and Macromolecular Chemistry, Ghent, BE; ² University of Antwerp, Department of Ophthalmology, Visual Optics and Visual Rehabilitation, Faculty of Medicine and Health Sciences, Antwerp, BE

Introduction
Corneal endothelial damage and diseases are two of the major contributors to blindness or severe visual impairment worldwide [1]. The corneal endothelium is the innermost cell layer of the cornea and consists of a cellular monolayer that maintains the stroma in a dehydrated state through a “pump-and-leak” mechanism. A critical loss of cells due to damage, disease or aging leads to corneal edema which in turn results in opacification of the cornea [2]. Currently, the only treatment consists of a corneal transplantation from healthy cadaveric donor tissue. Unfortunately, only 1 donor is available for every 70 cases [3]. To tackle this shortage, the present work focusses on the development of transparent (>90%), thin (≤5µm), multilayered sheets constituting a poly(D,L-lactide) (PDLLA) layer to provide structural rigidity and a crosslinkable gelatin-based hydrogel as an extracellular matrix (ECM) mimic. These sheets provide a substrate for corneal endothelial cells (CECs) to enable subsequent ocular implantation thereby restoring the damaged endothelium and the patient's vision.[4] Additionally, we aim to scale up the production of these membranes to make them easily tunable in thickness, as well as increasing and facilitating their large scale-production possibilities by using doctor blading.

Experimental Methods
Multi-layered sheets (ø=12mm) were developed through successive spincoating steps. A sacrificial gelatin layer (H₂O, 10w/v%) was spincoated on a glass plate followed by a PDLLA layer (Corbion, PLURASORB 20, THF, 4w/w%). Next, a layer of gelatin-methacrylamide-amino-ethylmethacrylate (Gel-MA-AEMA) [5], was spincoated (H₂O, 10w/v%) as final layer, after applying an argon plasma treatment (0.8mbar, 30s) to the PDLLA. Finally, crosslinkable gelatin was crosslinked using UV-A (6 mW/cm², 30 min) irradiation. Isolation of the sheets occurred by dissolving the sacrificial layer (H₂O, 40°C). Sheets were characterized for their transparency (UV-VIS/NIR, 390-700 nm), thickness (white light interferometry) and glucose permeability (side-by-side diffusion setup,) as well as for their surface composition (XPS) and compatibility with CECs using B4G12 cells. Additionally, PDLLA and gelatin were doctor bladed and the relationship between processing parameters and film thickness was investigated.

Results and Discussion
Multi-layered sheets were successfully produced. The sheet thicknesses ranged between 0.8 and 1.5µm, thinner than the natural Descemet's membrane (10-20µm). All produced sheets showed a transparency of >98% (wet state, 380-700nm). The sheets were sufficiently permeable (>2.36*10⁻³ cm/s) towards glucose, both in the presence and absence of the gelatin-derived coating. Upon seeding the sheets with B4G12 CECs, the cells developed their characteristic shape. Immunocytochemical staining confirmed the presence of Na⁺/K⁺ ATPase pumps and tight junctions (ZO-1), indicating good cellular proliferation. Doctor-blading proved to be an effective method to scale-up membrane production as well as to easily tune membrane thickness (2-50 µm).

Conclusion
Transparent (>90%), thin (<10 µm), multi-layered sheets were successfully produced. These sheets were sufficiently permeable for glucose. Additionally, the sheets were able to support the proliferation of B4G12 CECs. Additionally,
for future large-scale production, doctor blading can be an effective method, allowing for less inter-sample variability by producing large membrane sheets at one time. On top of this, the technique allows for facile tuning of membrane thickness, opening up production of membranes for other ocular applications.

Production of multi-layered membranes
Multi-layered membranes are obtained through successive spincoating steps. In a first step, a sacrificial gelatin layer is spincoated. Next, a PDLLA-based layer is coated to provide structural integrity. Before coating the final layer, a plasma treatment is performed to ensure covalent attachment of the final layer. Last, the final, gelatin based, layer is coated. The membrane is the subjected to UV-A irradiation to crosslink the crosslinkable gelatin derivative. Finally, the membrane is isolated by dissolving the sacrificial layer in warm water.

Introduction
Cold atmospheric plasma (CAP) is a source of complex chemically reactive components, which can exert many biological effects on cells. Interestingly, this novel technology has been shown to selectively kill cancer cells without damaging the surrounding tissues. Thereby, it would enable an alternative anticancer therapy, while avoiding undesired side effects found in radio- and chemotherapy. Among all components present in CAP, it has been shown that the oxygen and nitrogen reactive species (RONS) have a major contribution to this selective cytotoxic effect [1]. Currently, the way to apply a plasma treatment on a patient is still challenging because most of the direct CAP treatments of the tumor area would involve surgery. Interestingly, many studies demonstrated that RONS can be transferred to liquids, which can exert very similar anticancer effects compared to direct CAP treatment [2]. However, the delivery of RONS through non-viscous liquids is fast and poorly controlled, thus reducing the efficacy of the treatment [3]. To ameliorate the delivery of RONS, it has been shown that CAP-treated biopolymer solutions with the ability to form hydrogels can enhance the generation, storage, and release of RONS, resulting in an ideal approach for indirect CAP treatment of tumors [4]. Based on these findings, this work aims to explore the capacity of alginate-based formulations for generating and releasing RONS as a potential therapeutic approach in osteosarcoma cancer.

Experimental Methods
Sodium alginate (Panreac), was dissolved in distilled water at a concentration of 0.25%. The salt Na$_2$HPO$_4$ (Fluka) was added at different concentrations (100, 125, 150, 175, and 200 mM) to delay the gelation process, thereby obtaining an injectable formulation that solidifies in situ. The formulations were studied by oscillatory measurements in a rheometer (TA instruments) to determine the gelation time. To produce the plasma-treated hydrogels (PTH), 1 mL of 0.25% alginate was placed under the kINPen® plasma jet at 1sL/min gas flow and a distance of 10 mm. Plasma treatment times between 15s-5min were investigated. Afterward, 1mL of plasma-treated alginate was mixed with 50µL of 2.44M CaSO$_4$ (Merck) and 50µL of 125mM Na$_2$HPO$_4$ to trigger the crosslinking reaction. Finally, 200µL of PTH were poured onto MG-63 human osteosarcoma cells (ATCC). Then, the metabolic activity (Prestoblue™, ThermoFisher Scientific) and the cell viability (LIVE/DEAD™, ThermoFisher Scientific) were evaluated after 24 and 72h.

Results and Discussion
Regarding the formulation, results indicated that increasing Na$_2$HPO$_4$ concentration increases gelation time from 3 to 25 min. 125mM Na$_2$HPO$_4$ was selected for subsequent experiments since it showed a gelation time of 10min, which allowed easy handling of the hydrogel while providing feasible gelation time to work with cells. On the other hand, results demonstrated that plasma-treated alginate hydrogels can exert cytotoxic effects on MG-63 cells in a RONS-concentration dependent manner. A significant reduction was observed in the metabolic activity by the exposition of the cells to plasma-treated hydrogels as a function of plasma treatment time (Figure 1A). Short plasma treatment times did not affect cells, but from 1 min treatment on, a progressive cytotoxic effect was observed up to 5 min of plasma treatment. These results correlated with the live/dead staining (Figure 1B), where the number of viable...
cells (in green) decreased when increasing the plasma treatment time, showing the lowest number of viable cells in the 5 min plasma treatment condition.

**Conclusion**

The results obtained in the present work indicate that plasma-treated alginate hydrogels can be easily manipulated and injected in the desired location and, more importantly, that such hydrogels have a cytotoxic effect on MG-63 human osteosarcoma cells in a RONS-concentration dependent manner. Therefore, these results open the door for the use of alginate-based formulations as injectable RONS delivery systems in CAP-associated therapies for osteosarcoma treatment.

Introduction

Mandibular osteoradionecrosis (ORN) appears in 10% of patients after radiation therapy for ENT cancer treatment. For bone defects larger than 2 cm, the only existing treatment is major surgery with strong handicap for the patient. To the best of our knowledge, no synthetic bone substitute material is actually available to promote bone regeneration for ORN. In this context, the recent bone tissue engineering advances lead to the development of 3D porous scaffolds allowing cells colonization and growth [1]. The ideal scaffold suitable for ORN should be i) highly porous (volume, size), ii) bioreabsorbable with a controllable degradation rate, iii) antibacterial in order to limit infections and iv) bioactive to stimulate new bone formation and angiogenesis. Consequently, the aim of this work is to develop new macroporous organic/inorganic nanocomposite scaffolds respecting those criteria. Their preparation combines an innovative “bricks and mortar” strategy with the freeze casting process [2]. Indeed, these composites are based on biodegradable customized polymer (poly(D,L-lactide) (PDLLA), the “mortar”) grafted on Cu-doped silicate-based bioactive glass nanoparticles (BGN) (“bricks”) to improve both mechanical properties and tissue regeneration.

Experimental Methods

Binary SiO2-CaO BGN with and without Cu-doping were synthesized using Stöber-derived methods. Hybrid nanoparticles were obtained using a “grafting onto” strategy, leading to PDLLA-covalently functionalized BGN. Suspensions of those hybrid nanoparticles was then freeze casted to obtain a macroporous scaffold with a controlled continuous and anisotropic porosity. Physico-chemical (composition, structure), mechanical, in vitro (cytocompatibility and antibacterial tests on S. aureus and E. coli), and in vivo (biocompatibility and osteoconductivity after implantation in rat calvaria) properties were characterized.

Results and Discussion

Characterization of BGN (TEM, SSNMR, ICP-AES) highlighted the influence of synthesis condition (pH, order of reagent addition) on their final shape, diameter, composition and particularly Ca and Cu spatial location and insertion in the glass network. Thereafter well-defined PDLLA chains were successfully grafted onto BGN surface and the resulting hybrid particles fully described (SEM, DLS/zeta-potential, TGA and FTIR), in particular quantifying the amount of grafted polymer [3]. We demonstrated that the freeze casting process parameters such as temperature gradient) and/or suspension composition such as fillers rate strongly affect the final scaffold porosity and thus mechanical properties (SEM, X-ray μ-tomography, compression tests). In vitro biological study showed that SiO2-CaO BGN-PDLLA composite scaffolds were non cytotoxic for primary human fibroblasts culture. Unexpected results from both cytotoxicity and bacterial tests on Cu-doped materials demonstrated the prominence step of copper incorporation within bioglass network. Finally, in vivo implantations and the resulting cell colonization of pores emphasized the potential of these biomaterials.

Conclusion
All together these results validated for the first time that the “bricks and mortar” approach combined with the freeze-casting process is relevant to obtain scaffolds for bone substitution and that such macroporous nanocomposites are promising candidates for the treatment of ORN.

Building on established technology is no guarantee for success: challenges with the in vivo evaluation of an osteochondral implant based on a proven bone component

Florence Abinzano¹, Pawena Diloksumpan², Mylène de Ruijter¹, Anneloes Mensinga¹,², Saskia Plomp², Ilyas Khan³, Harold Brommer², Ineke Smit², Miguel Dias Castilho¹, Rene van Weeren², Jos Malda¹,², Riccardo Levato¹,²

Introduction
Articular cartilage defects remain a major challenge, as they will not heal naturally and often lead to the development of osteoarthritis. There are still no long-term regenerative options, with currently available treatments leading to fibrous repair tissue of insufficient quality. Implant-based approaches have shown promise, yet the fixation of the constructs is problematic.¹ Preculturing the construct prior to implantation, generating cartilage-like matrix production, might lead to improved repair tissue. The aim of this study was to evaluate the long term performance of a precultured, integrated osteochondral implant in an orthotopic equine model, based on a previously tested bone component.

Experimental Methods
The construct consisted of a 3D printed low-temperature setting bioceramic bone anchor which was firmly integrated to a cartilage-mimetic compartment. This cartilage zone consisted of a melt-electrowritten reinforcing polycaprolactone (PCL) mesh,² with articular cartilage-resident progenitor cells (ACPCs) seeded on top of it (Figure 1). As a control, implants without cells were used. The bone anchor had been previously shown to induce osteoregeneration when implanted in vivo into the hip bone (tuber coxae) of warmblood horses.³ To maximize cartilage matrix production before implantation, the constructs were precultured for 28 days supplementing the media with bone morphogenetic protein-9 (BMP-9).⁴ A cell-laden construct was press-fit implanted into surgically created defect site in the stifle joint of Shetland ponies, while a cell-free implant in the contralateral joint (n=8). Healing was monitored for 6 months non-invasively through radiographic examinations and quantitative gait analysis, after which the animals were humanely euthanized. After termination, implants were harvested and micro-computer tomography scans, mechanical analysis, biochemical analysis and histological examination were performed to assess functional outcomes.

Results and Discussion
In vitro maturation of the constructs prior to implantation resulted in abundant extracellular matrix production, rich in glycosaminoglycans (GAGs) and type II collagen (Figure 2.1), and low in type I collagen. During press-fit implantation, minor imperfections of the contours of the printed bone compartment lead to fragmentation of the edges of the brittle bioceramic scaffold. Gait analysis and radiographic examinations showed no clinical signs of lameness and no differences between cell-laden and cell-free constructs in terms of gait profile parameters (stride duration, head, pelvis and joint range of motion). Six months after implantation, fibrous tissue was found in all the defects, with no mechanical differences between the cell-laden and cell-free controls. Histological and biochemical analyses showed a remodelled matrix resembling fibrocartilage, with minimal amounts of GAGs and type II collagen present in the chondral region for both cell-laden and cell-free implants (Figure 2.2). The PCL meshes within the chondral compartment were still traceable in histological images. Quantitative micro-computed tomography showed collapse
of the bone anchor, low volume of mineralized neo-bone formation and minimal integration to the surrounding tissue, with no differences between cell-laden and cell-free implants (Figure 2.3).

Conclusion

It was concluded that the failure of the bone component of the integrated implant, resulting in the loss of mechanical support and improper fixation, strongly affected the overall outcome, hindering the evaluation of BMP-9 stimulated articular cartilage progenitor cells for \textit{in vivo} cartilage repair. Minor differences in the implant and the change in testing location, from the non-loading tuber coxae to the loading stifle joint, lead to completely different results. This outcome stresses the need of carrying out \textit{in vivo} pilot studies under exactly the same conditions before moving into a larger \textit{in vivo} study.

Development of biomimetic composites of PVA with Kevlar nanofibers, with superior tribomechanical properties

Andreia S. Oliveira¹,²,³, Rogério Colaço², Ana P. Serro¹,³, Nicholas A. Kotov⁴,⁵,⁶

¹ Instituto Superior Técnico, Universidade de Lisboa, Centro de Química Estrutural, Lisbon, PT; ² Instituto Superior Técnico, Universidade de Lisboa, Instituto de Engenharia Mecânica, Lisbon, PT; ³ Instituto Universitário Egas Moniz, Centro de Investigação Interdisciplinar Egas Moniz, Caparica, PT; ⁴ University of Michigan, Department of Chemical Engineering, Michigan, US; ⁵ University of Michigan, Biointerfaces Institute, Michigan, US; ⁶ University of Michigan, Department of Materials Science and Engineering, Michigan, US

Introduction
Aramid (poly(p-phenylene terephthalamide)) fibers, commercially known as Kevlar, are a class of organic materials with outstanding properties, such as mechanical robustness and thermal stability [1]. These fibers have been widely used to reinforce other polymers, improving their stiffness and strength. Recently, it has been shown that a nanoscale version of Kevlar - aramid nanofibers (ANFs) synthesized from their macroscale fabrics and yarns - can effectively reinforce polyvinyl alcohol (PVA) for the replacement of cartilage tissues, due to their proven biocompatibility and exceptional mechanical properties [2]. In this work, we prepare PVA+ANF composites under different conditions, to identify which production method can generate materials with superior mechanical and tribological performance, without compromising their water-retention ability, relevant in the mimicking of the natural tissues.

Experimental Methods
PVA (Mw146000–186000 Da) was dissolved in dimethyl sulfoxide (DMSO) (15% m/v), water (15% m/v), or trifluoroacetic acid (TFA) (7.5% m/v). Bulk Kevlar K29 (TEX 69) was used to obtain ANF solutions (2% m/v), which were also prepared in three different solvents: DMSO in the presence of potassium hydroxide [3]; water, pre-submitting the ANFs to a hydrothermal treatment under acidic conditions [4]; and a mixture of TFA and methanesulfonic acid (MSA) in a volumetric ratio of 4:1. Three different hydrogels (H-D, H-W and H-T) resulted from the combination of PVA:ANF solutions in a ratio of 10:1 (w/w), prepared in common solvents. The mixtures were poured into flat molds, cooled to room temperature, and dried at 40 ºC until reach a constant weight. Samples H-D and H-T were submerged in water for 3 days to solvent-exchange, before being put to dry. Then, the materials were washed in water and stored hydrated.

The nanofibers resultant from the ANF solutions were analyzed by scanning electron microscopy (SEM, JEOL JSM-7001F). The tert-butyl alcohol freeze-drying method [5] was applied to ANF samples prior to imaging. Hydrogels were characterized concerning their equilibrium water content, by comparing the hydrated weight of the materials with their dry weight. The mechanical performance was assessed through uniaxial tensile (0.5 mm/s) and unconfined compression (0.1 mm/s) tests, carried out in a texturometer (TA.XT Express Texture Analyzer, Stable Micro Systems). The friction coefficient of samples against 316L stainless steel (Ø6 mm balls), was measured in a pin-on-disk tribometer (TRB³, Anton Paar), in reciprocal linear mode, with loads of 5 and 20 N, using phosphate-buffered saline solution as lubricant.

Results and Discussion
SEM micrographs of ANF samples prepared in DMSO (ANFD), TFA/MSA (ANFTM), or hydrolysed with acid (ANFH) are displayed in Figure1. The images show the microscale morphology of ANFs, in which the nanofibers form a highly interconnected network.

The values of equilibrium water content (EWC) of PVA-ANF composites did not vary between H-D and H-W (≈61-63%) but were increased for H-T (≈68%).
The composites prepared in DMSO showed a maximum tensile strain of ≈258%, and ultimate tensile strength and elastic modulus of ≈4 MPa. In response to compression, these materials were the most rigid, presenting a modulus of ≈3 MPa. With regard to H-W samples, these hydrogels demonstrated an excellent improvement in tensile tests, revealing an elongation-to-break of ≈409% and ultimate strength of ≈9 MPa. This improvement may be explained by the increase in hydrogen bonding between PVA and ANF, caused by the acidic hydrothermal treatment, which led to the breakdown of amino bonds in the ANF chains, thus providing more available sites (–NH₂ and –COOH) to react with other functional groups [4]. H-T samples had the lowest mechanical strength and modulus, both in tensile and compression. In these composites, the increase in the water content and the reduction of the mechanical performance, suggest a decrease in hydrogen bonding between the forming polymers, resulting in a more porous and weakened structure.

Concerning tribological behaviour, the coefficient of friction (CoF) values of all composites were low and similar (≈0.07) when 5 N of force was applied. For 20 N, the CoF was 1.2x and 1.6x higher for H-D and H-T respectively, in comparison to H-W (≈0.09).

**Conclusion**

Our results indicated that the properties of PVA+ANF composites are dependent on the preparation method. ANF materials made from corresponding hydrogels, prepared in water (H-W) had an improved mechanical and tribological performance, without compromising their water-retention ability. The unique combination of properties should be attributed to the establishment of dense networks of hydrogen bonding interactions between the PVA and nanofibers.

Bioactive membranes for the treatment of osteoporosis-related fractures

Lúcia F. Santos, Ana S. Silva, Sara Nadine, Clara R. Correia, João F. Mano

University of Aveiro, CICECO - Aveiro Institute of Materials, Aveiro, PT

Introduction

Fragility fractures are a main consequence of osteoporosis, a major public health problematic whose treatment remains a challenge in the orthopaedic field. Recent evidence have demonstrated that an impaired periosteal activity is responsible for recurrent fractures. Thus, bone tissue engineering strategies focusing on periosteum repair may represent a promising approach to treat the fragility fractures occurring in osteoporotic people. We suggest the development of a natural-based regenerative membrane able to mechanically fix biological active capsules for bone regeneration. For that, we propose a micropatterned laminarin hydrogel composed of spaced micropillars that can act as on-site fixing agent for the biological active capsules, with suitable mechanical properties and adequate resorbable times for the regeneration of the injury. We expected that such device could be implanted by wrapping the membrane around the defect and guide bone regeneration.

Experimental Methods

Liquified capsules were produced by well-established procedures in the group,[1,2] comprising i) polycaprolactone microparticles for cell adhesion and ii) a rich cell niche of human adipose stem cells (hASCs) and human umbilical vein endothelial cells (HUVECs). Cells and microparticles were resuspended in a low viscosity sodium alginate solution and then, alginate microgels (capsules) were produced by electrohydrodynamic spraying using calcium chloride solution as a crosslinking bath. Lastly, layer-by-layer was performed using 3 different polyelectrolytes (chitosan, alginate and poly-L-lysine) and the process was repeated until a 10-layered membrane was created. Methacryloyl laminarin (MeLam) hydrogels composed by spaced micropillars were obtained by bringing a solution of MeLam in contact with an optimized PDMS master,[3] previously treated with plasma. The mold was exposed to UV irradiation during 10 min at 1.2 W/cm². Capsules with optimized sizes were entrapped within the micropillars of the MeLam hydrogels. To avoid the rupture of the capsules, the liquefied core was only obtained after capsules’ entrapment within the laminarin-based membrane, by chelation with ethylenediaminetetraacetic acid solution (EDTA). Since the periosteum is highly rich in fibroblasts, the bioactive membrane as placed in contact with a 2D bed of fibroblasts, to in vitro mimic the natural environment of the periosteum. The characterization of the capsules and membranes, the in vitro osteo- and angiogenic potential was also accessed for the individual components (membranes and capsules) and after their conjugation (membrane + capsules).

Results and Discussion

A MeLam micropatterned hydrogel with spaced micropillars was fabricated by soft lithography with pillars’ height of 300µm and a micropillars’ space of 160µm. As previously reported by the group, the maximum entrapment efficiency was obtained by matching the diameter of the micro-objects and the micropillars spacing.[3] In this sense, liquified capsules (containing cells and microparticles) were obtained with approximately 160 μm of diameter and were successfully entrapped within the laminarin membrane. After confirming the cell viability and proliferation for the individual components (membranes and capsules), the bioactive membrane (laminarin micropatterned hydrogel + capsules) was placed in contact with a 2D bed of fibroblasts during 21 days of culture to mimic the natural fibroblast environment of the periosteum. The results showed that the capsules were released from the membranes in the first days of culture and also incorporated the fibroblast cell layer. The osteogenesis of stem cells in our system was also demonstrated after 21 days of culture with the presence of osteogenic markers like osteopontin.
Conclusion
A bioinspired and natural-based membrane was microfabricated to accommodate bioactive capsules for periosteum regeneration purposes. The bioactive membrane is expected to induce regional bone formation and an overall stimulation of bone regeneration.

Introduction
The role of a biomaterial in osteogenesis is to act as a matrix for cell proliferation, osteogenic differentiation, and extracellular matrix formation, therefore facilitating the process of bone regeneration. The repair of critical-sized bone defects using tissue engineering approaches has been previously shown to be effective. Nano-hydroxyapatite (nano-HA) is the major mineral component of bone and part of the calcium phosphate family. Consequently, it is highly biocompatible, osteoconductive and forms strong bonds with native bone, making it an excellent candidate for use in bone tissue engineering [1].

Experimental Methods
Pure nano-HA in a powder and paste form, as well as substituted nano-HA with 50% and 100% Sr, were produced by wet chemical precipitation in the NETmix® reactor (FLUIDINOVA S.A.) using calcium, strontium and phosphorous salts as starting materials. Each material was suspended to a final concentration of 0.25% v/v against both pre-osteoblastic MC3T3-E1 cells and Peripheral Blood Mononuclear Cells (PBMCs). The latter have the ability to differentiate into fully formed osteoclasts with the use of macrophage stimulating factor (M-CSF) and receptor activator of nuclear factor kappa-B ligand (RANKL). Cytotoxicity of the materials was investigated in pre-osteoblasts using the PrestoBlue™ assay. Alkaline phosphatase (ALP) indicating osteoblast differentiation was determined using an enzymatic activity assay. Total soluble collagen secretion in the culture medium and calcium biomineralization were assessed in order to evaluate the formation of extracellular matrix. Gene expression of the osteogenesis-related markers ALP, Coll1-a1, osteonectin, osteopontin and osteocalcin was investigated by means of quantitative real time polymerase chain reaction (qPCR). Moreover, qPCR was performed to evaluate the osteoclastogenesis-related markers DC-STAMP, NFATC1, OSCAR and TRAP. Tissue culture treated polystyrene (TCPS) was used as control surface.

Results and Discussion
All nano-HA materials tested are not cytotoxic, show high cell viability and present a higher ALP activity on days 3 and 7 compared to the control, with the 50% Sr-containing nano-HA showing a significant increase. Calcium mineralization was higher on all materials compared to the control after 7 days in culture. Collagen secretion was high in all nano-HA materials, with the powder showing significantly higher values after 14 days. Gene expression levels of osteocalcin with the nano-HA materials were higher compared to the control after 14 days of incubation. As osteocalcin is produced by osteoblasts as a late marker of osteogenesis, we conclude that all nano-HA materials induce osteoblastic formation after 14 days of culture. Finally, the expression of the osteoclastogenesis related markers that did not show any significant differences compared to the TCPS control. Therefore, these results demonstrate that nano-HAs are promising materials for bone tissue formation.

Conclusion
The different compositions of nano-HA materials that were investigated displayed an excellent biocompatibility, significant cell adhesion and a high capacity of pre-osteoblastic cells for proliferation and osteogenic differentiation.
These data suggest that all types of the nano-HA materials have high osteogenic and low osteoclastogenic potential, rendering them promising for therapeutic approaches against osteoporotic pathological conditions.

**Introduction**

Osteoarthritis (OA) is a degenerative pathology with a global prevalence of 22.9% in individuals aged 40 [1], which leads to significant impaired of the quality of life and disabilities. The main features of OA are the complex interplay of inflammatory processes associated with the synovial membrane, articular cartilage (AC) degradation and remodelling of the subchondral bone (SB) [2]. Furthermore, during the OA pathogenesis, there is an increase in the catabolic protein’s expression by synoviocytes, chondrocytes and mononuclear cells, followed by action of stimuli such as cytokines or chemokine[3]. Although, several studies have been carried on deepening the knowledge on the onset of OA and its treatment, there are still uncertainties about a long-term surgical treatment for OA joints [4]. Our work aimed to develop an engineered in vitro model of healthy and osteoarthritic osteochondral human tissues (composed by subchondral bone and deep layer of AC) in order to increase our understanding on physiology, biology, and progression of OA diseases. The findings of this work could advance the understanding of the fundamental mechanisms underlying OA as a key tool for testing new therapeutic options that could be employed in the medical management of the disease.

**Experimental Methods**

For the SB layer, a polylactic acid (PLA) porous trabecular-like construct was 3D printed via Fused Deposition Modelling (Rokit INVIVO Bioprinter) and functionalized with gelatin (Gel) and hydroxyapatite (nHA) through immobilisation via poly-dopamine (DP) coating. For the AC deep zone, a photocurable Gellan Gum (GG; 3%w/v) multi-channels hydrogel structure was obtained via soft-lithography, adherent to the PLA scaffold. Chondrocytes (differentiated from Y201 bone marrow stromal mesenchymal stem cells) were encapsulated in each channel of GG layer within a chondroitin sulphate-based hydrogel [5], while Y2O1 cells were seeded on PLA scaffold (Figure 1). GG physical properties (water uptake capability, porosity via Scanning Electron Microscopy (SEM) and mechanical properties via compression and stress relaxation analyses) were evaluated. OA milieu was induced by IL-6, IL-1β and TNF-α addition to the medium. Cell viability was assessed for both phases of the construct via Live/Dead, metabolic activity (MTT for PLA and MTS for GG) and Immunostaining of nuclei and cytoskeleton (DAPI and phalloidin). The chondrogenic potential of cells and the effect of cytokines in the OA samples were evaluated through gene expression analysis, mucopolysaccharides quantification (Alcian blue) and calcium deposition (Alizarin Red).

**Results and Discussion**

GG hydrogel showed high water uptake capability (initial rapid uptake of 1433±57% at 3 h then achieving plateau), high porosity (pore range size of 100-150μm 30%) and suitable mechanical properties for AC application (48±5kPa as compressive Young's modulus). All the materials showed cytocompatibility in terms of cells viability and metabolic activity up to 7 days (Figure 2A). The effects of cytokines inducing OA decreased the mechanical properties (Figure 2B shows the stress-relaxation behaviour at day 14). The expression of chondrogenic markers (COL2A1, ACAN, SOX9) and the mucopolysaccharide quantification (0.36±0.01µg in the Healthy model compared to 0.22±0.02µg in the OA samples at day 21) (Figure 2D). OA model showed also increased OA-related molecule expression (COLL1,
MMP9-13, ADAMTS5) and Alizarin Red values (680±20µM for the OA-model compared to 550±10µM of the Healthy model) (Figure 2C).

Conclusion
We developed a high reproducible 3D in vitro OA model characterized by quickly manufacturing, easy manipulation and large availability. Our analyses demonstrated that the selected “cytokines cocktail” medium enrichment was a feasible process to reproduce the OA milieu in vitro. This construct could be applied to test new therapeutics and to study on cells crosstalk interactions.

**Introduction**

The progressive degeneration of Articular Cartilage (AC) due to Osteoarthritis (OA) is the most common and chronic form of joint disease in the Western World, affecting 10–12% of the global population for a total of 303 million people¹. To date, no specific therapy for a long-term surgical treatment for OA joints has been successful, mainly due to the lack of knowledge about the disease pathogenesis². Indeed, *in vitro* models of AC human tissues to study the OA progression are suitable candidates in increasing our understanding on AC physiology and biology and this could help in advancing the research into the causes of the OA disease at early stage as a key tool to investigate new therapeutic options in reliable and predictive models. In this work we developed an *in vitro* spheroid model of AC in Healthy and OA condition, with the aim of studying the disease evolution at cellular level. Current evidence suggests that pro-inflammatory cytokines are responsible for the catabolic process occurring in the pathological tissues. Herein, we designed and analysed a cytokine-induced OA spheroid model, obtained combining interleukin (IL)-1β, tumor necrosis factor-α (TNF-α) and IL-6.

**Experimental Methods**

For the formation of multicellular spheroids, human articular chondrocytes (HC) and immortalised mesenchymal cells differentiated in chondrocytes (Y201-Cs) were cultured in round-bottom 96-well plate. Three culture condition were set: Healthy (DMEM/F12), Low concentration Osteoarthritic (LC-OA) (DMEM/F12 loaded with: IL-1ß:1ng/mL, TNF-α:1ng/mL, IL-6:10ng/mL) and High Concentration Osteoarthritic (HC-OA) (DMEM/F12 loaded with: IL-1ß:5ng/mL, TNF-α:5ng/mL, IL-6:50ng/mL). Spheroids growth kinetics and metabolic activity was evaluated over 10 days of culture, in both healthy and OA conditions. Then, their metabolic activity was evaluated via MTS assay. After 10 days of culture, the spheroids were assembled and cultured for 14 days on a gelatin-coated poly(lactic-co-glycolic acid) electrospun membranes (10 spheroids/cm²), following a protocol in line with the clinically approved Chondrosphere® (CO.DON AG) technique³. Gene expression (SOX9, ACAN, COL2A1,MMP-13 and ADAMTS-5), Histology (H&E, PicroSirius Red and Alcian Blue) and Immunohistochemistry (IHC) (Collagen type II and Aggrecan) analyses were performed to evaluate the quality of the tissue produced in the set conditions.

**Results and Discussion**

Both cell type showed a decrease of spheroid diameter (~35%) over culture in healthy condition, while the dimension was stable for the spheroids under OA state. decreased over culture, while it increased for Y201-Cs in all the three condition. Instead, for both cells, at day 10 HC-OA sample showed an increased metabolic activity, possibly due to the biosynthesis of inflammatory and degradative proteins involved in the OA pathogenesis⁴. Gene expression, histology and immunohistochemistry demonstrated the successful role of the cytokine in modulating the expression of matrix metalloproteinases and cartilage ECM proteins (Figure 1). Both HCs and Y201-Cs showed a decreased expression of SOX9, ACAN and COL2A1 at day 21 compared to the Healthy model and an overexpression of pathological marker MMP-13 and ADAMTS-5. To confirm this, we demonstrated that both cells population in Healthy state, produced higher amount of collagen and glycosaminoglycans by Picrosirius red and Alcian Blue stainings and specifically Collagen Type II and Aggrecan, by IHC compared to OA conditions. Finally, H&E staining demonstrated...
that the obtained healthy cartilage-like tissue was more intact compared to the pathological one, that appeared more fragmented especially for the HC cells.

**Conclusion**

In this work we optimised an approach to obtain an *in vitro* model of articular cartilage tissue in healthy and pathological state. Also we demonstrated that a low concentration of cytokines is sufficient to obtain lower expression of anabolic genes and higher expression of catabolic genes by cells, together with a lower production of collagen type II and aggrecan. Finally, we showed how it is possible to get a reliable *in vitro* model even with a bankable cell line (Y201-C), with the related advantages in terms of low-cost, high reproducibility, high number of cells available, fast time for producing it compared to primary chondrocytes.

Development of osteogenic microenvironments using cationic liposomes embedded into polyelectrolyte multilayer system

Yazmin A. Brito Barrera1, Matthias Menzel2, Christian Schmelzer2, Christian Wölk3, Thomas Groth1,4

1 Martin Luther University Halle Wittenberg, Department Biomedical Materials/Institute of Pharmacy, Halle (Saale), DE; 2 Fraunhofer, Department of Biological and Macromolecular Materials/Institute for Microstructure of Materials and Systems (IMWS), Halle (Saale), DE; 3 Leipzig University, Pharmaceutical Technology/Institute of Pharmacy/Faculty of Medicine, Leipzig, DE; 4 Martin Luther University Halle Wittenberg, Interdisciplinary Center of Materials Science, Halle (Saale), DE

Introduction
Cationic liposomes of OO4 lipid and dioleoylphosphatidylethanolamine (DOPE) contain a higher amount of amino groups than classical lipids that can be used for lipofection. Here, a polyelectrolyte multilayer system (PEM) made of chondroitin sulphate (CS) and collagen type I (Col I) was prepared by Layer-by-Layer technique (LbL), which is a method to fabricate surface coatings by alternating adsorption of polyanions and polycations. Due to their intrinsic charge, the liposomes can be used as a polycation and can be embedded in the terminal layers of PEM for the controlled release of the cargo (lipophilic or hydrophilic models) in the liposomes into C2C12 cells (myoblast). As well, the use of Col I and CS should mimic the extracellular matrix of bone and the addition of a functional cargo like Dexamethasone can induce osteogenic differentiation for future applications such as bone replacement therapies.

Experimental Methods
Characterization of the liposomes was evaluated regarding their size distribution using dynamic light scattering (DLS) and morphology by micrographs of freeze-fracture TEM and Cryo TEM. Physicochemical studies of PEM were done to characterize layer growth (surface plasmon resonance), thickness (ellipsometry), topography (atomic force microscopy). The substrates were coated with PEM consisting of CS, liposomes, Col I as terminal layers. Cell adhesion and liposome uptake studies by C2C12 cells were carried out with immunofluorescence staining and flow cytometry analysis. The osteogenic differentiation was evaluated using histochemical staining by Alizarin Red and the detection of alkaline phosphate activity (ALP).

Results and Discussion
The DLS measurements show two sizes of populations between 70-100nm and 300-700nm. In the characterization of PEM, SPR results show a linear growth behavior with an increase in the angle shift. Liposome adsorption measured lead to a significant increase in thickness. AFM studies indicated a change on the surface before and after deposition of the liposomes on PEM. The cell adhesion studies show that there were significantly more cells adhering on PEM with liposomes as a terminal layer and with the addition of one bilayer as a terminal. The concept to add two layers more after the liposomes were not only to protect liposomes from degradation but also to improve cell adhesion. The quantification of liposome uptake indicated that 50.8% of the cells internalized liposomes with Texas Red dextran were positive and 90.5% of cells were Rhodamine-DOPE-positive. Consequently, efficient uptake of liposomes can be assumed for both conditions. As a proof of concept, dexamethasone (Dex) was incorporated in the lipid bilayer of liposomes to induce differentiation of C2C12 cells into osteoblasts. Quantitative measurement of ALP activity shows an increase in samples where Dex-loaded liposomes were embedded in comparison to the positive and negative control. Histochemical staining by alizarin red s indicates the formation hydroxyapatite.

Conclusion
This work has shown that deposition of cationic liposomes composed of the co-lipid DOPE and OO4 lipid with cargo like dexamethasone in a PEM made from CS and Col I can be used to induce osteogenic differentiation of cells \textit{in situ}.

Biofabrication in commercial setting

Gabor Forgacs

University of Missouri-Columbia, Missouri, US

Biofabrication is typically defined as the generation of biologically functional products composed, among others, of living cells. In this talk I will present examples of commercial products created by methods that fall within the above definition of biofabrication but at the same time point beyond it. Specifically I will discuss how biofabrication methods can be applied to making leatherlike materials and cultured meat even though the final products obviously do not have biological functionality, as they contain no living material when used or consumed. I will also point out how biofabrication can help to mitigate critically important sustainability issues associated with industrial leather and meat production.
3D Bioprinted Interphase-based bone in vitro models

Alvaro Sanchez-Rubio, Vineetha Jayawarna, Stylianos Sarrigiannidis, Matthew Dalby, Manuel Salmeron-Sanchez

University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB

Introduction
In vitro models, which allow to study tissues and organs outside their biological context, are key tools in not only fundamental and applied research but also the pharma industry. However due to the complexity of native tissues, which display heterogeneity in topographical, physicochemical and biological features, creating these models remains a challenge. Until now, being able to mimic that heterogeneity was not possible. However, 3D bioprinting due to its free-form and multimaterial fabrication capabilities has enabled producing constructs that include specially tailored regions that can more appropriately mimic each of the areas present in native tissue, including different chemical cues, physical properties and cell types. In this work, by using 3D Bioprinting we overcome the tissue complexity challenge and engineer interphase-based in vitro models that consider the physicochemical and biological heterogeneity of native bone to achieve the complexity inherent to the vascular bone unit, where vascular and mineral component can be found together and in close interaction. Especially relevant considering that alterations to this interaction leads to several bone pathologies, like osteoarthritis or osteoporosis. Therefore, it is crucial to reproducibly fabricate models that allow to study this system and the interactions present within, so to gain a better understanding of the biological processes, and to more efficiently discover and develop drugs that would act upon it.

Experimental Methods
Different hydrogel systems (Alg/Gel and GelMA) were prepared by dissolving the given polymers at different ratios. Photoinitiators were added to UV-Crosslinked systems. The printed Alg/Gel and BiogelX™-bioink-RGD structures were exposed to different concentrations of CaCl2 solutions to crosslink after printing, while GelMA structures were exposed to UV light for different times. Different cell types (hMSCs and HUVEC) were laden to the hydrogels and printed, in mono- and co-culture conditions. Mechanical properties of the hydrogels were studied using Rheology and Nanoindentation. NeutrAvidin (NA) was used to assess chemical separation of compartments. Further modification of the hydrogels was done by using peptide-coupled alginate (Alg-RGD) or adding Fibronectin (FN) and custom peptide fragments (CPF), which include the gelatine binding domain of FN together with the Growth Factor (GF) binding domain. BMP-2 and VEGF were also added to the system. Release of these proteins was studied using BCA and ELISA. Viability was studied using commercially available Live/Dead kits.

Results and Discussion
Reproducible 7mm diameter, interphase-based constructs were obtained using extrusion-based bioprinting. Stiffness measured varied with polymer concentration and crosslinking times, ranging from below 10 KPa to over 40KPa for soft and rigid gels, and showed increasing stiffness values when either polymer concentration or crosslinking times were used. Constructs with different stiffnesses in each of the compartments were achieved. NA imaging showed clearly separated and adjacent compartments within the same construct and sustained released of the protein into the media. Similarly, we proved presence and clear separation of BMP-2 and VEGF in either compartment of the bone-chip. Immunostaining indicated the ability of FN and CPF to bind to Gelatine, in both 2D and 3D. In addition, when either FN or CPF were used, growth factors were released slower into the media, when compared with non-functionalized bioinks. Viability up to 21 days for MSCs remained over 80% while HUVEC, stayed around 70% for the first 3 days and then decreased, although the morphology of both cell types remained rounded.

Conclusion
Constructs with different compartments were obtained, which specifically mimic each of the regions in the vascular bone unit, having different physicochemical and biological properties. This ability to include different stiffnesses and GF in each compartment of the model overcomes the simplicity found in previous models and shows a higher resemblance to native bone architectures. The throughput of the system indicates the potential of 3D Bioprinting for the generation of reproducible organotypic in vitro models. The functionalization of the bioink by both FN and CPF showed promising results in producing Gel-based bioinks with enhanced GF-binding properties. Bioinks exhibited low toxicity, although further studies need to be done to assess osteogenic and vasculogenic differentiation within the bone-chips.

Modeling of Pancreatic Tumors using 3D Bioprinting

Cristina Banda Sánchez, Nieves Cubo Mateo, Jesús Frutos Díaz-Alejo, Julie Earl, Icíar González Gómez, Luis M. Rodríguez Lorenzo

Introduction

Cancer modeling has been of special interest since it paves the way for easing and modulating preclinical research model’s conditions. Relevant advantages are the higher similarity to in vivo systems compared to 2D culture, and preclinical allogenic equivalence compared to animal models. Since pancreatic cancer holds still a low survival rate, strongly dependent on the moment of diagnosis, new therapies urge to be tested, thus advances in 3D modeling of equivalent tumor environments are required.

The objective of this project is the 3D bioprinting of pancreatic tumor models based on PANC-1 laden human plasma, sodium alginate (SA), methylcellulose (MC) bioinks.

Experimental Methods

A. Bioink’s Preparation

The proposed ink is composed of 3% SA and 9% MC in human plasma. Every procedure is accomplished under sterility conditions inside a laminar flow cabinet. Fresh frozen human plasma (obtained in compliance with the standards of the American Association of Blood Banks) is thawed at 37ºC and mixed first with SA under stirring, and then MC with a spatula. Thereafter, PANC-1 cells, cultured in 10% FBS 1% L-Glu 1%Pen/Strep RPMI medium at 37ºC and 5% CO₂, are trypsinized and counted to adjust the desired cell concentration in PBS. After mixing the cells with the ink using a spatula, a final concentration of 5·10⁵ cells in each of the printed constructs is obtained.

B. Optimization & Characterization of the bioink

Ink’s mechanical properties are rheologically characterized on rheometer ARG2 (TA instruments) with a sandblasted parallel plate D = 25 mm geometry at 37ºC before, during, and after gelation event upon addition of 1.5% CaCl₂ crosslinker. Oscillatory frequency sweeps are performed to evaluate the viscosity behavior at the shear thinning region; shear thinning coefficients are obtained as in [4]. Thixotropy and degree of recovery after structural disruption are computed for characterizing printability. Gelation kinetics are measured in a time sweep for 30 min, where crosslinker 1.5% CaCl₂ is added 1 min after start recording.

C. 3D Bioprinting

Cell-laden bioink solution is loaded into a 5 mL cartridge, then stored at RT for stabilization of bioink’s rheological properties. Pneumatic extrusion Inkredible 3D printer (Cellink) is used for dispensing the hydrogel ink through a conical nozzle (D = 410 μm). Cylindrical constructs of D = 15 mm are printed in 6P-culture well plates. Printed hydrogels are crosslinked for 20 min with 1.5% CaCl₂; it is then removed, replaced with fresh medium, and incubated at 37ºC 5% CO₂.

D. Viability assay on cell-laden constructs

Cellular survival and proliferation are assessed with a Live/Dead viability kit (ThermoFisher Scientific #L3224) according to the manufacturer’s protocol. Afterward, constructs are imaged in a fluorescence microscope (PAULA, Leica Microsystems) for green (live) and red (dead) spectra. Viability is screened at 1, 3, 7, and 11 days post-printing.

Results and Discussion
A. Optimization & Characterization of the bioink
The end of LVR is determined by the critical yield point, $\gamma_c = 154 \, \mu\text{Nm}$ in non-crosslinked plasma-based ink; frequency sweep experiments are performed below that value. The ink has a rate index $n = 0.28$, showing highly shear thinning behavior. It yields a gel-like consistency prior to crosslinking at rest, along with a fast recovery rate of 89% in the first 60 s after disruptive shear stress application, simulating the printing process.

B. 3D Bioprinting
At the time of printing, the bioink shows great printability in terms of layer stacking, shape consistency, CAD fidelity, no ink clumping at the tip of the nozzle, and homogeneous qualitative ink composition. The average required printing pressure, constant during the whole process, is 136 KPa. Past 20 min from crosslinker addition, the constructs have swelled slightly doubling the filament diameter, yet not clogging the printed grids destined for nutrient and oxygen exchange.

C. Viability assay on cell-laden constructs
Embedded PANC-1 cells survive and proliferate within the printed constructs after at least 7 days of culture renovating fresh medium periodically, as illustrated in Figure 1. Viability at day 1 suggests that the printing process was barely detrimental for cells. A week after, cells remain alive and proliferate; the red fluorescent channel is merged with the green one. Almost no red light was detected, meaning average low dead cell’s quantity, thus biocompatibility of the ink.

Conclusion
The presented bioink candidate, made of PANC-1 cell line, sodium alginate, methylcellulose, and human plasma has shown valuable characteristics: great printability, biocompatibility, structural integrity, and consistent mechanical properties. Simplified pancreatic tumor models were printed and cultured for 11 days, and cells were shown to be proliferating within the constructs for at least a week. Further experiments with different culture media conditions, printed patterns, and pancreatic cancer cell lines are ongoing.

Acknowledgement
This research was funded by AEI/FEDER UE (DPI2017-90147-R) Spain. Special thanks to Cellink for providing Inkredible printer, and Hospital Ciudad de Coria for the plasma supply.

Figure 1: Viability of cell-laden bioprinted constructs
Viability and proliferation of printed PANC-1 cell-laden plasma-based inks using LIVE/DEAD cell kit (L3224, Invitrogen). Live (green) and dead (red) cells within constructs were screened (from left to right) at day 1, day 3, and day 7 post-printing.

Hierarchical biomaterials via photopatterning-assisted additive manufacturing

Dalia Dranseikiene, Elia A. Guzzi, Raffaele Bischof, Dhananjay V. Deshmukh, Mark W. Tibbitt

ETH Zürich, D-MAVT / Macromolecular Engineering Lab, Zürich, CH

Introduction

Additive manufacturing (AM) or biofabrication of tissue mimics often requires control of bioink properties at different scales, which is not accessible by a single approach. AM approaches can be grouped into two broad subcategories: 1) extrusion-based and 2) stimulus-based (e.g. light). Extrusion-based AM allows the use of multiple bioinks in a single print, but the resolution is limited by the nozzle size. Photo-triggered AM offers higher spatial resolution, but usually only single material is utilized. To overcome these limitations, we developed an approach to fabricate hierarchical biomaterials via combined extrusion–photopatterning AM (Fig. 1).

Experimental Methods

The base formulation of universal nanocarrier ink (UNI) consisted of 1 wt% hydroxypropylmethylcellulose (HPMC) and 15 wt% PEG-b-PLA nanoparticles. Gelatin methacryloyl (GelMA, DoF = 70%) was combined with UNI formulation at either 5 or 10 wt%.

Shear rheometry (MCR 502; Anton-Paar; Switzerland) was used to characterize the viscoelastic properties of different biomaterial inks and to investigate the cross-linking kinetics for the control of mechanical properties via photopatterning.

To prepare the hierarchical structures a pneumatic-driven 3D printer (BioX; Cellink, Sweden) and a digital micromirror device DLP® E4750LC (EKB Technologies Ltd; Israel) with 405 nm LED light source were used.

Uniaxial tensile tests (MTS Systems; USA) were performed on the patterned structures to evaluate if the composite structures comply with the rule of mixtures.

Finally, to ensure cytocompatibility of the process human mesenchymal stem cells (hMSCs) were encapsulated in UNI–GelMA and 3D scaffolds were fabricated with a combined extrusion-photopatterning AM technique.

Results and Discussion

The combination of UNI platform with GelMA ensured shear-thinning and self-healing properties required for extrusion-based AM, which were not present in pure GelMA formulations at 37°C. All UNI–GelMA inks had similar shear-thinning behavior and were able to reform after high strain intervals (γ = 100 %, ω = 10 rad s⁻¹).

In order to replicate the process of photopatterning, in which specific hydrogel regions were photopolymerized for longer duration, the cross-linking kinetics of both UNI–GelMA-5 and UNI–GelMA-10 were investigated upon exposure to visible light (λ = 405 nm, I = 10 mW cm⁻²) for different time intervals. A step-wise photopolymerization approach was also tested, in which the sample was initially only partially cross-linked for a short period, equilibrated, and then further exposed to light to reach complete cross-linking of UNI–GelMA. This allowed us to tune the mechanical properties by altering the duration of photopolymerization.

Due to the large difference in storage modulus obtained with UNI–GelMA-10 after two intervals of photopolymerization (ΔG’ > 10 kPa), this formulation was further used for tensile test measurements. Bulk samples cross-linked for short (t = 10 s) and long (t = 60 s) durations had one order of magnitude difference in the final elastic modulus (E₁ = 10 s = 6.4 ± 2.9 kPa and E₁ = 60 s = 28.9 ± 4.4 kPa). Composite structures were fabricated in a step-wise approach: initially the matrix was homogeneously partially cross-linked, and in a second step the reinforcement structures were patterned on the matrix. Different volume fractions of reinforcement were photopatterned in the scaffolds (Fig. 2a). To determine the efficiency of reinforcement, the experimental mechanical data for the 16% and
33% fiber reinforced samples was compared with standard composite theory. The measured elastic moduli of hydrogel scaffolds were comparable to the theoretical rule of mixtures. Biocompatibility of the combined AM process was verified by processing UNI-GelMA-5 bioink with hMSCs via both extrusion and photopatterning. There was no significant difference in cell viability found between the groups of samples that were either only photocrosslinked for different durations or printed by extrusion and then crosslinked. Moreover, cell morphology changes over time in all tested conditions showed that the combined AM process did not impair cell spreading (Fig. 2b).

**Conclusion**

In this work, we showed the possibility to combine structural control from both photo-triggered and extrusion-based AM. In the future, this hybrid approach could be exploited to fabricate more complex constructs for tissue engineering with hierarchical material organization, from micro- to macro-scale.

Sacrificial thermoresponsive Poly(2-cyclopropyl-oxazoline) as a beneficial material for freeform 3D printing and channel network generation in hydrogels

Vincent T. Mair, Ilona Paulus, Jürgen Groll, Matthias Ryma

Julius-Maximilians-Universität Würzburg, Department for Functional Materials in Medicine and Dentistry, Würzburg, DE

Introduction

Most 3D-printing technologies rely on the vertical stacking of layers, whereas each layer provides the structural integrity for the upcoming one. An especially interesting technique, which overcomes these layer limitations, is freeform printing. In the context of biofabrication, this method has been applied for the creation of sacrificial 3D-structures based on carbohydrates for perfusable channel generation in tissue engineered constructs. However, carbohydrate scaffolds do not intrinsically provide a suitable tool for channel creation in extracellular matrix (ECM) mimicking hydrogels. The main reasons are the fast dissolution in aqueous solutions, which leads to the collapse of channels before hydrogels can crosslink, and the osmotic pressure on nearby cells during dissolution of the sugar. To overcome the disadvantages of carbohydrates, scaffolds needed to be dip or spray coated to increase stability during hydrogel gelation and hinder dissolution of the sugar in the hydrogels. However, these methods are cost-, time- and labor-intensive and coating becomes less accurate with increasingly complex scaffolds.

In this study, we established freeform printing of the thermoresponsive polymer poly(2-cyclopropyl-oxazoline) for the creation of freestanding sacrificial scaffolds, which overcomes the disadvantages of carbohydrates by providing stability during hydrogel creation and cytocompatibility during dissolution without requiring post-processing.

Experimental Methods

With PtycloPrOx, we were able to create single freestanding filaments. We observed that an increase in temperature during printing leads to the generation of fibers with increased diameters, based on the lower viscosity of the polymer during printing. An increasing feedrate also led to an increased fiber diameter and vice-versa, since faster movement leads to the deposition of less material in the same distance. With this, fibers can be created ranging from diameters below 100 µm up to 450 µm. Furthermore, we printed single freestanding fibers with various angles from 0° to 90°, proving the applicability of the polymer for more complex structures.

Results and Discussion

Another important factor for the creation of complex scaffolds via FFP is the introduction of fiber fusion. As a first proof-of-principle, we printed 2 straight fibers, which were connected by a bridging free-hanging filament (Figure 1 A). With this, we were able to stack several units in Z-axis by filament fusion (Figure 1 B, C). To prove the suitability in 3 dimensions, we further created stacked cube structures with several fiber thicknesses by varying the temperature (Figure 1 D, E) and generated spiral structures (Figure 1 F).

In conclusion, the basic requirements for FFP, namely control of fiber thickness, stacking and filament fusion were established. To prove the advantageous channel creation with scaffolds based on PtycloPrOx without the need for post-modification, we exemplary embedded the spiral structure in Agarose. After crosslinking and temperature decrease below the LCST of PtycloPrOx, we were able to flush out the polymer and create empty channel structures (Figure 2 A, B). Perfusion of these channels was shown by the addition of a dye (Coomassie blue) (Figure 2 C), proving the suitability of the polymer for channel creation.

Conclusion

Page 259 of 2028
In summary, we were able to adapt the thermoresponsive polymer PcycloPrOx to FFP. It was shown that freestanding interconnected scaffold structures with fiber fusion and stacking can be created. This method enables cytocompatible channel creation, without leaving non-dissolvable remnants behind. In conclusion, the addition of thermoresponsive poly(2-oxazoline)s to the FFP-library opens up great opportunities for the usability of one-step channel network creation in tissue engineering constructs.

Bioprinting of spatially defined co-cultures of mammalian cells and photosynthetically active microalgae as alternative concept for post-implantation oxygen supply

**Sophie Dani**¹, Johannes Windisch¹, Felix Krujatz², Michael Gelinsky¹, Anja Lode¹

¹ Technical University Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE; ² Technical University Dresden, Institute of Natural Materials Technology, Dresden, DE

**Introduction**

One strategy in the treatment of Diabetes Type 1 is the transplantation of allogenic pancreatic Islets of Langerhans to restore the endogenous insulin production. To avoid the administration of immunosuppressants and prolong the life span of the transplant, the islets can be protected from the recipient's immune system by encapsulation in alginate hydrogels. However, this measure impedes the islet's oxygen supply, reducing their functionality and survival rates.

The co-cultivation with photosynthetically active microalgae is an alternative concept for blood-independent oxygen supply. In our lab, both islets and microalgae were successfully plotted within a hydrogel blend of alginate and methylcellulose (algMC) previously [1, 2]. However, mammalian cells and microalgae have fundamentally different environmental and nutritional demands, yet the needs of both cell types needed to be met in a co-culture. Challenges are the identification of a suitable microalgae partner, the establishment of process conditions which support the survival and function of both cell types and the development of a co-culture medium that ensures a successful long-term cultivation.

**Experimental Methods**

As a model cell type for Islets of Langerhans, INS-1, an immortalised cell line of murine beta-cells was used for all experiments. Microalgae strands investigated were *Chlorella sorokiniana*, *Scenedesmus sp.*, *Coelastrella striolata* and *Coelastrella oocystiformis*. The mammalian cell culture medium is composed of Roswell Park Memorial Institute (RPMI) 1640 Medium (Gibco), 10 % heat inactivated fetal calf serum (Corning), 1% ampicillin (Roth), 5% HEPES pH 7.4 (Roth), 1% L-Glutamine (Biochrom GmbH) and 1% mercaptoethanol sodium pyruvate (Gibco). The microalgae medium “Tris minimal”, consisting of tris buffer, a salt solution and trace elements, was prepared as described previously [3], however ammonium chloride was substituted for 0.75 g/L sodium citrate. The bioink used for plotting consisted of 3 % alginate (Sigma) and 9 % methylcellulose (Sigma) dissolved in phosphate buffer saline (INS-1) or water (microalgae). Strands were deposited by extrusion-based multi-channel plotting using a 3.1 Bioscaffolder (GeSiM mbH). After plotting, the constructs were cross-linked in 70 mM strontium chloride solution. Both cell types were cultivated in 37 °C and with 5 % CO₂. If illuminated, a homogenous light source of 150 µmol/m²s (PAR) intensity was used. Different mixtures of the mammalian and the microalgae media were tested regarding their effect on viability and function of both cell types.

**Results and Discussion**

Using 3D bioplotting, both cell types suspended in a bioink consisting of algMC could be placed in close proximity, to ensure efficient oxygen transfer, but without direct cell-cell contact. Two parameters of co-cultivation were set already in the beginning of this work: a cultivation temperature of 37 °C and the necessity of a light source to enable photosynthesis.

The influence of light on INS-1 was not previously described in the literature. Cultivation of INS-1 under white and red illumination of the same intensity revealed that under white light, cell viability and insulin secretion were drastically reduced, while red light had no influence on either cell survival or functionality of INS-1.

In order to find a microalgae strand that can grow under these conditions, four heat-resistant strands were investigated regarding their photosynthetic activity and their survival and growth rates after plotting. *Scenedesmus*
sp. showed a high photosynthetic yield in red light that was not reduced in the presence of glucose - a mandatory component of mammalian cell culture medium –, indicating a stable autotrophic portion in its metabolism. Plotting and immobilization had no negative impact on viability and growth rate as well. Since the INS-1 as heterotrophic cells have very specific needs in order to grow and exhibit a natural insulin response, the co-culture medium suitable for both cell types is close to the standard medium composition for INS-1. It was shown that ¼ of RPMI could be substituted with microalgae medium without loss of function of the INS-1 when the additives, as described above, are kept in the original concentration. On the other side, replacement of ¼ of RPMI by TP is sufficient to ensure the viability of the microalgae, if the trace element supplement was kept in its original concentration and the in cell culture normally used antibiotic streptomycin was replaced by 1% ampicillin. With this co-culture medium, both cell types show unimpeded functionality and growth.

**Conclusion**

In this work, spatially defined co-cultures of *Scenedesmus* sp. and INS-1 were established and all necessary parameters for a successful co-culture were developed. Viability, proliferation, and function of both cell types in these conditions were confirmed which now paves the way for novel strategies of oxygen supply.

Introduction

Osteoarthritis (OA) is a painful and debilitating condition that affects over 40 million people just in Europe (1). Together with the knee, the hip is one of the joints most frequently involved in OA. One of the two main causes for hip OA is hip dysplasia (HD) (2). HD is characterized by the instability of the hip joint and is caused by incomplete coverage of the femoral hip by the acetabulum. The most common surgical treatment to correct dysplasia involves the re-alignment of the hip socket (osteotomy) or the insertion of a bone graft (shelf arthroplasty) to enlarge the acetabulum (3). The success rate of this procedure is relatively low (40 to 60%) due to the challenges in shaping and positioning of the bone graft to the defect size with associated accelerated graft resorption or impingement of the femoral head (4). In an attempt to overcome these limitations, implants are developed that can ensure a perfect fit to the defect size, facilitating optimal integration and durable restoration of the hip socket.

Experimental Methods

In this study, we have developed a mechanical competent and fully resorbable magnesium phosphate (MgP) - based implant to enlarge the acetabulum. The appropriate design was obtained from CT-scans of eight dog patients and fabricated using a room-temperature extrusion-based process (5). The implants were printed with two various core fiber spacing of 1 mm and 0.7 mm (abbreviated as IFS-1 and IFS-0.7, respectively). The mechanical compatibility of the implant as well as stability and optimal femoral coverage in the load-bearing quadrant of dog model is being investigated using a custom-built mechanical set-up simulating canine hip joint forces (Fig. 1).

Results and Discussion

In order to evaluated the mechanical performance of the base material and respective implants internal architecture three-point bending tests were carried out. Under three-point bending, IFS-1 and IFS-0.7 implants presented similar load-displacement curves (Fig. 2A-C). Curves started with steep slope in the elastic region, following by an inflexion point after the yield until maximum force was reached. Moreover, our results demonstrate that the 3D-printed implant design adapted well to the acetabulum of canine dysplastic hips, while the flexible MgP material composition supported fixation with metallic screws. Implants were able to withstand a maximum force of 200N without failure and a significant plastic deformation, which confirmed a proper fixation of the implant to the defect side (Fig. 2D-E). For the ex vivo biomechanical test, after 15 days in enzymatic media, implants exhibited not significant deterioration of the external architecture was observed to maintained but with the presence of slight material gaps and alternation of smoothness (Fig. 2F-H). Although a significant decrease in mechanical properties was observed after 15 days degradation under this extreme punctual compressive load, it was notable to observe that implant with a loss in weight fraction of material equivalent to 48% did not lose completely the mechanical integrity.

Conclusion
The patient-specific design will provide a perfect fit resulting in optimal integration and durable restoration of the hip socket. The implants will provide a stable, long-term and regenerative solution that will fully integrate with the host bone tissue.

Novel approaches in 3D and 4D printing, microfluidics and other emerging techniques for developing precise 3D tendon and other musculoskeletal tissue substitutes and 3D models to understand regeneration mechanisms. Cellular approaches, including those focusing on strategies for modulating inflammatory processes to trigger regenerative responses of tissue engineering therapies.

The keynote will focus on innovative technologies such as magnetic assisted 3D printing and microfluidics that, combined with adequate cellular approaches, can be used to either develop biomimetic/functional constructs for tissue regeneration or more realistic 3D tissue models to study tissue pathologies/healing mechanisms.
S05-KL01

Magnetic Assisted 3D bioprinting and mechanoactuation technologies for achieving advanced biofuntionality of 3D constructs and precise models to engineer the regeneration of tendons

Manuela Gomes1,2

1 3B’s Research Group-University of Minho, I3Bs Research Institute, Guimaraes, PT; 2 ICVS/3B’s, PT Government Associate Laboratory, Braga/Guimaraes, PT

The poor healing ability of tendons as well as the limitations of currently used therapies have motivated tissue engineering (TE) strategies to develop living tendon substitutes. However, the limited knowledge on tendon development and healing processes has hindered the design of TE procedures that more closely recapitulate tendon morphogenesis.

Our lab has been exploring the development of unique cell-laden 3D magnetically responsive systems that recapitulate key features of the native tissue and that can be further remotely modulated both in vitro and in vivo by the application of external magnetic stimuli. We are exploring conventional and innovative tools such as multimaterial 3D bioprinting to design magnetic responsive systems mimicking specific aspects of tendon tissue architecture, composition and biomechanical properties, which, combined with adequate stem cells, shall render appropriate behavioural instructions to stimulate the regeneration of tendon tissue. Simultaneously, the 3D cell-laden magnetic system shall enable sophisticated 3D tissue models to unravel mechanisms behind tendon homoeostasis and repair that will support the base knowledge to establish rational design criteria for the biofabrication of living tendon substitutes offering the prospect of tendon regeneration as opposed to simple tissue repair.

Introduction

Tendons are indispensable in the human body. Connecting muscle to bone, they provide strength, withstand tension and release stored energy1. Hand tendon traumas comprise around 10% of all emergency department visits and up to 20% of all injuries treated2. Current treatment methods have several shortcomings, including an insufficient mechanical strength, possible adhesion reactions with surrounding tissue and inflammation issues. The current research aims to create a structure to counter both mechanical and biological problems. A reinforced, multi-layered tubular polymeric construct is electrospun. The construct is composed of three layers: an inner electrospun layer containing an anti-inflammatory component (Naproxen), a middle layer with a braided monofilament as a reinforcement layer and an outer electrospun layer containing an anti-adhesion component (hyaluronic acid)3 (Fig 1).

Experimental Methods

A novel acrylate endcapped urethane-based poly(ε-caprolactone) precursor (AUP) was developed and characterized measuring the acrylate content and the molar mass using 1H-NMR spectroscopy. This AUP polymer was benchmarked against commercially available poly(ε-caprolactone) (PCL). After characterization, the materials were electrospun into the construct layers, also including the active compounds (Naproxen and HA). The final constructs were mechanically evaluated using suture retention and ex vivo tensile tests on sheep tendons. An in vitro study was also performed using an MTS assay and Ca-AM/PI staining. Finally, the materials were tested on their degradability (Fig 2).

Results and Discussion

NMR allowed to determine the MM of the PCL diol (1931 g∙mol⁻¹), the MM of the AUP (3336 g∙mol⁻¹) and the acrylate content (0.554 mmol∙g⁻¹). During the electrospinning, a comparison was made between pure PCL and AUP/PCL blends. Both led to homogeneous fibers. However, PCL clearly led to thicker fibers (8.77 ± 1.88 µm) than the blend (4.30 ± 0.41 µm). The monolayered AUP/PCL reached a significantly higher (p < 0.05) average suture retention strength (0.79 ± 0.17 MPa) than the monolayered PCL (0.50 ± 0.09 MPa). This could be linked to the stronger, crosslinked network of AUP. Tensile tests indicated ultimate strengths of 0.81 ± 0.04 MPa and 1.17 ± 0.30 MPa respectively. Considering the strength required for the final application (4 MPa needed4), the constructs are not strong enough. In a subsequent step, the reinforced triple-layer electrospun construct was then processed including the active compounds (hyaluronic acid and Naproxen) and the intermediate tubular braid. In vitro assays using human fibroblasts showed that incorporation of the active components was successful and not-cytotoxic. It was hypothesized that the AUP/PCL HA is preferred over PCL HA as the high initial leaching of HA in the PCL HA could potentially be...
detrimental for the cells. This prolonged release could be attributed to the more densely covalently crosslinked network of the AUP/PCL. Ex vivo tensile tests on sheep tendons with the monolayered and multilayered PCL and AUP/PCL repair constructs resulted in ultimate stresses of 0.39 ± 0.10 MPa and 0.27 ± 0.11 MPa for the monolayered PCL and AUP/PCL respectively and 8.56 ± 1.92 MPa and 8.36 ± 0.57 MPa for the multi-layered PCL and AUP/PCL respectively. The period in which the constructs need to remain mechanically stable is 8 weeks. After that, the lesioned tendon passes to an advanced healing. Degradation tests have shown that no statistically significant decrease (p < 0.05) in weight was observed over this period, which proves their stability. Both multilayered structures fulfilled the required strength for tendon repair. Interestingly, the AUP/PCL electrospun multilayered structures showed smoother edges than the PCL constructs, making manipulations with tendons easier.

**Conclusion**
The aim of this study was to develop a better solution to repair deep flexor tendons compared to the current state-of-the-art. The constructs were proven to be stable for the required 8 weeks, after which the lesioned tendon moves to an advanced healing. Anti-adhesion (HA) and anti-inflammatory (Naproxen) compounds were successfully introduced in the electrospun constructs. In vitro assays showed that incorporation of these bio-active components was successful and not-cytotoxic for human fibroblasts. These tests also indicated that HA induced a burst release in the PCL constructs, while a prolonged release in the stronger and denser network of AUP/PCL. The mono-layered constructs were insufficiently strong (< 4 MPa) for the intended application. Introduction of an intermediate braided monofilament layer between the electrospun layers led to strengths of 8.56 ± 1.92 MPa as shown by ex vivo sheep tendon tensile tests. It can thus be concluded that the multilayered AUP/PCL electrospun structures represent a very promising mechanical and biological solution to repair deep flexor tendons. A follow-up in vivo study in rabbits is ongoing.

**Acknowledgement**
The authors would like to acknowledge Prof. J. Martins and Mr. Tim Courtin of the NMR department for helping with the NMR measurements and Cousin Biotech for providing the monofilament. The work of N. Pien was supported by a Vanier Canada Graduate Scholarship. P. Dubruel, S. Van Vlierberghe and A. Mignon would like to acknowledge the financial support of the Research Foundation Flanders (FWO) under the form of various research grants. I. Peeters would like to acknowledge the financial support of the UGent Bijzonder Onderzoeksfonds (BOF: Grant no: 01D28316).
Research concept

Within the project, the precursors were first synthesized. They then were combined with anti-adhesive and anti-inflammatory compounds and processed through electrospinning. The final construct exists out of 3 layers, whereby each active compound is in one of the outer layers with a braided monofilament in between those layers. Finally, the constructs were mechanically (ex vivo) and biologically (in vitro) characterized. Currently an in vivo study is ongoing on rabbits.

A wear model to predict in-vivo damage of ACL grafts

Deyo Maeztu Redin¹², Julien Caroux¹², Pierre-Yves Rohan³, Hélène Pillet³, Alexia Cermolacce⁴, Julien Trnka⁴, Mathieu Manassero⁴, Véronique Viateau⁴, Laurent Corté¹²

¹ École Nationale Supérieure des Mines de Paris, Centre des Matériaux, Évry, FR; ² ESPCI, Molecular, Macromolecular Chemistry and Materials, Paris, FR; ³ Arts et Métiers, Institut de Biomécanique Humaine Georges-Charpak, Paris, FR; ⁴ École Nationale Vétérinaire d’Alfort, Laboratoire de Biologie, Bioingénierie et Bioimagerie Ostéo-Articulaire, Maisons-Alfort, FR

Introduction

Anterior cruciate ligament (ACL) reconstruction is a common surgical procedure with overall good outcomes (75%-97%) [1]. Nonetheless, the etiology of ACL reconstruction failure is often unclear. In the frame of surgery planning and graft design, it is of interest to understand and model the mechanisms underlying graft damage. Impingement — interference of the implant with other structures like cartilage and bone — is considered a major reason of failure [2]. Its occurrence is highly sensitive to anatomical variability and graft positioning during surgery. These uncertainties raise a special concern for preclinical trials, since the anatomy of sheep, standard animal model used for ACL grafts, is particularly prone to ACL impingement. In this study, we hypothesise that impingement alone is not sufficient to predict the damage of grafts in-vivo: knee kinematics and the effect of wear due to friction of the graft against the joint surfaces need to be considered. To address this question, we used a sheep model of arthroscopic ACL reconstruction to assess the location and severity of wear occurring on the graft during flexion-extension of the knee. We confronted this damage predictor to in-vivo indicators of damage.

Experimental Methods

Seven sheep (20-41 months, healthy, nulliparous, pre-alpine breed) underwent ACL reconstruction using tendon autografts. The limbs were explanted at three months after ligamentoplasty. For each specimen, biplanar radiographs were acquired using a low-dose X-ray system (EOS, EOS Imaging, Paris, France) and 3D digital models of the femur and the tibia were obtained through a reconstruction algorithm described in a previous study [3]. The cadaveric sheep knee specimens were then tested in vitro using a motorised device to record knee kinematics in flexion-extension. Graft damage was characterised by necropsy observations and ultimate tensile strength (UTS) measurements [4]. The 3D images and kinematic data were used to construct a digital model of each knee (Figure 1). Correlations (Pearson, r) between UTS and model variables (predictors) were studied.

Results and Discussion

From the reconstructed position of femur and tibia of each specimen, we computed the maximum values of strain, torsion angle and impingement volume underwent by the graft during knee flexion-extension. When compared to UTS, none of these variables explain the resistance of the grafts in vivo (r=0.175, r=-0.148 and r=-0.706 respectively) Using kinematic data, a wear model based on Archard’s equation⁵ was thus proposed to assess local wear produced in a knee flexion cycle. The maximum wear attained on the graft (wear index) showed a strong negative correlation with UTS (r=-0.898) and explained the differences among specimens (Figure 2 a). Local wear was compared to necropsy observations, where damage zones were consistent with the predictions (Figure 2 b and c).

Conclusion

These results show that wear is a good predictor of ACL graft damage in-vivo. The simplicity of the proposed wear criterion permits its direct use in surgery planning and implant design to minimise the risk of implant failure. Its application to sheep anatomy provides a straightforward way to increase efficiency and predictive power of preclinical testing, and to reduce the costs, time and number of animals.
Figure 1

Reconstructed 3D images of femur and tibia showing knee flexion-extension kinematics of a limb; $\theta$ knee flexion angle. Data obtained three months after ligamentoplasty.

Figure 2

Figure 2: a) Scatterplot of UTS and wear index. Both variables are negatively correlated; dashed line gives best linear fit. b) Necropsy observation of an operated knee at 3 months after ACL reconstruction. Black arrow indicates damage on the tendon autograft. Crosses show the location of the femoral and tibial insertion points. c) Corresponding prediction of local wear on the graft for the same knee. Black arrow indicates the location of the maximum wear index on the reconstructed ACL.

**Introduction**

The hypovascular and hypocellular nature of tendon tissues severely limits their healing capacity and contribute for loss of functionality and propensity to injury. Although tendon healing follows the common tissue repairing stages of inflammation, proliferation and remodeling, this process is governed by complex biological factors and cellular crosstalk mechanisms that are still poorly understood. A major obstacle to the scientific and clinical advancement of tendon therapies is the lack of reliable and valid models allowing to decipher fundamental aspects of tendon physiology and pathology, as currently available 2D cell cultures and small animal models have shown limited biological relevance. Microengineered 3D models enabling the mimicry of native tissue’s structure and function through the precise deposition and assembly of materials and cells might provide a solution for this challenge. Here we hypothesize that by combining platelet lysate (PL) hydrogel coatings with tendon inspired fiber assemblies with defined 3D architecture, we would be able to recapitulate the biophysical and biological cues of both healthy and diseased tendon microenvironments at the required throughput to produce microphysiological systems for **in vitro** modeling.

**Experimental Methods**

3D microengineered tendon units recreating both physio- and pathological tendon microenvironments were fabricated. Electrospinning was first used for the production of continuous anisotropic fibers [1] that were afterward twisted into more complex yarns to reconstruct the hierarchical 3D structure of healthy tendon fascicles and used as core elements for the production of composite living fibers (CLFs) [2] recreating the structural anisotropy existing in healthy tendon microenvironments (CLFs-Healthy). In contrast, fibrous cores with isotropic topographies were produced to recreate diseased-like extracellular matrix (ECM) organization and induce the expression of degenerative-related markers, as commonly observed in tendinopathies (CLFs-diseased). Human tendon-derived cells (hTDCs) were selected as a native tissue cell source widely used in **in vitro** tendon modeling. To fabricate the CLFs, hTDCs were encapsulated within PL hydrogel coating shells. These PL shells were intended to replicate the interstitial tendon ECM and providing a source of growth factors, structural proteins, and other signaling biomolecules that promote fast construct cellularization and effective matrix deposition, while guiding the hTDCs phenotype commitment depending on the core’s topography. This concept was combined with 3D printed support frames to produce multiplexed assemblies allowing the rapid generation of large numbers of highly reproducible sample replicates fitting multi-well plate formats.

**Results and Discussion**

We harnessed on the synergy between the biological signaling of PL components with the controlled 3D architectures of electrospun microfibers to produce CLFs emulating healthy or diseased tendon tissue states (Fig.1). In CLF-Healthy, encapsulated hTDCs presented high cytoskeleton polarization and alignment, expressed tendon-related markers (scleraxis, tenomodulin, and Mohawk) and deposit a dense tenogenic ECM. In contrast, cell crowding without marked preferential orientation and high ECM deposition were observed in CLF-diseased. Moreover, the observed phenotypic drift characterized by the increased expression of non-tendon related markers and smooth
alpha muscle actin, a myofibroblastic marker, was also reflected on an increased collagen type III / collagen type I ratio. This diseased-like profile was further evident on the observed imbalance between matrix remodeling and degradation effectors, as characteristic of tendinopathy.

**Conclusion**

In summary, taking advantage of biophysical and biological cues for the induction of regenerative and pro-fibrotic phenotypes in human tendon-derived cells, we fabricate microengineered 3D *in vitro* models of tendon healthy and diseased states. Overall, the developed microphysiological systems hold great promise as tools to study tendon physiology and pathology, offering a reliable high-throughput alternative to existing options in the search for new tendon therapies.

Piezoelectric bioink for skeletal muscle tissue engineering.

Claudia Paci1,2, Federica Iberite1,2, Lorenzo Vannozzi1,2, Lorenzo Arrico1,2, Enrico Catalano1,2, Leonardo Ricotti1,2

1 Scuola Superiore Sant'Anna, The BioRobotics Institute, Pisa, IT; 2 Scuola Superiore Sant'Anna, Department of Excellence in Robotics & AI, Pisa, IT

Introduction

3D bioprinting has the potential for becoming a future breakthrough method in the implementation of skeletal muscle tissue engineering. In this domain, the physico-chemical properties of bioinks constitute a crucial aspect that can drive an appropriate cell differentiation [1]. Material chemical cues and mechanical properties have been widely investigated in the last decade. Less explored, yet intriguing, can be the incorporation of exogenous factors (e.g., electrical, magnetic or mechanical stimulation) to further boost cell differentiative processes.

Piezoelectric nanomaterials have been used as nanoscale transducers able to convert mechanically-induced deformation into an electrical cue when invested by an ultrasound wave (acting as a wireless source of mechanical energy). This paradigm has shown beneficial effects on different cell types, in particular accelerating the differentiation of neural and muscle precursors [2,3]. However, no research groups have explored the inclusion of piezoelectric nanoparticles in a bioink used for 3D bioprinting of skeletal muscle cells so far. This work shows preliminary results on the properties of a piezoelectric bioink based on Pluronic/alginate doped with barium titanate nanoparticles and the biological response of C2C12 cells encapsulated in it.

Experimental Methods

BaTiO3 nanoparticles (BTNPs, diameter: ~ 80 nm) were sterilized by autoclave, then added to a filtered solution of propylen glycol alginate (PGA) in deionized H2O at a ratio 1:1 BTNPs/PGA. PGA was used to achieve a stable dispersion of the nanoparticles. A Pluronic/alginate hydrogel (20% w/w Pluronic F127, 2% w/w alginate) was prepared as described in [4]. Four bioink types were prepared: one based on bare Pluronic/alginate without nanoparticles and three ones doped with BTNPs at concentrations of 100, 250 and 500 μg/mL, respectively.

The four bioinks were loaded with C2C12 myoblast cells at a density of 2x10^6 cells/mL. The bioinks were then printed with a 3D Bioplotter (Envisiontec GmbH), depositing one layer (7x7 mm^2) of parallel fibers (nozzle diameter: ~ 250 μm) at 37°C with a pressure of 0.4 bar and a relative speed of 10 mm/s. The constructs were then crosslinked with 1 mL of a 25 mM CaCl2 solution for 10 min.

SEM imaging and EDX were carried out with a Helios NanoLab 600i Dual Beam system provided with a Bruker Quantax EDX Detector.

Rheometric analyses were carried out through an Antoon Paar MCR 302 Rheometer using a plate-and-plate geometry at 37°C.

For viability tests, the four constructs were maintained for 72 h in DMEM supplemented with 10% FBS and 1% Pen-Strep (basal medium). On day 1 and day 3, cell viability was evaluated using LIVE/DEAD™ and PrestoBlue™ assays (Invitrogen).

For differentiation experiments, two constructs (non-doped and doped with 250 μg/mL BTNPs) were cultured in basal medium for 5 days and then cultured for 7 days in two different differentiation media. Medium 1 consisted of DMEM supplemented with 1% ITS, 1% FBS and 1% Pen-Strep. Medium 2 consisted of DMEM supplemented with 10% HS, 1% Pen-Strep and 50 ng/mL IGF-1. After 7 days, the expression levels of GAPDH, MYOD1, MYOG, ACTA1, MYH2, MYH4, CSRP3 and ACTN2 were assessed through real-time qRT-PCR.
All experiments were performed at least in triplicates for each condition.

**Results and Discussion**

Preliminary printing efforts (Figure 1a) allowed selecting 0.4 bar as the optimal pressure value, which was used for the following experiments.

SEM images and EDX results (Figure 1b) showed that BNTPs were uniformly dispersed in the printed hydrogels, even at high concentrations of nanoparticles.

Rheometric results are shown in Figure 1c. No significant differences were observed between the different bioinks in terms of storage, loss moduli and viscosity. Viscosity decreased under shear strain, showing a shear-thinning behavior.

Viability tests (Figure 2a,b) revealed a good cytocompatibility of doped structures up to a BNTP concentration of 250 μg/mL. Hydrogels doped with 500 μg/mL BNTPs showed lower cell viability. Thus, the highest nanoparticle concentration was excluded. The bare bioink and the one doped with 250 μg/mL BNTPs were tested in the subsequent differentiation experiment.

After 7 days of differentiation, gene expression was compared with respect to GAPDH. Results are shown in Figure 2c. Medium 1 led to better results in comparison with medium 2. Interestingly, the nano-doped bioink promoted a significantly higher expression of *MYOD1*, *MYOG*, *ACTA1* and *CSRP3* (key genes in the early myogenesis phases), with respect to the bare one.

**Conclusion**

The preliminary results reported in this work demonstrate the potential of piezoelectric bioinks for the development of 3D bioprinted skeletal muscle constructs. Future experiments will focus on ultrasound stimulation of such constructs, thus to exploit the piezoelectric nature of the embedded nanoparticles and to achieve an indirect electrical stimulation of the differentiating cells, boosting myogenesis in 3D bioprinted systems.

Introduction

Volumetric muscle loss (VML) resulting from traumatic incidents drastically decreases muscle regeneration capacity and lacks treatments1. Tissue engineering approaches using biomaterials to guide the functional regeneration of tissues and organs are of high potential for VML management. Among biomaterials, hydrogels are promising therapeutic candidates due to their excellent biocompatibility, their similarity to native extracellular matrices (ECM) in terms of water retention and cell adhesion, and injectable potential. However, their regeneration capacity is strongly reliant on the presence of a porosity to allow cell infiltration and efficient vascularization. Therefore, the aims of this study were (1) to find the optimum conditions of a recently developed hydrogel composed of poly-lysine dendrimers (DGL) and NHS-polyethylene glycol (PEG) hydrogel to interact with muscle cell progenitors (myoblasts) and then (2) create a porosity inside the network through a novel biocompatible effervescent approach suitable with its injection. Finally, the ability of these new porous and injectable formulations to sustain myoblast proliferation and differentiation were evaluated for skeletal muscle regeneration purposes.

Experimental Methods

To determine the most suitable environment for myoblasts, dense hydrogels were prepared by mixing various ratios and concentration of DGL (third generation) and PEG-NHS (MW 2kDa), and their mechanical properties were measured in compression. Mouse myoblasts (C2C12) were cultured on 2D hydrogels and their proliferation, spreading and mobility were quantified using image analysis and time-lapse video microscopy. Formation of skeletal muscle cells (myotubes) was appreciated with myosin heavy chain (MHC) antibody staining. To obtain a porosity suitable with injection, acetic acid (Aa) and potassium carbonate (Kc) were dissolved to DGL and PEG solution precursors with a surfactant. Resultant solutions were subsequently injected using a dual-chamber syringe connected to a static mixer and the porosity characterized by image analysis from 200 µm stacks realized by confocal laser scanning microscopy. EPH cytocompatibility toward human dermal fibroblasts was studied along with their biocompatibility in subcutaneous injection in mice. Effervescent porous hydrogels (EPH) ability to sustain muscle cell proliferation in 3D was finally explored by evaluating the behaviour of human primary myoblasts seeded on EPH of various concentrations.

Results and Discussion

As hydrogel stiffness was modulated from 10 to 150kPa (Fig.1A), C2C12 behaviour in proliferative conditions was strongly influenced in terms of cell spreading, morphology and mobility on the support. The optimal behaviour was observed for hydrogels between 50 and 150 kPa (Fig. 1B). Surprisingly, C2C12 subsequent ability to differentiate after 6 days was greatly linked to the DGL/PEG ratios, irrespectively of hydrogels stiffness. Therefore, conditions of interest for myoblasts proliferation and differentiation could be targeted for the engineering of a porosity able to sustain cellular infiltration inside the hydrogel. Through careful optimization of effervescence parameters, we found that with the correct ratio of Aa and Kc, we obtained a spontaneous and interconnected porosity remnant of the
produced CO\textsubscript{2} bubbles entrapment inside simultaneously generated DGL/PEG network (Fig. 1C). Resultant effervescent porous hydrogels (EPH) with pore size of about 200 µm and a porosity of 75 % sustained cellular infiltration and spreading (Fig. 1D). Moreover, EPH were proven biocompatible by subcutaneous injection in mice (Fig. 1E) with extensive vascularization (Fig. 1F) confirming their potential for regeneration purpose.

EPH suitability for myoblasts differentiation was assessed by seeding primary human myoblasts\textsuperscript{2} (phMs) on the top of 2 mm thick EPH cylinders. Formation of skeletal muscle cells (myotubes) was appreciated with myosin heavy chain (MyHC) and α-actinin antibodies staining after 6 and 10 days in serum-depleted medium showing an extensive cell fusion with visible striation (Fig 2A, B and C). As a striking result, spontaneous contractions of phMs were observed and maintained up to 6 days inside EPH. The presence of quiescent satellite cells inside EPH was evaluated with myogenic regulatory factor Pax7, early stage myogenic marker MyoD and cell cycle marker ki67. The presence of quiescent and non-differentiated cells inside EPH was confirmed after 6 and 10 days in differentiation(Fig 2D and E). These results consolidate EPH potential for muscle fibre maturation while preserving a pool of reserve cells\textsuperscript{3}, holding promise for tissue engineering applications.

**Conclusion**

Hence, we describe here a novel porous hydrogel with potential as scalable solution for VML treatments, providing an optimal support for muscle cells progenitors to differentiate into contractile myotubes, while maintaining a pool of undifferentiated, quiescent cells within a swift and straightforward injectable delivery.

Biomaterials field is growing in the last decades due to the increased life expectancy of the world population. Nowadays, the study of biomaterials has been extended to several areas with a focus on the volume and surface properties. Thus, the discussion of advances in new materials with multifunctional surfaces becomes strategic to our area.
ESB-SLABO S-KL01

New trends in multifunctional surface modification of stable and biodegradable biomedical implants

Julietta Rau

Italian National Research Council (CNR), Institute of the Structure of Matter (ISM), Rome, IT

In a near future, a substantial increase of biomedical implants’ demand is expected due to a dominant demographic phenomenon - population ageing and life expectancy rising. The main requests for implants are good osteointegration and long-term stability. For this purpose, metallic implants are coated with biomimetic functional materials improving their properties, and consequently, their integration with the surrounding hard tissue. In this work, the results obtained for novel biomaterials possessing various functional characteristics designed for coatings on titanium and on biodegradable metal alloys are reported. In the case of biodegradable implants, the focus points are controlling their degradation rate and imparting them with additional bioactivity properties. The developed coating materials are based on substituted calcium phosphates and bioactive glasses of innovative composition, containing trace elements with therapeutic functions, which are involved in natural bone and connective tissue formation. The effect of trace elements on cell functions is dose-dependent and its release is carefully tuned. Various aspects of coatings’ development, among them antibacterial properties, are focused. The coatings’ deposition procedure and corresponding conditions are selected. Comprehensive characterization of the coatings is performed: structural, morphological, mechanical, wetting contact angle, and magnetic properties, electrochemical tests in simulated body fluid, etc. are reported. In vitro bioactivity, microbiology and cell tests results are presented, focused on material-cell interactions, and, in particular, on trace ion influence. The obtained results suggest that novel biomimetic nanostructured implant materials can be particularly relevant for new strategies in tissue replacement and regeneration.
Functionalization of materials for biomedical applications using anodic oxidation

Ana Paula R. Alves Claro

São Paulo State University, Materials and Technology, Guaratinguetá, BR

In recent years, titanium alloys have been studied as substitute materials for bone tissue repair. These materials are considered bioinert, i.e., they do not induce a specific response after implantation in the host. Another class of metallic materials used in the biomedical area, for the production of implants, are biodegradable metals, and their use has progressively increased in the last 5 years. These materials have the advantage that they are eliminated from the body gradually and do not need to be removed using surgical techniques. For these two kinds of materials, it is possible to improve their use, from the functionalization of the surface. Anodic oxidation has a prominent role among the different techniques used to produced well-ordered tube structures in metals surfaces. The size of the nanopores or nanotubes, the thickness of the layer, and the surface roughness could be easily controlled by optimizing the experimental parameters such as voltage, temperature, and time, which will affect positively the biological properties and response of these surfaces. Studies have been indicated the viability of this technique and the increase of the performance of these materials. The use of anodic oxidation on degradable metals even affected their degradation rate with values higher than those verified for materials without surface treatment. In the case of titanium alloys, an increase in cell adhesion and proliferation was verified, which accelerated the osseointegration process.

Investigating the potential of gelMA-encapsulated human iPSC-derived chondrocytes for joint surface regeneration

Hannah Agten1,3, Inge Van Hoven2, Samuel Ribeiro Viseu2, Jasper Van Hoorick4, Luis Freitas Mendes1,2, Sandra Van Vlierberghe4, Frank P. Luyten1,2, Veerle Bloemen1,3

1 KU Leuven, Prometheus, Division of Skeletal Tissue Engineering, Leuven, BE; 2 KU Leuven, Skeletal Biology and Engineering Research Center, Leuven, BE; 3 KU Leuven, Materials Technology TC, Campus Group T, Leuven, BE; 4 Ghent University, Polymer Chemistry & Biomaterials Group, Centre of Macromolecular Chemistry, Ghent, BE

Introduction
Joint surface defects in articulating joints have limited healing potential and can extend into the underlying subchondral bone. Osteochondral defects are a strong risk factor to develop osteoarthritis. Tissue engineering strategies therefore aim at a sustainable repair of deep joint surface defects in an early stage. The production of living implantable cell-based 3D constructs is promising, but a lack of suitable cell sources and insufficient process reproducibility and design complexity and have hampered the translation into a clinically relevant product. Recent advances in additive manufacturing have paved the way for extrusion-based bioprinting, an enabling technology that could overcome these limitations by layer-by-layer deposition of bioinks consisting of cells encapsulated in hydrogels.

Experimental Methods
In this study, bioprintable methacrylated gelatin (gelMA) was combined with human iPSC-derived chondrocytes, with the aim of producing cartilaginous tissue analogs. After crosslinking the bioink with the help of Li-TPO photo-initiator at 365 nm in polytetrafluoroethylene moulds, cell-laden gel constructs (4x4x2 mm³) were cultured in chondrogenic medium for up to 4 weeks. In vitro performance was evaluated using histology, immunohistochemistry and unconfined uniaxial compression and compared to controls cultured in standard growth medium. Additionally, constructs were implanted ectopically in nude mice 24h after preparation as well as after 21 days of in vitro culture for in vivo evaluation after 4 weeks.

Results and Discussion
Histology showed a homogeneous cell distribution in the cross-linked hydrogel, with an increasing number of cells over the course of the study, as also confirmed by DNA quantification. Moreover, on day 21, significantly more cells were present in the constructs cultured in differentiation medium as compared to those cultured in standard growth medium. After 21 days in differentiation medium, the cell-laden constructs deposited a sulphated glycosaminoglycans (GAGs) matrix in the hydrogel as documented by Alcian Blue- and Safranin O staining. In addition, these GAGs were uniformly distributed throughout the construct. Immunohistochemistry also indicated the uniform distribution of collagen type II, whereas collagen type I was only present in a thin layer on the outer surface. In growth medium, no relevant deposition of matrix components was observed, with only very limited Safranin O staining in the pericellular space. These findings were confirmed by uniaxial compression tests, indicating no significant changes in stiffness of the constructs in growth medium, as opposed to a 3 to 4–fold increase in the differentiation conditions. Samples implanted in vivo subcutaneously in nude mice generated cartilage-like constructs after 4 weeks, that were more intensely Safranin O positive than those cultured in vitro only. When 21 days of in vitro priming preceded the implantation, we observed more mature matrix formation compared to early implantation.

Conclusion
iPSC-derived chondrocytes encapsulated in gelMA can generate robust cartilage-like tissue analogs in vitro and in vivo. When primed with a potent chondrogenic medium, a more mature type of cartilage is observed. Taken together,
these data suggest that gelMA combined with iPSC-derived chondrocytes is a potent bioink for off-the-shelve bioprinting strategies for joint regeneration.

Anand constitutive model of the pure titanium thermoplastic deformation process

Jakub Bańczerowski, Marek Pawlikowski

Warsaw University of Technology, Faculty of Production Engineering/Institute of Mechanics and Printing, Warsaw, PL

Introduction

Pure titanium requires plastic deformation processing in order to increase its strength [1]. This process depends on many parameters such as strain rate, temperature, coefficients of strain hardening and softening and others [2]. To ensure stability and repeatability of this process, constitutive equation must be applied [3]. The goal of the study is to formulate a new constitutive model describing the process. The behavior of the material during deformation indicates its viscoplastic character, which can be described by Anand model [4].

Experimental Methods

CP titanium (Ti) samples were compressed at elevated temperatures (775 K÷875 K) at different strain rates ($\varepsilon=10^{-2}\div10^1$) to the constant strain $\varepsilon=0.6$ in a Gleeble thermomechanical simulator. The data in the form of stress-strain graphs was acquired from the experiment and served to calculate material parameters for this equation.

The Anand model defines strain rate as:

$$\varepsilon_p = A\ast\exp\left(-\frac{Q}{RT}\right)\ast\sinh\left(\xi*(\sigma/s)\right)^{1/m}$$

(1)

where $\varepsilon_p$ [s-1] is strain rate, $\xi$ - stress multiplier, $s$ - material constant characterizing effects of strengthening mechanisms, $m$ - strain rate sensitivity, $Q$ [kJmol$^{-1}$] - activation energy of plastic strain, $R$ - universal gas constant, $T$ [K] - temperature, $\sigma$ [MPa] - flow stress;

Equivalent stress is as follow:

$$\sigma = cs; c<1$$

(2)

where $c=(1/\xi)*\sinh^{-1}\left\{[\varepsilon_p/A*\exp(Q/RT)]^m\right\}$

(3)

The rate of variable $s$ changes is described in the following evolution equation:

$$s_r = h(\sigma, s, T)\varepsilon_p$$

(4)

The function $h$ is associated with dynamic recovery and strain hardening. The specific form of this equation is given:

$$s_r = h_0*(A-(s/sr))^{a}*\text{sign}(1-(s/sr))\varepsilon_p; \quad a>1$$

(5)

where

$$s_g = s_d*A*\exp(QRTn)$$

(6)

Variable $s_g$ is a saturation value of $s$, $h_0$ - hardening/softening constant, $n$ - strain rate sensitivity, $s_d$ - coefficient of deformation resistance.

Analogically we can formulate saturation value of stress $\sigma_g$:

$$\sigma_g = (s_g/\xi)^{A*(\varepsilon_p/\exp(Q/RT))^{m}}*\sinh^{-1}\left\{[\varepsilon_p/A*\exp(Q/RT)]^m\right\}$$

(7)

Finally, we can formulate stress as:

$$\sigma = \sigma_g - [(\sigma_g - c\sigma_0)^{1-a} + (a+1)(ch_0*\sigma_0^{a})^{1/(1-a)}]$$

(8)

where $\sigma_0$ is the initial value of $s$.

To acquire all the constants following procedure was applied. Saturation stress was determined from the stress-strain graphs. The variables $A$, $Q$, $\xi$, $m$, $s$, $n$ were calculated using nonlinear least square method. The $\xi$ parameter is
selected in such a way, that c variable in (2) is less than 1. The constants $ch0, cs0, a$ are determined by the nonlinear square fit from the constant strain rate data.

**Results and Discussion**

Models fitted to data were relatively precise with the R-square equal 0.935. Confidence bounds were 0.95. The model describes much better deformation processes in higher temperatures (875 K).

**Conclusion**

The applied model provides precise fit mostly in plastic deformation zone. Anand model is promising, due to its ability to predict material behavior during both, elastic and plastic deformation. The further work should apply this model into the finite element simulation of the titanium processing in order to find the best input parameters leading to desired material properties.

Modulation of microenvironment of cells by bioactive surface coatings based on layer-by-layer technique

**Thomas Groth**¹, Reema Anouz¹, Husnia Kindi¹, Yazmin B. Barerra¹, Christian Woelk², Christian Schmelzer³

¹ Martin Luther University Halle-Wittenberg, Institute of Pharmacy, Department Biomedical Materials, HALLE, DE; ² Leipzig University, Institute of Pharmacy, Pharmaceutical Technology, Leipzig, DE; ³ Fraunhofer Institute for Microstructure of Materials and Systems, HALLE, DE

Introduction

Layer-by-Layer technique (LbL) has been widely used to make bioactive and biomimetic multilayer surface coatings and 3D systems. The wide range of polyelectrolytes from synthetic and natural sources as well as complexation conditions can help to tailor the microenvironment of cells towards molecular composition and mechanical properties. Particular interesting is the fact that extracellular matrix (ECM) components, such as proteins, proteoglycans and glycosaminoglycans (GAG) can be used for multilayer formation due to their polyelectrolyte character. In addition, also larger charged entities such as liposomes or lipoplexes can be used for the multilayer formation process. Eventually, LbL provides an elegant tool to mimic the complex composition of ECM by selection of components that address integrins and growth factor receptors to promote growth and differentiation of cells. Further strategies of using LbL can also be based on cross-linking them with metal ions and in situ transfer of drugs or nucleic acids to program cell behavior. We intend here to provide a brief survey on the potential of LbL technique to control differentiation of stem and other cells by selection of ECM components, strategies of cross-linking, uploading of growth factors.

Experimental Methods

Layer-by-layer technique was performed by dip coating glass slides or silicon wafers as model surfaces in polyelectrolyte solutions (polyanions and polycations) until a minimum of 10 layers was achieved. Collagen I and chitosan were used as polycations. Chondroitin sulfates, and hyaluronan either in native form or oxidized by sodium periodate were used as polyanions. Oxidation of GAG was done to permit intrinsic cross-linking with polycations through imine bond formation. Additionally, uploading of growth factor BMP-2 or cross-linking the multilayers with metal ions calcium, cobalt, copper, and iron ions was done. Different types of cells were cultured on multilayers including C2C12 myoblast, the multipotent mouse fibroblast C3H10T1/2 or adipose-derived stem cells (ADSC). Cell culture was done under standard conditions without differentiation factors. Cell adhesion was studied by confocal laser scanning microscopy staining focal adhesions, cell cytoskeleton and nuclei. Cell differentiation was assessed by CLSM staining matrix components, RT-PCR and histochemical staining.

Results and Discussion

Studies with ADSC and C2C12 myoblasts that were cultured on multilayers made from either native or oxidized chondroitin sulfate showed that multilayers prepared from oxidized GAG are not only stiffer than those made of native GAG, but promoted osteogenic differentiation of ADSC to a higher extent. In addition, it was observed that uploading the growth factor (GF) BMP-2 to multilayers made of oxidized GAG inhibited the release of BMP-2 accompanied by stronger spreading of C2C12 myoblasts and significantly more osteogenic differentiation of these cells compared to multilayers made of native GAG. The underlying mechanism of this enhanced activity of BMP-2 on cross-linked multilayers is probably related to a juxtacrine presentation of the GF to the corresponding receptor and a cross-talk to integrin related signaling pathways as found in other studies. Further studies were done with multilayers made of native hyaluronan and chitosan (Chi/HA)5 cross-linked by metal ions Ca²⁺, Co²⁺, Cu²⁺ and Fe³⁺. Most
interestingly, Fe\(^{3+}\) metal ions promoted adhesion and spreading of C3H10T1/2 cells greatly on the low adhesive [Chi/HA]₅ PEM system. The intrinsic cross-linking of multilayers with Cu\(^{2+}\) and Fe\(^{3+}\) ions led to increased metabolic activity in cells after 24 h and induced cell differentiation towards adipocytes in the absence of any additional adipogenic media supplements. We found indications that cross-linking of [Chi/HA]₅ with metal ions multilayers can occur both through coordination chemistry but also Coulomb interaction, particularly for Ca\(^{2+}\) and Fe\(^{3+}\) with carboxylic groups of HA. However, the assume that major effects on cell spreading and differentiation are not based on the minor changes of physicochemical properties of cells, but rather the chemical effects of metal ions taken up by cells.

**Conclusion**

Overall, the studies demonstrate the potential of LbL technique to fabricate multifunctional surface coatings for implant materials or tissue engineering scaffolds that can control the microenvironment of cells by changing chemical cues through the selection of matrix components and uploaded growth factors that correspond to the composition of desired tissues (e.g. chondroitin sulfate, collagen I and BMP-2 for bone). Moreover, intrinsic-cross-linking that represents a biocompatible, non-toxic procedure to cells is not only changing mechanical properties of these coatings, but also controls the release and presentation of growth factors or metal ions permitting cell differentiation without exogenously added factors.

Glycerylphytates: alternative bioactive natural-based crosslinkers for the fabrication of hydrogel matrices in tissue engineering

Ana Mora-Boza\textsuperscript{1,2}, Andrés J. García\textsuperscript{1}, Julio San Román\textsuperscript{2}, Blanca Vázquez-Lasa\textsuperscript{2}

\textsuperscript{1} Georgia Institute of Technology, Woodruff School of Mechanical Engineering and Petit Institute for Bioengineering and Bioscience, Atlanta, US; \textsuperscript{2} Institute of Polymer Science and Technology (ICTP-CSIC) and CIBER-BBN (Health Institute Carlos III), Spanish National Research Council, Madrid, ES

Introduction
A major objective in regenerative medicine research is the development of bioactive hydrogels to be applied as functional tissue matrices in regenerative medicine. Thus, many efforts are focused on new crosslinking agents and strategies that provide suitable hydrogel matrices for effective tissue regeneration. Here, we established the synthesis and application of a novel family of natural-occurring crosslinkers derived from the antioxidant agent, phytic acid. Phytic acid has attracted much attention in the biomedical field as it is claimed to act as an anticancer agent, as a lipid peroxidation inhibitor, as a preventive agent of calcifications, and as an anti-osteoporotic compound \cite{1}. Our novel crosslinkers, glycerylphytates (G\textsubscript{x}Phy), were obtained through a condensation reaction between phytic acid and glycerol, focusing on the development of two crosslinkers, G\textsubscript{1}Phy and G\textsubscript{3}Phy, that were successfully applied for the preparation of bioactive hydrogel-based matrices using traditional fabrication techniques (e.g. solvent casting) and next generation of biofabrication techniques (e.g. 3D printing and microfluidics), where the choice of an appropriate crosslinker will determine the successful synthesis of effective hydrogel matrices.

Experimental Methods
Glycerylphytate (G\textsubscript{x}Phy) crosslinkers were obtained through a condensation reaction between phytic acid and glycerol. Two G\textsubscript{x}Phy crosslinkers having different content of glyceryl moieties were synthetized, G\textsubscript{1}Phy and G\textsubscript{3}Phy. The condensation reaction and synthesis of phytic acid derivatives were confirmed by \textsuperscript{1}H NMR and \textsuperscript{13}C NMR spectroscopy, elemental analysis, TGA, and ICP-OES. Antioxidant activity was evaluated by Ferrozine and lipid peroxidation assays, and their biological behaviour was assessed on human mesenchymal stromal cells (hMSCs). G\textsubscript{x}Phy compounds were applied as ionic crosslinkers for the preparation of: (i) 2D chitosan hydrogel membranes using solvent casting methodology; (ii) 3D printed multi-layered scaffolds using a dual-step crosslinking strategy; and (iii) bioactive stem cell-laden chitosan-based microgels using droplet-based microfluidics.

Results and Discussion
A novel family of crosslinking agents based on phytic acid, G\textsubscript{x}Phy, were developed. Specifically, we focused on two derivatives, G\textsubscript{1}Phy and G\textsubscript{3}Phy, which incorporated an average of one and three glyceryl moieties, respectively. Both G\textsubscript{x}Phy compounds demonstrated excellent antioxidant activities and improved cytocompatibility in comparison to its precursor \cite{2}. These crosslinking agents are novel at two different levels: G\textsubscript{x}Phy act not only as cytocompatible and natural-occurring crosslinkers with powerful gelation properties, but also as biologically active components of the developed systems in comparison to other traditionally applied crosslinking agents that lack of bioactivity (e.g. TPP, genipin).

G\textsubscript{3}Phy was applied as ionic crosslinker of chitosan membranes, providing improved osteogenic and osteoinductivity potential by increasing calcium deposition, and alkaline phosphatase (ALP) activity on cultured hMSCs in absence of any typical osteoinducer agent \cite{3}. These G\textsubscript{3}Phy-crosslinked membranes provided a suitable environment for hMSC culture and differentiation into osteoblastic lineage, arising as attractive substrates for guided bone regeneration. G\textsubscript{1}Phy was applied for the fabrication of 3D printed scaffolds using a dual crosslinking strategy for natural-based polymer inks based on chitosan and methacrylated gelatin (GelMA). The applied methodology...
consisted of an initial UV photopolymerization step simultaneously to 3D deposition, followed by a post-printing ionic crosslinking treatment with G1Phy. This approach enabled the fabrication of 3D scaffolds with high shape fidelity and resolution, without the collapse of the consecutive printed layers. Our G1Phy ionic crosslinking agent provided adequate swelling and long-term stability properties to the 3D scaffolds, and good in vitro biological performance of 3D printed multi-layered structures on L929 fibroblast cultures, which showed successful results in terms of adhesion, spreading, and proliferation in comparison to TPP [4]. Finally, G1Phy was used for the generation of chitosan-lactate microgels in a flow-focusing microfluidic device via in situ crosslinking reaction for hMSCs encapsulation applications. The incorporation of G1Phy to chitosan-based microcarriers provided them with some remarkable features in terms of enlargement of viability of encapsulated hMSCs and upregulation of paracrine signaling at adverse conditions (e.g. oxidative stress and inflammation) [5].

**Conclusion**

The developed crosslinking agents were efficient in fabrication of hydrogel matrices in different biofabrication strategies, and demonstrated their versatility and suitability for tissue engineering and regenerative medicine fields. We envision that they will have a profound impact on the preparation of natural-derived hydrogels systems.

Methacryloyl mucin - tannic acid double network hydrogels

Elena Olaret, Brindusa Balanuca, Andra M. Onas, Jana Ghitman, Horia Iovu, Izabela C. Stancu, Andrada Serafim

University Politehnica of Bucharest, Advanced Polymer Materials Group, Bucharest, RO

Introduction

Mucin represents the major component of mucus and contains a long polypeptide backbone on which dense brushes of carbohydrate chains are grafted \[1\]. The complexity of its structure proved to be appealing and mucins have been studied for applications as carriers for bioactive species \[2\], coatings with improved tribological performance \[3,4\] or anti-fouling agents \[5\]. However, its use in the biomedical field is still underexploited.

This work presents a two-step procedure of obtaining double network (DN) systems based on methacrylic anhydride-modified mucin (MuMA) by (1) covalent bonding of MuMA methacrylate groups through radical photo-polymerization, leading to single network (SN) hydrogels and (2) hydrogen bonds (H-bonds) formed between the carboxyl side groups of the protein with the hydroxyl groups of tannic acid (TA).

Experimental Methods

Following the synthesis and characterization of MuMA, various SN stable hydrogels were prepared using reaction media with different pH values. The SN hydrogels were converted into DN systems through incubation in TA solution. The affinity for aqueous media of both SN and DN hydrogels was assessed and the mechanical properties of the obtained systems were evaluated both at macroscale - through rheology and compression tests and microscale - through nanoindentation tests.

Results and Discussion

Results on the characterization of the newly obtained product (MuMA) revealed that (i) the mucin protein structure was not altered by the methacrylation and (ii) MuMA maintains the pH dependency of the pristine mucin leading to different folding of the protein chains, as shown by circular dichroism spectroscopy (fig. 1). Following the photo-polymerization of the double bonds of the methacryloyl groups, DN systems were obtained through the incubation of the obtained SN hydrogels in tannic acid (fig. 2, A). The successful formation of a secondary network was demonstrated for all systems by the noteworthy differences in swelling ability, referring to both the time required for attaining the hydration equilibrium, as well as their swelling content (approx. three times higher in SN vs. DN systems) (fig. 2, B). Furthermore, mechanical tests showed that the supplementary crosslinking leads to more robust systems that require additional effort to be deformed: the SN hydrogels break around a strain of 30 – 40 %, but are able to undergo higher deformation, while the DN systems require a significantly higher stress to be deformed at the same strain value (around 1.5 ÷ 3 fold for a 30% deformation). While the rheological tests showed that the supplementary reinforcement of the hydrogel brought by the presence of H-bonds was not accompanied by the stiffening of any chain parts, the nanoindentation tests revealed an immobilization of the macromolecular chains on the surface of the synthesized materials which might be beneficial for cells adherence.

Conclusion

The registered results demonstrated the ability of MuMA to form robust DN systems with the ability to uptake large amounts of aqueous media without losing their integrity. The high water uptake ability and macro and micro scale mechanical properties, indicate that these systems may find applications in the field of load bearing soft tissue regenerative medicine. Further studies will envisage the stability of these systems in simulated body fluids and their ability to sustain cell adherence and proliferation, using relevant cell cultures.

Photocrosslinkable hydrogels from solubilized extracellular matrix of the amniotic membrane

Inês A. Deus, Catarina A. Custódio, João F. Mano

University of Aveiro, Department of Chemistry, CICECO - Aveiro Institute of Materials, Aveiro, PT

Introduction
Recently, three-dimensional (3D) cell culture platforms have emerged as valuable tools with potential to increase the accuracy of in vitro studies. Inspired by the extracellular matrix (ECM) that compose living tissues, these platforms have been designed to support the attachment and growth of cells, therefore providing reliable data on how they behave and respond to stimulus when within their natural environments\(^1\). Despite the great advances made on the design of such materials, including the development of decellularize matrices and ECM-based hydrogels, recapitulate the complexity and function of human native tissues, while producing cost-effective and safe materials, remains a challenge\(^2\).

Towards this goal, here we propose the use of perinatal tissues as a source of proteins to develop 3D cell culture platforms. Amniotic membrane (AM) is the innermost part of the foetal membrane which surrounds and protects the fetus during gestation. The potential of this tissue has long been recognized in tissue engineering and regenerative medicine applications due to its richness in ECM proteins and other important components, including growth factors and cytokines\(^3\). However, its use for cell culture applications remains quite under explored, probably due to the lack of adequate mechanical properties of the so far described AM-based hydrogels\(^4\). Here, we report the development of a chemically modified AM-based hydrogel which can be cured upon light exposure and tuned according to the intended application.

Experimental Methods
Human placenta was obtained from consenting mothers in a collaboration with the Centro Hospitalar do Baixo Vouga (Aveiro, Portugal). The AM was isolated from the rest of the tissue, decellularized using detergents (sodium dodecyl sulfate (SDS) and Triton X-100) and solubilized with pepsin. Decellularization efficiency was analysed by histomorphological analysis, 4',6-dimidino-2-phenylindole (DAPI) staining and DNA quantification. ECM preservation was also assessed by quantifying collagen and glycosaminoglycans before and after processing. AM methacrylated (AMMA) was produced by reacting the AM-derived ECM with methacrylic anhydride at two different ratios to obtain distinct degrees of modification\(^5\). Thereafter, AMMA hydrogels were prepared with concentrations of 1, 2.5 and 5\% (w/v) and polymerized upon UV light irradiation in the presence of a photoinitiator. The resulting hydrogels were characterized in terms of structure and mechanical properties through cryoSEM, compression tests and rheological analysis. For cell culture experiments, human bone marrow stem cells (hBM-MSCs) were encapsulated and maintained in culture for 7 days. Cell viability, morphology and proliferation were assessed at pre-determined time-points.

Results and Discussion
In this work, a detergent-based protocol was used to decellularized human AM. Histomorphological analysis and DAPI staining revealed no cell nucleus and good retention of key ECM components. These results were corroborated by DNA, collagen and GAGs quantification. After decellularization, AM was digested with pepsin which resulted in a soluble form of the ECM (dAM-derived ECM).

AM-derived ECM was reacted with methacrylic anhydride (MA) to produce a photopolymerizable material. TNBSA was used to confirm functionalization and assess methacrylation degree. Varying the ratios of MA to AM concentration resulted in the production of materials with low (AMMA100) and high degree (AMMA300) of modification.
modification. Robust hydrogels were obtained with concentrations ranging from 1 – 5% (w/v). Developed hydrogels had different porosities and stiffness as revealed by CryoSEM and compression/rheological tests, respectively. No effects were detected in hydrogel’s water content. Together, these results suggest the production of tuneable materials.

Lastly, cell culture experiments were conducted to evaluate the cytotoxicity and cell supporting ability of AMMA hydrogels. As depicted on figure 2, encapsulated hBM-MSCs were able to adhere and proliferate up to 7 days in culture. Live/dead images revealed no cytotoxic effects, while DAPI/Phalloidin staining evidenced good cell-ECM intertalk. MTS assay and DNA content results were consistent suggesting suitable proliferation rates.

**Conclusion**

Here, we demonstrated for the first time that solubilized AM-derived ECM can be successfully modified with photoresponsive groups to produce an easy-to-handle and highly versatile biomaterial. It is important to note, that as fully human, these materials have great potential to improve the accuracy of in vitro studies and possibly accelerate the process of drug development, reduce costs currently associated to late-stage drug failures and reduce or completely eliminate the use of animal models. Additionally, as a xeno-free option this platform may be used to expand cells intended for cellular therapies or to develop tissue-like constructs avoiding the risk of xenogeneic disease transference and reducing the probability of adverse immune responses.

Introduction
Balanced parenchymal-stromal cells and cell-matrix interactions are central to breast tissue homeostasis and become dysregulated in diseases such as cancer. The breast tissue microenvironment is complex, and in vitro models that recapitulate both its 3D architecture, the direct contact between different cell types, and cell-matrix interactions, are still scarce (Rodrigues, J. et al, 2020). To address this challenge, we designed a hybrid hydrogel system integrating both stromal and parenchymal breast tissue. For the stromal compartment, we built a porous 3D printed alginate scaffold seeded with human mammary fibroblasts (hMF). After hMF colonization, the pores were filled with in situ forming alginate hydrogel (Bidarra, et al, 2016) with mammary epithelial cells (MCF10A) that developed into prototypical mammary gland-like organoids, in direct contact with hMF and their ECM. After co-culture, the whole system could be dissolved under mild conditions, allowing both cell and ECM recovery for downstream analysis, thus proving to be an excellent tool for dissecting stromal-epithelial cell crosstalk in vitro, in both health and disease contexts.

Experimental Methods
Ultra-pure alginate was grafted with integrin-binding (RGD) and protease-sensitive (PVGLIG) peptides and used as scaffolding material (Fonseca, K.B. et al, 2011). Extrusion 3D printing was used to build ionically crosslinked multi-layered porous scaffolds of RGD-alginate, which were freeze-dried and then re-hydrated before hMF seeding. Gel-precursor solutions of RGD/PVGLIG-alginate with MCF10A cells and crosslinking agents (CaCO3, GDL) were added to the pores, forming a hydrogel in situ. In both compartments, cell and ECM morphology/distribution and phenotypic makers were analysed by immunostaining and confocal microscopy of whole-mounted samples. After co-culture, the system was dissolved (EDTA) and cells were recovered, isolated by FACS and analysed by RT-PCR. The ECM retained in the hydrogel was analysed by proteomics.

Results and Discussion
Upon rehydration, the 3D printed scaffolds perfectly fitted the wells of 48 well-plates. The seeded hMF were able to adhere, proliferate and produce endogenous ECM, uniformly colonizing the filaments of the scaffolds, without clogging the pores. The gel precursor mixture of RGD/PVGLIG-alginate with MCF10A cells completely filled the pores, where epithelial cells proliferated and formed acinar-like structures, recapitulating the mammary gland. The modification of alginate with protease-sensitive peptides created a permissive environment for hMF migration/invasion, promoting the direct contact between epithelial organoids, fibroblasts and ECM. To prove the ability to recover both the cells and the ECM after co-culture in 3D, the whole system was dissolved and the retrieved cell populations were isolated by FACS, followed by RT-PCR analysis that confirmed the expression of prototypical phenotypic markers. The ECM retained in the dissolved hydrogel was analysed by proteomics, which allowed the identification of different types of matrix proteins.

Conclusion
This hybrid hydrogel system provides an easy-to-use platform for studying stromal-parenchymal interactions in vitro, recapitulating both an ECM-like 3D microenvironment and heterotypic cell-cell interactions. Significantly, it allows both the cells and their ECM to be recovered under mild conditions for subsequent analysis.

Rheological properties and speeds of the mechanical waves in Elastin-
Like Recombinamers Catalyst-Free Click Gels

Julio Fernández-Fernández¹, Luis Quintanilla-Sierra¹, José C. Rodríguez-Cabello¹

¹ Universidad De Valladolid, GIR BIOFORGE, Valladolid, ES; ² Universidad De Valladolid, GIR BIOFORGE, Valladolid, ES; ³ Universidad De Valladolid, GIR BIOFORGE, Valladolid, ES

Introduction
Hydrogels are water-swollen polymeric materials that keep a distinctive three-dimensional structure and can act as a scaffold as well as mimic the properties of various tissues in the body [1]. Because of that, researchers have been interested on the mechanical properties with a wide range of methods and experiments, such as, rheology to study the viscoelastic behaviour [2], or ultrasounds tests to measure the speed of sound. We show a practicable option to study the viscoelastic models in a wider range of frequencies that a convectional rheometer does and to measure the speed of the mechanical waves by the through transmission technique with small punctual piezoelectric as transducers and receptors. The main objective is to get the rheological models and the speed of the mechanical waves in Elastin-Like Recombinamers Catalyst-Free Click Gels (ELR-CFCGs)[3] from mechanical waves propagation.

Experimental Methods
Elastin-Like Recombinamers[4] are a kind of artificial peptide polymers made by recombinant DNA technologies and combined by VPGXG pentapeptide repeat units where X can be any amino acid except proline. Once they are synthesized by E. coli fermentation, they are chemically functionalized to get a chemical hydrogel by chemical click reaction between them. As regard the methods, the experimental arrangement consists of a punctual piezo transmitter and receptor with the test hydrogels placed in between them. Different electrical waves in the frequency range 10-2000 Hz generated by a function generator are activated to the transmitter to produce compressional waves propagating through the hydrogel reaching the piezoelectric used as receptor; later this device switches mechanical waves into electric signals that are monitored in an oscilloscope.

Results and Discussion
When square waves are applied, the behaviour of these hydrogels shows that at frequencies lower than 100 Hz the elastic behaviour is obvious, but at frequencies higher than 2 kHz the Newtonian liquid behaviour rules. Thanks to mathematical software, these data can be fitted to the Kelvin-Voigt model ($R^2 > 0.9$) indicating a viscoelastic behaviour of these biomaterials. In connection with sinusoidal waves, the through transmission technique reveals a range of mechanical waves velocities between 1220-1900 m/s and a range of Young’s modulus between 2-6 MPa, comparable to values of the human tissues [5].

Conclusion
We showed a new way to characterize the mechanical properties of hydrogel with the use of mechanical waves and we can conclude that cross-linked Elastin-Like Recombinamer hydrogels can replicate accurately the viscoelasticity and stiffness of tissues. These kinds of hydrogel can be used in Tissue Engineering and Regenerative Medicine.

Colloidal Gel Supra- assemblies as 3D Dynamic Platforms for Focalized Therapeutics Delivery

Pedro Lavrador, Leandro Gonçalves, Vítor M. Gaspar, João F. Mano

Universidade de Aveiro, Department of Chemistry - CICECO – Aveiro Institute of Materials, Aveiro, PT

Introduction
Colloidal gels (CGs) represent unique biomedical platforms comprised of nanoparticle building blocks that self-assemble via inter-nanoparticle interactions into higher order 3D multifunctional systems.[1] In these modular platforms, because nanoparticles can operate as reservoirs for both hydrophobic and hydrophilic bioactive molecules, the high nanoparticle content of CGs can be leveraged for designing long-term bioactive depots intended for advanced tissue engineering strategies.[2] Such is particularly attractive considering the limited therapeutic efficacy of locally administered nanocarriers due to poor retention at the injection site and the inability to envision standalone administration regimens. Gathering on this, we design a universal CG platform that includes two different systems that first self-assemble into macrosized 3D constructs via electrostatic interactions and can be additionally covalently crosslinked on-demand (Fig. 1): (i) a moldable, injectable single-network CG system (snCG) comprised solely from non-covalent interactions between cationic PLGA-PEI nanoparticles and anionic Zein-hyaluronan (HA) nanogels that can autonomously shed multi-particles upon injection; and (ii) a moldable, injectable and photocrosslinkable CG system assembled from electrostatic interactions between cationic PLGA-PEI-methacrylate nanoparticles and anionic Zein-HA-methacrylate nanogels, that can be on-demand photocrosslinked in situ, generating a tough double network CG (dnCG) with enhanced mechanical robustness and long-term resistant fit-to-shape features. The biomedical versatility of these bioinstructive platforms is demonstrated by loading snCGs with anti-inflammatory Quercetin flavonoid to attenuate pro-inflammatory activated macrophages. Then, dnCGs were also validated as long-term systems for chemo-phototherapeutic platforms for cancer therapy.

Experimental Methods
Cohesive CGs were manufactured by centrifugation of colloidal suspensions of complementary nanoparticle building blocks, i.e., anionic Zein-HA and cationic PLGA-PEI nanoparticles for snCGs, and methacrylated counterparts Zein-HAm and PLGA-PEIm for dnCGs. The resulting colloidal gels were molded into different shapes in in-house produced circular molds. For dnCGs covalent interlinking, the photoinitiator lithium phenyl-2,4,6-trimethylbenzoylphosphinate was added followed by exposure to UV light (E = 3.68 W/cm²). To produce bioactive CGs, Zein-HA nanogels were loaded with Quercetin – snCGs, whereas chemotherapeutics (DOX) and photothermal agents (ICG) were loaded in dnCGs building blocks. For cellular assays prostate cancer cells and LPS activated THP-1 derived macrophages were employed to evaluate the anti-inflammatory and anti-tumoral potential of the different platforms.

Results and Discussion
An optimized nanoprecipitation protocol enabled the successful one-step formulation of surface-engineered cationic PLGA-PEI and anionic Zein-HA nanocarriers with low polydispersity index and oppositely-charged zeta-potential. Such building blocks were combined and compacted under centrifugation, rapidly producing macroscopic nanostructured CG constructs with homogeneous distribution of nanoparticle species throughout the network, as showcased by confocal imaging upon loading of hydrophobic fluorophores (Figure 2). Rheological studies investigating viscosity as a function of shear rate demonstrated that CGs exhibit shear-thinning behavior and fit-to-shape properties. Importantly, dnCGs could permanently retain their shape upon photocrosslinking. This additional crosslinking also improved CGs compressive modulus as assessed by mechanical compressive tests. Moreover, the Page 301 of 2028
Nanoparticulated supra-assembled platforms showed efficient loading of different bioactive molecules (flavonoids, chemo-phototherapeutics), while maintaining their original physicochemical properties (i.e., shape and hydrodynamic size). Upon snCGs direct contact with M1-Macrophages a dampening of the pro-inflammatory response was observed. On the other hand, dual-loaded dnCGs promoted a more pronounced anti-tumoral effect in cancer cells when compared to their single loaded counterparts.

Conclusion
In conclusion, we developed highly modular and nanostructured CG supra-assembled 3D platforms with different physicochemical and mechanical features for focal therapeutics and particles delivery. The two CG systems were first self-assembled and crosslinked by electrostatic interactions that in snCG allowed for autonomous particle shedding from the 3D platform along time. The introduction of a secondary on-demand photocrosslinking led to the manufacture of electrostatic and covalently interlinked double-network CGs capable of better withstanding mechanical loading and resist degradation in physiological environment for longer time. Overall, the different single and double network supra-assemblies demonstrate valuable properties for operating as delivery systems for localized bioinstruction of endogenous microenvironments or for cancer therapy.

1 MERLN Institute, Maastricht University, Maastricht, NL; 2 Ghent University, Ghent, BE; 3 Avroxa BVBA, Ghent, BE

Introduction

Native tissues are characterised by 3D structural anisotropy and a distribution of cells which determines the specific cell-cell and cell-extracellular matrix (ECM) interactions that dictate tissue function. The spatial distribution of cells and ECM in tissues is not arbitrary, with interconnected lumen structures and specifically located cell populations creating a fundamental structure-function relationship that determines the role of specific tissues. Therefore, the capability to mimic this 3D environment is key for a correct in vitro construction of tissues and for future tissue engineering applications.

Here we present a templating strategy using a thermally responsive polymer and we show the fabrication, in one step, of a network of interconnected channels within a hydrogel. While other polymers have been previously described for similar applications, including pNIPAM and PnPrOx [1][2], we uniquely show that our template can create a defined 3D polymer scaffold to which cells can adhere, leading to the subsequent formation of a channel network that directly incorporates cells.

This approach is based on a family of bespoke poly(2-oxazoline)s (PAOx) that have been specifically designed to have a uniquely tunable range of lower critical solubility temperature (LCST), above which it remains insoluble and below which it is triggered to dissolve.

Experimental Methods

We characterized the LCST by monitoring polymer solubility via optical transmission. We did this by preparing polymer films, via spin coating a polymer solution on coverslips, and monitoring the water contact angle (WCA) when the polymer and water are maintained at temperatures ranging from 37°C to 5°C.

In addition, we characterized the mechanical and melt rheological properties of the PAOx and, based on this, optimized the production of polymer filaments via fused deposition modelling (FDM) and melt electrowriting (MEW). We were able to generate filament scaffolds ranging in diameter from the millimeter to micron scale. Using an in-house customized microscope stage with temperature control and time lapse stereomicroscopy, we directly monitored the dissolution dynamics of these polymer filaments while being held at 37°C and from 37°C to 5°C, mimicking the transition of the scaffold from a cell incubator to a standard lab refrigerator.

Results and Discussion

We found that each PAOx formulation had a well-defined LCST between 30°C and 5°C, correlating to the theoretical LCST based on the specific formulation.

All polymer formulations retained a WCA above 60 degrees at 37°C and underwent a rapid transition to a WCA below 10°C. We compared the performance of our polymer to pNIPAM, to which cells poorly adhere without bioactivation, and PnPrOx, which has been reported to directly support cell adhesion. Consistent with this behaviour, pNIPAM maintained a low WCA at all temperatures while PnPrOx underwent a similar temperature-dependent transition from >60°C to <10°C, suggesting that our PAOx polymer family is compatible with protein and cell adhesion. Each polymer variant underwent dissolution, which was complete within 15 minutes of reaching the minimum temperature of 5°C. pNIPAM fibers and PnPrOx also displayed the expected thermally-triggered dissolution, but also...
were found to be mechanically weak even when maintained at 37°C. In contrast, our PAOx variants retained robust mechanical properties when maintained above the LCST.

We designed a PDMS fluidic system to use a 1 mm diameter filament within a hydrogel (Fig. 1). A 4 mg/ml collagen pre-gel solution was used to embed the filaments, crosslinked the gel at 37°C, and then triggered to dissolve. We showed the formation of a patent channel that was perfusable with gravity-driven fluid flow, visualized via fluorescence microscopy of a fluorescent nanobeads suspension. Caco-2 epithelial cells were seeded within the 1 mm channel, confirming biocompatibility of the hydrogel platform is maintained and, in parallel, creating simplified 3D in vitro gut model. To explore the use of PAOx microfilaments, we focused on the biomimetic formation of Schwann cell-lined microchannels to guide axon growth. We created a customized support system to facilitate microfiber handling and confirmed that rat Schwann cells (rSCs) could adhere to the polymer fibers. The seeded templates were embedded within collagen and cooled, with rSCs found to localize to the resulting microchannels. These channels were also able to support axon growth from iPSC-derived human sensory neurons.

**Conclusion**

Here we have demonstrated value of this novel templating technology to generate different in vitro models and established its potential for other 3D in vitro model and tissue engineering applications.

Polycaprolactone-bioactive glass hybrids as a controlled release platform for the delivery of therapeutics in bone tissue engineering

Lukas Gritsch¹, Cédric Bossard¹, Christiane Forestier², Edouard Jallot¹, Henri Granel³, Yohann Wittrant³, Jonathan Lao¹

Université Clermont Auvergne, LPC - Laboratoire de Physique de Clermont, Clermont Ferrand, FR; Université Clermont Auvergne, LMGE - Laboratoire Microorganismes: Génome et Environnement, Clermont Ferrand, FR; INRAE - Institut national de la recherche agronomique (INRAE), Clermont Ferrand, FR

Introduction
Bioactive organic/inorganic hybrids hold promising results as candidates for the fabrication of bone and cartilage tissue engineering (TE) scaffolds: they combine the mineralization potential of bioactive glasses with the processability and mechanical properties of bioresorbable polymers. In addition, they are prepared at low temperature, making them compatible with the design of controlled release technologies. Recently, we developed a polycaprolactone/bioactive glass (PCL/BG) hybrid using calcium alkoxides as calcium source¹. Its superior properties for bone grafts and TE scaffolds were confirmed benchmarking against a sector leader². Fostered by the promising results of this investigation, we explored the possibility to further enhance the intrinsic biological properties of PCL/BG hybrids by loading therapeutics stimulating bone regeneration, for instance by promoting correct differentiation, stimulating mineralization and protecting from the risk of bone infections (osteomyelitis). Two case studies investigating organic molecules will be presented: fisetin, an osteostimulative polyphenol, and rifampicin, a RNA synthesis blocker known for its effectiveness against osteomyelitis³.

Experimental Methods
PCL/BG hybrids were synthesized by sol-gel chemistry following a published protocol¹. The therapeutic agents were blended with the polymer prior to synthesis. Several concentrations were tested and the loading efficacy and release profiles were measured. Ion release was analyzed by ICP-OES while organic molecules were quantified by UV-Vis spectrophotometry. The response of primary osteoblasts was characterized with particular emphasis on their differentiation (alkaline phosphatase activity) and bone-specific gene expression (COL1A1 and RUNX2). The performance of antibacterial hybrids containing rifampicin was assessed. Gram+ Staphylococcus aureus and Gram- Pseudomonas aeruginosa and Escherichia coli were selected due to their high occurrence in bone infections. In parallel, fisetin-loaded samples were also implanted in vivo in a mouse model.

Results and Discussion
The sustained antibiotic release from PCL/BG hybrids was successful. The material gradually delivered 50% of loaded rifampicin within two weeks, inhibiting bacterial growth (Figure 1). In particular, the reduction in colonies of S. aureus, the major strain responsible for osteomyelitis, was more than 99.999%.

PCL/BG hybrids can simultaneously release therapeutic ions to stimulate osteoblast differentiation (silicates) and to enhance apatite formation (calcium), while degrading at a tailored rate that matches bone regrowth. As demonstrated in an in vivo rat model, tissue ingrowth is higher than the one achieved by market competitors. In addition, doping the hybrid with fisetin was confirmed as an effective approach to further improve the already outstanding biological performance of PCL/BG hybrids, increasing tissue ingrowth almost twofold (from 30% to 55%). MicroCT confirms that newly formed bone around fisetin-doped scaffolds is more abundant than around undoped ones, and thus superior to commercial alternatives (Lubbock®, OST Laboratoires, France). Histological analysis confirmed these findings (Figure 2).

Conclusion
Tailored doping of our biomaterial can significantly enhance the response of osteoblasts, strongly inhibit the bacteria responsible for osteomyelitis and offer superior bone regeneration compared to currently commercialized synthetic bone grafts. These results support the development of PCL/BG hybrids into a platform technology for the controlled and sustained release of diverse therapeutic agents, including but not limited to the ones described in this work: therapeutic ions, polyphenols and antibiotics.

Introduction
Various traditional methods are used as drug delivery systems that usually result in pain and poor administration of nucleic acid and drug molecules [1]. A painless micro-sized device capable of delivering drugs easily and efficiently, with no side effects, would present an attractive solution [2]. Additive manufactured microneedle (MN) arrays have been considered as an innovative platform for an optimal and cost-effective design and manufacture, eliminating the traditional system's disadvantages. This research aims to develop 3D-printed 316L stainless steel MN array, with optimal mechanical/biological properties, for disease management and treatment. A computational modelling approach was developed to determine the optimal geometrical features and mechanical properties of the MN arrays. Experimental investigations were also conducted using a Design of Experiment (DoE) approach to validate the computational data and optimise the printing parameters.

Experimental Methods
Individual needles were generated using SolidWorks (DS SolidWorks Corp., USA) software. The 3D model of MN arrays was discretized with tetrahedral elements. Young’s modulus and Poisson’s ratio values of 195 GPa and 0.25 were applied [3]. The compression and penetration studies were conducted using explicit dynamic analysis (ANSYS, Inc., USA). Parametric studies, changing needle height (300, 500, 1,000 μm) and aspect ratio (3:1, 4:1, 5:1), were used to determine the mechanical and geometrical properties for computational simulations. The analysis was completed by adding an external force by a stainless-steel rod (generated using SolidWorks) at a velocity of 3,000 mm/s [4] to a fixed MN array (Figure 1a). A DoE study (Design Expert 11, Stat-Ease, Inc., USA) was used to determine and optimise the influence of printing parameters on the geometric features (needle height, aspect ratio, surface area, and tip diameter) and mechanical properties (compressive strength, yield strength, and Young’s modulus) of MN arrays. The MN arrays were printed using the Direct Metal Laser Melting (Concept Laser Mlab, GE Additive, Germany) process, changing the laser speed (500–700 mm/s), power (35–70 W), and trace width (0.09–0.12 mm) followed by electropolishing [5]. The 3D printed MN arrays were characterised in terms of their morphology and geometry (SEM and Optical microscopy). Mechanical properties under a displacement rate of 5 mm/min were also determined (Figure 1b).

Results and Discussion
The computational study demonstrated an improvement in the compressive strength due to the increase in the needle height (0.95 GPa for 300 μm compared to 1.18 GPa for 1,000 μm) and aspect ratio (1.16 GPa for 3:1 and 1.28 GPa for 5:1). An increase was also observed from the results following the experimental compression testing. The differences between compressive strength from the experimental and computational studies varied from 0.5% to 1.6%, thereby validating the simulation studies. A difference between CAD file and actual (3D printing) dimensions was determined from the micrographs (post-electropolishing), providing a reduction of 30% in needle height and 20% in base diameter (Figure 2a). SEM analysis demonstrated the presence of un-melted particles, which decreased in number after electropolishing (Figure 2b). DoE analysis and optimisation indicated that a high laser power (70 W)
and speed (600 mm/s) could lead to optimal geometrical and mechanical properties without significant effect of trace width (p-value: 0.139) (Figure 2c).

**Conclusion**

The present study demonstrated the successful 3D printing of MN arrays. The variation of the needle height and aspect ratio demonstrated the greatest effect on the mechanical properties for both computational and experimental studies. The difference between simulation and experimental data was calculated <2%, leading to similar results in terms of the mechanical properties. The present study concluded that MN arrays with 1,000 μm height, 4:1 aspect ratio, printed using a laser power of 70 W, speed of 600 mm/s, and trace width 0.12 mm could lead to optimal dimension and mechanical properties. Overall, these findings provided a better understanding of the geometrical features of the MN arrays as drug delivery system. Future work will optimise and develop the post-processing steps to deliver the required structure, performance and cost.

Fernandes\textsuperscript{1,2}, Alessandra Zonnari\textsuperscript{2}, Ricardo Abreu\textsuperscript{1,4}, Sezin Aday\textsuperscript{2}, Inês Albino\textsuperscript{2}, Ana Branco\textsuperscript{2}, Cátia Seabra\textsuperscript{2}, Marta Barão\textsuperscript{2}, Tânia Barata\textsuperscript{2}, Ermelindo Leal\textsuperscript{2}, Paul Quax\textsuperscript{3}, Margreet de Vries\textsuperscript{3}, Eugénia Carvalho\textsuperscript{2}, Lino Ferreira\textsuperscript{1,2}

\textsuperscript{1} University Coimbra, Faculty of Medicine, Coimbra, PT; \textsuperscript{2} University Coimbra, Center Neuroscience and Cell Biology, Coimbra, PT; \textsuperscript{3} University Leiden, Leiden Medical Center, Leiden, NL; \textsuperscript{4} University Maastricht, Maastricht, NL

Introduction

Extracellular vesicles (EVs) are secreted by virtually all the cells in the body and are key mediators of intercellular communication. EV cargo provides a snapshot of the cell proteome, metabolome and transcriptome and therefore EVs are often used as biomarkers (1). Additionally, EVs can be used as therapeutic agents, both in their native form or modulated using bioengineering strategies. However, in many cases, the bioactivity of native EVs is insufficient to elicit a therapeutic effect (2). To overcome this, we developed a platform capable of modulating native EVs with miRNAs, non-coding RNAs capable of modulating gene function at a post-transcriptional level. We used high-throughput screening approaches to identify miRNAs capable of enhancing the survival of endothelial cells (ECs) under hypoxia (0.1% O\textsubscript{2}) and subsequently, we developed a platform that allowed us to efficiently conjugate a pre-selected miRNA onto EVs. Ultimately, we showed that miRNA-modulated EV can be used to efficiently deliver miRNAs into target cells and improve the functionality of native EVs for a selected therapeutic application, namely the regeneration of diabetic wounds in mice.

Experimental Methods

Selection of the miRNA of interest: A library of 2080 miRNAs was transfected into ECs using RNAiMax and 48 h after transfection, cells were exposed to hypoxia (0.1% O\textsubscript{2}) in the absence of growth factors for a further 48 h. High-content image analysis was performed to identify miRNAs capable of enhancing the survival of ECs and follow-up assays were used to confirm the selected hits. For subsequent validation in vitro, we selected two hits and used RNA-Sequencing to identify their pro-survival mechanism of action. The pro-survival effect was finally confirmed in vivo using a matrigel plug assay using cells transfected with the selected miRNA.

miRNA-modulated EVs: EVs were isolated from human cord blood-derived mononuclear cells and characterized using western blot analysis (identification of EV markers), nanoparticle tracking analysis (particle quantification and size distribution), protein quantification and dynamic light scattering (zeta potential) as previously described by us (3). Following, a selected miRNA, known to enhance the survival of ECs, was transfected into EVs using Exo-Fect\textsuperscript{\textregistered} and qPCR was used to confirm the transfection. Internalization and intracellular trafficking of native and miRNA-modulated EVs was analyzed in ECs, fibroblasts and keratinocytes. Finally, miRNA-modulated EVs were topically administered (2x/day for 10 days) on excisional wounds of STZ-induced diabetic mice.

Results and Discussion

RNA-Sequencing followed by gene ontology analysis showed that the selected pro-survival miRNAs elicited a pro-inflammatory program that ultimately led to enhanced survival of ECs exposed to hypoxia conditions. Furthermore, based on the list of putative targets selected from the RNA-Seq dataset, we were able to identify a set of genes that, upon inhibition with siRNA, pheno-copied the pro-survival effect of the selected miRNA. After unravelling the mechanism of action of the selected miRNA, we tested the pro-survival effect using an in vivo matrigel plug assay. In brief, ECs were transfected for 48 h with the pro-survival and subsequently embedded in a matrigel plug and
transplanted into the back of immunodeficient mice. Our results showed that, compared with miRNA-scramble transfected ECs, ECs transfected with the pro-survival miRNA had a statistically significant increase in survival after 3 days. After confirming the pro-survival effect in vivo, we used ExoFect to transfect the miRNA onto EVs. Upon transfection, our results showed a >30 000-fold increase in miRNA expression compared to native EVs. Moreover, miRNA-modulated EVs were efficiently internalized by all the cells involved in skin wound healing, particularly keratinocytes and ECs, and the colocalization of miRNA-modulated EVs with the endo-lysosomal compartment differed from their native EVs. Compared to their native counterparts, miRNA-modulated EVs showed significantly lower levels of colocalization with endolysosomal compartments suggesting a more efficient escape from this degradation pathway. Finally, we showed that topical administration of miRNA-modulated EVs into the wounds of diabetic mice significantly accelerated the healing kinetics, partially by enhancing wound vascularization and re-epithelization.

**Conclusion**
In conclusion, we showed that the bioactivity of native EVs can be further enhanced by the transfection of pre-selected biomolecules of interest, in this case a pro-survival miRNA identified using high-throughput screening approaches. Importantly, we showed that miRNA-modulated EVs differed from their native counterparts in terms of internalization and this can be explored to enhance their therapeutic efficacy. Importantly, the selection of the biomolecules to be incorporated into EVs can endow them with novel properties that can play a crucial role in Regeneration of damaged and worn-out tissues.

Competitive Binding and Molecular Crowding Regulate the Cytoplasmic Interactome of Non-Viral Polymeric Gene Delivery Vectors

Julien Gautrot, Danyang Li, Fengjing Qu, Lan Chang, Alex Raynold

Queen Mary, University of London, School of Engineering and Materials Science, London, GB

Introduction

Although polycationic vectors display excellent performance in vitro with many cellular systems, their clinical use remains very restricted. To some level, this is due to the poor compatibility of such systems with biological fluids and tissues. In addition, in contrast to the processes controlling the complexation, targeting and uptake of polycationic gene delivery vectors, such as poly(ethylene imine) and poly(dimethylaminoethyl methacrylate), the detailed molecular mechanisms regulating their cytoplasmic dissociation remains poorly understood. Upon cytosolic entry, gene delivery vectors become exposed to a complex, concentrated mixture of molecules and biomacromolecules.

Experimental Methods

To explore cytosolic release mechanisms, we characterised the cytoplasmic interactome associated with a polycationic vector based on poly(dimethylaminoethyl methacrylate) (PDMAEMA) brushes grafted from nanoparticles. To quantify the contribution of different classes of low molar mass molecules and biomacromolecules to RNA release, we used fluorescence microscopy and developed a kinetic model based on competitive binding.

Results and Discussion

Cationic brushes were found to be particularly effective at trapping small RNAs, resulting in high knock down efficiencies. However, how such stable association is disrupted in the cytosol was not clear. We propose that the molecular structure and architecture (in particular the high surface density) of cationic brush-decorated nanoparticles, together with the cytosolic molecular crowding, modulate competitive binding and, in turn, the long term release of RNA. Based on these observations, we chemically designed polymer brushes with improved RNA retention in the cytosol, avoiding burst release, and enabling to achieve long term (at least 10 days) knock down (>70%) with one single transfection.

Conclusion

Our data demonstrate that the complex crowded cytosolic environment regulates RNA desorption from polyplexes via competitive binding. Understanding the mechanism regulating cytosolic dissociation will enable the improved design of cationic vectors for long term gene release and therapeutic efficacy.

Introduction

Intracellular delivery of biomolecules is extremely useful for the manipulation of cellular processes, cell reprogramming and gene editing. In the last decades, gene editing has shown potential for the treatment of several genetic mutations and offers the promise of treatment for brain diseases, mediated by either silencing or editing disease-specific genes [1]. Gene editing therapeutics based on the clustered regularly interspaced short palindromic repeats (CRISPR) show great promise for treating genetic diseases. CRISPR consists of a DNA-cutting enzyme called Cas9 and a short RNA (sgRNA) that guides the enzyme to a specific region on the genome so that it can cut this region out [2]. Unfortunately, viral delivery methods of CRISPR-Cas9 and sgRNA may cause genomic undesirable side effects because of the prolonged expression of the CRISPR system [3]. In addition, they do not offer temporal and spatial resolution to allow an extra-level of safety. Some non-viral systems were described using gold NP [4]; however, without spatio-temporal control. Photoactivatable CRISPR with a modified Cas9 enzyme that incorporates light-responsive domains or site-specific caging groups as well as photo-activatable gRNAs [5] have been described recently. These systems have limitations because they respond to blue or UV radiation which has relatively low in vivo penetration. Here, we propose a formulation that has the capacity to release intracellularly the Cas9/sgRNA complex with remote control, using near infrared (NIR) light as a trigger. The formulation is based in gold nanorods (AuNRs) conjugated with oligonucleotides that hybridize with part of the sgRNA inserted in the catalytic site of Cas9. Once the formulation is activated by NIR, the heating of the AuNR leads to the de-hybridization of the oligonucleotide and release of the CRISPR system.

Experimental Methods

For proof of concept we designed a sgRNA for GFP knockdown. Cas9/sgRNA-DNA-AuNR were incubated in d2GFP-Hela cells and used for laser-induced release of Cas9/sgRNA complex. The gene editing was evaluated by the GFP knockdown. Then, we evaluated the in vitro gene editing in different brain cell populations (NSC, microglia and neurons). For that the different cell populations was isolated from a transgenic mice Ai9 with a cassette inserted into the Gt(ROSA)26Sor locus with a LoxP-Stop-LoxP-ttdTomato sequence, for the editing we developed two sequences of sgRNA for the deletion of stop sequences and expression of ttdTomato.

Results and Discussion

Different ssDNA sequences were screened for the immobilization of the Cas9/sgRNA complex in the surface of AuNRs, and thus to identify one that could facilitate cell internalization of the formulation as well Cas9/sgRNA delivery after NIR laser activation. We have identified one sequence that allowed high immobilization of Cas9/sgRNA and its intracellular delivery by a short NIR pulse. More than 60% of the cells were knockdown by this approach in less than 3 days. The biological effect of gene editing was maintained for more than 5 days demonstrating that the cut of genomic DNA was precise in the targeted location. In the brain cell population, we observed around 11% of gene editing in NSC, 30% in microglia cells and 18% in neurons. Preliminary in vivo results show a good gene editing expression two weeks after the intracranial injection of the nanoformulation in hippocampus of adult Ai9 mouse brains.

Conclusion
We report for the first time a non-viral gene editing formulation with efficient spatio-temporal control. This strategy may increase the in vivo safety of gene editing systems.

Small siRNA polyplexes for tumor tissue penetration

Cristina Casadidio¹², Roberta Censi², Piera Di Martino², Wim E. Hennink¹, Tina Vermonden¹

¹ Utrecht University, Pharmaceutics, Utrecht, NL; ² University of Camerino, School of Pharmacy - Drug Delivery Division, Camerino (MC), IT

Introduction
In the recent pharmaceutical scenario, nucleic acids (NA) based therapeutics have shown outstanding applicability in different disease treatments, not least the formulation of mRNA-based vaccines against COVID-19 [1, 2]. In the oncology field, gene therapy is not that far advanced in clinical reality due to NA in vivo instability and low cell transfection efficiencies of naked NA. To overcome these challenges, one of the strategies used is the complexation of anionic NA via electrostatic interactions with cationic polymers, leading to the formation of polyplexes [3].

Experimental Methods
In this study, the synthesis of a methoxypoly(ethylene glycol) poly[2-(dimethylamino)ethyl methacrylate] (mPEG-pDMAEMA) diblock copolymer was optimized via reversible addition-fragmentation chain-transfer (RAFT) polymerization and this polymer was used as polymeric carrier for NA condensation. Particle size and polydispersity index (PDI) of polyplexes were determined by dynamic light scattering (DLS) while ζ-Potential was measured by laser Doppler electrophoresis (LDE) at 37°C in HEPES buffer (20 mM, pH 7.4). Stability studies of polyplexes were performed via agarose gel retardation assay after incubation up to 24h in culture medium supplemented with 10% of fetal bovine serum (FBS). To resemble in vivo conditions, small polyplexes were tracked in vitro using 3D multicellular tumor models (spheroids). For this purpose, homo- and hetero-spheroids of avascular ascites models were optimized by co-culturing ovarian cancer cells with primary mouse embryonic fibroblasts in different ratios (2:5, 1:1 and 5:2). The fibroblasts present in the 3D spheroids were used to mimic the stroma, a tissue composed of cancer associated fibroblasts and extracellular matrix, which might interfere with polyplexes penetration in vivo. Confocal images were recorded to track fluorescently labelled polyplexes at different time points and processed as optically sectioned images [4].

Results and Discussion
As shown in Fig. 1, 80% of PD polymer conversion was achieved after 8h while full conversion was reached only after 24h, leading to high PDI values. Well-defined mPEG-pDMAEMA (PD) diblock copolymers bearing a thiocarbonylthio (CTA) end group were synthesized via fast polymerization up to 8h. The kinetics of polymerization was slowed down after 10h, likely due to loss of CTA active groups. Following the commonly observed controlled radical polymerization kinetics, the average molecular weight (Mn) of PD increased linearly with the conversion, according to GPC and ¹H-NMR measurements. Afterwards, the PD diblock copolymer of 35.2 kDa was used to condense the anionic NA, forming polyplexes in which siRNA polyplexes were compared to pDNA polyplexes. Condensed siRNA polyplexes prepared at N/P charge ratio of 5, showed a size of 25 ± 2 nm in HEPES solution, while pDNA polyplexes were 162 ± 11 nm at N/P 5. Agarose gel electrophoresis revealed stable siRNA polyplexes upon 24h incubation with culture medium plus 10% of FBS, while free siRNA was observed when incubated in presence of heparin (as destabilizing negatively charged molecule). For in vitro experiments, homo and hetero-spheroids with a reproducible size of ~200 mm were developed. To assess the validity of the 3D models, MTS and live/dead assays were performed with monolayer cultures of cancer cells and fibroblasts (at different ratios), proving high levels of cell viability. Real-time penetration studies revealed that siRNA-polyplexes after 24h of incubation were able to reach the core of live-cell spheroids with ~60% of penetration area, while pDNA-polyplexes were mainly located in the rim, reaching only ~30% of penetration. These results proved that the mechanism of polyplexes
penetration into 3D spheroids is size-dependent. Regarding the influence of stroma in the siRNA polyplexes penetration, no significant differences among cancer-associated and hetero-spheroids were recorded (Fig. 2).

**Conclusion**

PD diblock copolymer proved to be a versatile polymeric carrier for delivery of siRNA. For therapeutic purposes, size-tuned siRNA polyplexes have high potential to exploit penetration into tissues and enhance eradication of the tumor mass. The results revealed that the penetration ability of siRNA polyplexes independent of cell type composition of the spheroids. The next steps in our research will focus on the use of these self-assembled siRNA polyplexes as potential tool for local treatment of ovarian cancer.

Advanced multilayered three-dimensional epithelium-stroma-endothelium in vitro intestinal model to perform reliable drug permeability studies

Maria H. Macedo¹,², Andreia S. Barros¹,², Elena Martínez⁴,⁵, Cristina C. Barrias¹,², Bruno Sarmento¹,³

¹ Universidade do Porto, I3s - Instituto de Investigação e Inovação em Saúde, Porto, PT; ² Universidade do Porto, ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Porto, PT; ³ CESPU - Coopérativa De Ensino Superior Politécnico Universitário, Gandra, PT; ⁴ IBEC - Institute for Bioengineering of Catalonia, Barcelona, ES; ⁵ CIBER-BBN – Consorcio Centro de Investigación Biomédica en Red de Bioingeniería, Biomateriales y Nanomedicina, Madrid, ES

Introduction
The drug development field is constantly growing and the requirement for tools that can speed up the early pharmacokinetic phases, reducing animal experiments and, thus, decreasing time and costs, is unquestionable. In oral delivery, understanding the absorption in the small intestine in an early stage of the drug development process is paramount, since the small intestine is the place where the absorption process mainly occurs. In vitro models, due to their cost-benefit, are routinely used, but current 2D models are too simplistic and have several drawbacks, not representing the native tissue, which impacts permeability outcomes [1,2].

Experimental Methods
A new 3D in vitro model was developed, comprising 3 different layers: the epithelium, with Caco-2 and HT29-MTX cells, mimicking the intestinal enterocytes and the mucus producing goblet cells, respectively; the lamina propria, composed by a collagen layer with human intestinal fibroblasts (HIF) embedded, providing 3D biological support to the epithelium; and an endothelial layer, surrogating the absorptive capillary network, mimicking the last barrier compounds need to cross before systemic circulation. The crosstalk between the different cells present in the model and their impact on the contractile ability of fibroblasts was assessed by dosing the amounts of transforming growth factor beta (TGF-ß), endothelin-1 (ET-1) and platelet derived growth factor (PDGF) present in the cell culture medium and measuring the activity of metalloproteinases (MMPs) 2 and 9.

The developed 3D model was characterized in terms of genetic expression of intestinal differentiation markers and drug transporters. The presence of drug transporters, tight junctions (TJs) and mucin 2 (MUC2) was confirmed by immunostaining. Activity of P-glycoprotein (P-gp) was confirmed with a transport assay with Rhodamine 123 (Rho 123) and permeability assays with 3 model drugs with different absorption profiles were performed and further correlated with in vivo values.

Results and Discussion
The contraction of collagen by fibroblasts is extensively reported and can be a great drawback when using this material to developed platforms to test permeability. It was observed that secretion of higher amounts of TGF-ß and ET-1 by Caco-2 and HPMEC (endothelial) cells into the medium could lead to a higher activity of MMP2 and MMP9 and, therefore, to a higher ability of the fibroblasts to contract the collagen layer in which are embedded, as already reported in the literature [3,4]. Curiously, it was observed that when HT29-MTX cells are included in the model, the fibroblasts are not able to contract the collagen hydrogel and this relates to lower amounts of TGF-ß, ET-1 and MMPs in the medium.

Genetic expression of intestinal markers showed similar levels between the 3D models and the 2D control. Regarding drug transporters, expression of P-gp and Multidrug Resistance Protein 2 (MRP2) was lower in the 3D models when
compared to 2D, a positive result since these transporters are normally overexpressed in the Caco-2 model, leading to an underestimation of the permeability of compounds that are their substrates [5]. The transport assay with Rho 123 confirmed the genetic expression results. In terms of TJs, no differences were observed between the models, although there was a decrease in the transepitelial electrical resistance (TEER) of the 3D models, becoming closer to in vivo values. The secretion of MUC2 was confirmed. In terms of permeability, data obtained for the 3D Co-culture model without the endothelial layer presented levels more similar with in vivo absorption. For the novel 3D model, the addition of the endothelium rendered a decrease in permeability, which was expected, since there is an additional layer hindering absorption. However, it can be important when studying the interaction of compounds with the endothelium.

Conclusion
The presence of HT29-MTX cells in the model may inhibit the secretion of soluble factors by the other cells present in the model, preventing the contraction of collagen by fibroblasts. This finding can be very important when developing models to test permeability, in order to avoid collagen contraction.

The novel 3D Co-culture model showed a better correlation with in vivo results in terms of expression of drug transporters, barrier tightness and, most importantly, permeability outcomes. The addition of the endothelial layer in the developed 3D model lead to a decrease in the permeability of compounds, which was expected having into account there is an additional layer hindering the passage of compounds. The novel 3D model has the potential of speed up the initial phases of drug development, providing more trustable results than the currently used 2D models and, therefore, decreasing animal experiments and contributing to the 3R’s policy.

Polysaccharide-based emulsifier for lung administration via inhalation

Raquel Gracia1, Marcos Navascuez1, Janire Alkorta1, Marco Marradi2, Natividad Diaz1, Hans-Jürgen Grande1, Iraida Loinaz1, Fernando López-Gállego2, Jordi Llop3, Damien Dupin1

1 CIDETEC, Basque Research and Technology Alliance (BRTA), Donostia-San Sebastian, ES; 2 CIC biomaGUNE, Basque Research and Technology Alliance (BRTA), Donostia-San Sebastian, ES; 3 University of Florence, Department of Chemistry “Ugo Schiff”, Sesto Fiorentino, IT

Introduction
Nanoemulsions are heterogeneous systems based on the dispersion of nanodroplets (< 500nm) of one phase emulsified in a second immiscible phase, resulting very attractive for encapsulation of active molecules in cosmetic and pharmaceutical formulations.1,2 Low molecular weight surfactants commonly used to stabilise emulsions can exhibit undesired cytotoxicity,3 while macromolecular PEGylated synthetic emulsifiers such as Cremophor, poloxamers and Triton X, have recently raised concerns due to Complement Activation-Related Pseudoallergy (CARPA).4,5 Thus, there is an urgent need for sustainable emulsifiers from natural resources. In this work, we systematically investigated the capacity of Dextran polysaccharide (DXT) and Dextran-based single chain nanoparticles (DXT-SCPN) functionalised with methacrylate (MA) groups (DXT-MA and DXT-SCPN-MA, respectively) or carboxylate groups (DXT-COO- and DXT-SCPN-COO-) to stabilise O/W emulsions produced by sonication. The best DXT emulsifier was then used for the encapsulation of FES drug and administered via inhalation to healthy rat to study the residence time of the drug.

Experimental Methods
Each dextran derivative (DXT-R) was dissolved in deionized water in an 8 mL glass vial. To this solution, the oil was added. The relative amounts of DXT-R, water and oil were modified to reach always a final amount of 2g. The emulsion was then formed by sonication (0°C, no stirring) using an UP400S (Hielscher) system at 100% of amplitude and pulse during 4 minutes (400 W) with a H3 sonotrode tip (3 mm diameter, 100 mm length).

Results and Discussion
Pristine DXT did not show any interfacial activity and a clear phase separation was observed after sonication of vegetable oils (such as olive oil and sunflower oil) with 0.5 wt% of an aqueous solution of DXT. On the other hand, stable O/W emulsions were achieved with our four selected stabilisers with the same vegetable oils. As expected, the presence of hydrophobic MA groups resulted in enhanced interfacial activity. Counter-intuitively, highly hydrophilic DXT-COO- and DXT-SCPN-COO- showed sufficient interfacial activities to stabilize O/W emulsions. However, DXT-MA proved to be the most performing stabilizer and the most straightforward to produce. The presence of ester bonds generated during the production of DXT-MA, together with the absence of interfacial activity of the pristine DXT, suggests that lipases or esterases may catalyse their hydrolysis, compromising the stability and offering triggered release. Therefore, we selected Candida Antartica Lipase B from (CALB), an enzyme widely employed in a diversity of biotechnological applications. After 20h incubation, droplet aggregation and coalescence were observed by Laser Diffraction (LD), while creaming effect and phase separation were visually observed after 40h. On the other hand, the same emulsion without the enzyme remained unaltered. These results confirmed that CALB triggers ester bond hydrolysis from DXT-MA, recovering pristine DXT with no interfacial activity, and ultimately compromising the emulsion stability and sustaining the demulsification process. Stability of DXT-MA-stabilized emulsions proved to be poor in PBS. Thus, taking advantage of the presence of MA group, dithiol crosslinker was added to the oil phase resulting in the crosslinking of the DXT-MA adsorbed at the interface. DLS and LD studies in different physiological media showed a stability enhancement of the nanoemulsions.
Then 16α-[18F]Fluorosteradiol (FES) was encapsulated as model cancer drug in the crosslinked nanocarrier at 5wt% in the oil phase. The resulting nanoemulsion with an hydrodynamic diameter of around 230nm was administered via intratracheal injection to healthy rat and compared to the drug alone. The residence time of the drug in the lung was monitored by PET-SPECT after radio-labelling the drug. It was shown that the nanoemulsiones allowed the drug to be retained longer in the lung. While around 60% of the encapsulated drug remained available after 40 min, the free drug was cleared within a few minutes. This result indicates that DXT-MA could be used as nanocarrier to prolong the residence time of hydrophobic drugs in the lungs after intratracheal administration.

**Conclusion**

In conclusion, a minor modification of natural DXT polysaccharide is sufficient to confer interfacial activity and stabilize O/W emulsions. The resulting emulsions are enzyme-responsive thanks to the presence of ester bonds. In addition, improved stability was obtained by crosslinking the DXT-MA adsorbed at the interface. After lung administration, DXT-MA-stabilized emulsions proved to improve drastically the residence time of hydrophobic drug in the lungs. These properties open opportunities for lung infections treatments and lung cancer.

Poly(urethane)s by synthesis: versatile materials for challenging applications in the biomedical field

Gianluca Ciardelli1,2, Susanna Sartori1, Rossella Laurano1, Alessandro Torchio1, Valeria Chiono1,2, Monica Boffito1,2

1 Politecnico di Torino, Department of Mechanical and Aerospace Engineering, Turin, IT; 2 CNR, IPCF, Pisa, IT

Introduction
Poly(urethane)s (PUs) show an enormous diversity of chemical compositions and properties. Their complex chemical structure which typically comprises three monomers (i.e., a diisocyanate, a macrodiol and a chain extender) allows the synthesis of a virtually infinite number of different materials. For instance, both biostable and biodegradable PUs can be obtained by tuning macrodiol chemistry; on the other hand, macrodiol selection can also lead to either thermoplastic or stimuli-responsive water-soluble materials. Another key PU building block is represented by the chain extender which can be exploited to include into the polymer backbone specific moieties, such as cell adhesive motifs (e.g., RGD), enzyme-degradable sequences (e.g., elastase-sensitive Ala-Ala), pendant functionalities available for further functionalization (e.g., amino groups). In this contribution, a plethora of PUs has been designed and processed into many different devices (i.e., 3D scaffolds and hydrogels) to demonstrate the huge potential of customized PUs in properly answering to the demanding and specific requisites for medical device engineering in tissue engineering (TE) and pharmacology.

Experimental Methods
PUs were synthesized through a two step procedure according to well-established protocols in our group. PUs were chemically characterized and their cytocompatibility was evaluated according to ISO rules. Then, thermoplastic PUs synthesized using poly(caprolactone) (PCL) diol and different chain extenders (e.g., N-Boc serinol, 1,4-cyclohexanedicarboxylate, L-Lysine ester) were mechanically, structurally, and thermally characterized to investigate the role of the chain extender in determining PU properties. Finally, PUs were processed into 3D matrices through thermally induced phase separation, surface functionalized with fibronectin, and colonized with rat neonatal cardiomyocytes (CMs). Amphiphilic water-soluble PUs synthesized using Poloxamer 407 (P407) were tested as constituents of thermosensitive hydrogels for the localized delivery of drugs with different wettability (e.g., ibuprofen, ibuprofen sodium salt) and biomolecules (e.g., bovine serum albumin). The same PUs were blended with cyclodextrins (CDs) to design supramolecular (SM) gels for the release of curcumin (Cur). The exposure of amino groups along PU chains was exploited to graft photo-sensitive moieties (e.g., acrylate, norbornene, thiol) to design hydrogels with additional photo-responsiveness. Hydrogels were characterized by tube inverting test and rheology, meanwhile swelling, stability and release profiles of encapsulated payloads were tested in physiological-like conditions (i.e., pH 7.4, 37°C). Hydrogel printability was also tested using a commercial 3D bioprinter.

Results and Discussion
All PUs were successfully synthesized and exhibited biocompatibility. PCL-based PUs showed tunable mechanical properties through a proper chain extender selection (Fig.1A). The elastomeric PU synthesized using L-Lysine ester was processed into 3D scaffolds with mechanical properties replicating those of myocardial tissue (Fig.1B). Surface functionalization was successfully attained through plasma treatment in the presence of acrylic acid followed by fibronectin grafting via carbodiimide chemistry. CMs colonized the scaffolds and exhibited prolonged beating up to 1 month, thus making the developed matrices suitable for cardiac TE, both for regenerative and modelling purposes. Aqueous solutions of P407-based PUs exhibited improved thermal gelation (i.e., faster gelation at lower temperatures) and mechanical properties compared to P407-based ones (Fig.1C). PU gels allowed a prolonged and...
sustained release of different therapeutic agents over time. Injectable and self-healing SM gels were designed at PU and CD concentrations within 1-5 and 8-10 %w/V, respectively (Fig. 1D).\textsuperscript{4} CDs were also exploited to form inclusion complexes with Cur, allowing the encapsulation of this poorly water-soluble drug at high content and providing a protective environment to the drug molecules. Sustained and prolonged release of active Cur was observed up to 4 days. A PU suitable for further grafting of photo-sensitive groups was also synthesized using an amino-group bearing chain extender.\textsuperscript{5} Thermo- and photo-sensitive hydrogels were successfully photo-cured with Vis light and exhibited different mechanical properties depending on the grafted moieties along PU chains. Finally, PU hydrogels turned out to be printable under mild conditions, with good fidelity of the printed structs to the CAD design.

**Conclusion**

PU versatile chemistry can be widely exploited to fabricate both porous structs and injectable formulations for drug delivery and 3D bioprinting. PU biomaterials could thus represent valuable and reliable building blocks in the establishment of new TE and pharmacological strategies, thanks to the possibility to ad-hoc engineer polymers finely matching the highly demanding requisites of different biomedical applications.

Introduction
Piezoelectric nanogenerators (NGs) convert the ambient mechanical energy produced by physical changes into electricity. NGs smaller than a cell can be integrated into microdevices for local cell stimulation. Among them, ZnO nanosheets (NSs) have been proved biocompatible and able to electrically stimulate human osteoblast-like (1) and muscle cells. These microdevices can be remotely activated by ultrasounds and allow a better spatial resolution to treat single cells (2). In this work, millions of reproducible microdevices, incorporating piezoelectric ZnO NSs with volumes below 25 μm³ were manufactured. These fabricated microdevices were later tested to assess their cytocompatibility, electrical effect and position with respect to the cell. Piezoelectric nanogenerators (NGs) convert the ambient mechanical energy produced by physical changes into electricity. NGs smaller than a cell can be integrated into microdevices for local cell stimulation. Among them, ZnO nanosheets (NSs) have been proved biocompatible and able to electrically stimulate human osteoblast-like (1) and muscle cells. These microdevices can be remotely activated by ultrasounds and allow a better spatial resolution to treat single cells (2). In this work, millions of reproducible microdevices, incorporating piezoelectric ZnO NSs with volumes below 25 μm³ were manufactured. These fabricated microdevices were later tested to assess their cytocompatibility, electrical effect and position with respect to the cell.

Experimental Methods
Piezoelectric microdevices were fabricated patterning a silicon wafer with millions of microparticles through microfabrication processes and the hydrothermal synthesis of the ZnO NSs. These microdevices were 'peeled off' and suspended in deionized water, then, sterilized by ethanol. The cytotoxic effect of the microdevices was assessed using a Live/Dead Kit (Invitrogen) on a cell culture of human osteosarcoma cells (Saos-2 cells) after 1 and 7 days culturing both cells and the microdevices (2:1 ratio). The samples were fixed and dehydrated to analyse the position of the microdevices with respect to the cells using SEM (Auriga-40 Carl Zeiss) and confocal laser scanning microscope (CLSM, Leica SP-8 DIVE). Complementary experiments testing the electrical stimulation of cells by measuring intracellular calcium increases through fluorescence intensity (Fluo-4AM) in the confocal laser scanning microscope (CLSM, Leica SP-5) are being performed (1, 3). After culturing together the microdevices with the Saos-2 cells (2:1 ratio) for 24 h, the microdevices are excited using an ultrasonic transducer (OPTEL, 2 MHz and 10 MHz). Images of osteoblasts are captured every 1 s for 15 min.

Results and Discussion
The microfabrication process and the hydrothermal growth provide a great homogeneity and reproducibility for the fabrication of the microdevice. The cytocompatibility results indicated above 90% of live cells on day 1 and above 85% on day 7, without significant differences with negative controls. Three different positions are taken by the microdevice (Figure 1): inside the cell (internalized), outside the cell with the NSs towards the cell membrane (top down) and with the NSs towards the surrounding medium (face up). The results show that 49% of the cells were in contact with one microdevice, 25% with two, and 12% with three microdevices. Among them, the 47% of these cells did not internalize any microdevice. The position of the microdevices could be controlled by functionalizing them. We can validate the electrical stimulation of the cells by exciting these microdevices through ultrasounds, based on
previous works (1). We expect a positive effect on cell differentiation and proliferation in cells that are in contact with microdevices due to the increase in cell activity. We hypothesize that the microdevices with NSs towards the cell membrane could electrically stimulate osteoblasts (1, 3), whereas the internalized microdevices could interfere the intracellular pathways.

**Conclusion**
Simple, cost-effective, technologically-reproducible microdevices with ZnO NSs were fabricated. The newly developed microdevices are cytocompatible on human osteosarcoma cells and can excite the cell electrically in response to ultrasonic actuation. These added suspended microdevices were in close contact with cells, both internalized and outside the cell membrane, which is important to ensure the electric stimulation.

Conductive resorbable hyaluronic acid-based hydrogels for tissue stimulation and monitoring

Rachel Auzély-Velty², Isabelle Texier¹, Maxime Leprince¹,²

¹ CEA of Grenoble, LETI/DTBS/L2CB, Grenoble, FR; ² University Grenoble Alpes, CERMAV, Grenoble, FR

Introduction
Due to their low elastic modulus, high hydration and electrical properties, conductive hydrogels are suitable candidates for electronics/soft tissue interface. Recently, conductive hydrogels have been developed based on commercial PEDOT:PSS (3,4-poly(ethylenedioxythiophene : poly(styrene) sulfonate) [1]. However, those hydrogels display some limitations for in vivo implantation due to problems of biocompatibility and biodegradability of PSS. In this work, we intended to replace PSS by a modified hyaluronic acid derivative, acting at the same time as the dopant of PEDOT, and as an extracellular-matrix-mimicking building block for the construction of the hydrogel matrix. The resulting new PEDOT-based conductive hydrogel displays enhanced biocompatibility, and biodegradation features. These properties enable the design of soft transient electronic devices, which could avoid explantation surgery.

Experimental Methods
HA was chemically modified in order to achieve a suitable dopant for PEDOT. It was sulfated (HAS) to increase its acidity and global negative charge, and phenylboronic acid (PBA) moieties were introduced to enhance hydrophobic interactions with PEDOT domains. The resulting biopolymer was cross-linked using adipic dihydrazide acid, simultaneously with EDOT polymerization, resulting in a conductive hydrogel (Fig.1). Material electrochemical and mechanical properties were studied through cyclic voltammetry, electrochemical impedance spectroscopy (Fig. 2.), electron microscopy, swelling and rheology characterizations. Hydrogel cytocompatibility and biodegradation rate were investigated as well. Ex-vivo experiments are presently on-going on rat brain slices to assess hydrogel electrical stimulation properties.

Results and Discussion
PEDOT:HAS-PBA material exhibited a high conductivity of 2-3 S/cm, among the highest of PEDOT:biomolecule reported in literature [2]. The conductive hydrogel appeared soft, with an elastic modulus (G’ ≈ 4 kPa) close to that of brain tissue. It displayed a high charge storage capacity of 2.90 ± 0.30 mC/cm², in addition to a low impedance around 650 Ω at 1 kHz (Fig. 2). Degradation study showed a mass loss around 70 % in 56 days when incubated at 37°C with hyaluronidase, making it suitable for midterm in vivo stimulation treatment. In vitro assays demonstrated hydrogel non-cytotoxicity (according to ISO 10993_5 standards). Based on these positive results, PEDOT-HAS-PBA conductive hydrogels are presently being tested for the ex vivo stimulation of brain tissue sections.

Conclusion
The newly-designed conductive PEDOT:HAS-PBA based hydrogel appeared as perfectly biocompatible, biodegradable, and exhibited unprecedented conductive and electrochemical properties among PEDOT:biomaterial-based conductive hydrogels described in the literature. The total control over material synthesis enabled a fine tuning of electrical and mechanical properties, resulting in a wide range of potential applications, from tissue stimulation to conductive medium for electro-sensitive cells, which are presently being investigated.

Introduction
Tissue engineering and regenerative medicine strategies are the best current approaches to cure neurological diseases. Induced pluripotent stem cells (iPSCs) can provide a source of autologous neural stem cells (NSCs) to treat them. The use of scaffolds can assist in NSC transplantation to the target tissue and promote tissue integration and enable a more efficient differentiation of cells to a favorable phenotype.

Coaxial electrospun fibers, composed of 2 layers, make ideal scaffolds for neural applications due to their versatility: 1) tunable fiber diameter and mechanical properties, 2) creation of chemically-independent layers and with different bioactivities, and 3) potential controlled-release of encapsulated substances. In this work we describe the development of coaxial fibers-based platforms, suitable for electrical stimulation of iPSC-driven NSCs (iNSCs).

Experimental Methods
PCL-PANI and PGS solutions were prepared and coaxial fibers were electrospun under the following conditions: shell solution (PCL-PANI) at 3 mL h\textsuperscript{-1}, core solution (PGS) at 1.5 mL h\textsuperscript{-1}, 22.5 kV, 20 cm, 21 \textdegree C, relative humidity of 40 - 50 \%. PCL-PANI and PCL fibers were used as controls. An air-blower was used to force fiber deposition on the collector. Fiber morphology and diameter was evaluated through scanning electron microscopy (SEM). Coaxial structure was evaluated through transmission electron microscopy (TEM) and complementary physico-chemical properties by differential scanning calorimetry (DSC) and Fourier-transform infrared spectroscopy (FTIR). The following critical fiber properties for neural cell culture were evaluated: electroconductivity (4-probe method), stiffness (mechanical properties), hydrophilicity (contact angle), and in vitro stability/biodegradability (PBS and lipase-solution). To test biocompatibility, iPSCs were differentiated into iNSCs, transferred to the fibers and further differentiated. The effect of electrical stimulation on iNSCs neural fate was also investigated. Cell were stimulated (1 V cm\textsuperscript{-1}, 100 Hz, pDC) for 30 days, and neural profile was evaluated through immunofluorescence (IF) and quantitative polymerase chain reaction (qPCR).

Results and Discussion
The produced coaxial PCL-PANI/PGS fibers have an average diameter of 951±465 nm and an electroconductivity of 0.063±0.029 S cm\textsuperscript{-1}. The mechanical properties (\(\varepsilon\) of 1.3 MPa) and hydrophilicity (38\textdegree) allow NSC differentiation. Coaxial fibers degrade in the presence of a human lipase (72\% weight-loss in 12 hours). Neural differentiation of iPSCs occurs normally on the coaxial fibers, and the application of electrical stimulation improves neural maturation. In particular, we observe the expression of higher levels of synaptophysin (synaptic vesicles), NEF-H (mature neurons), CACNA1C (functional neurons) and VGLUT1 (glutamatergic neurons), accompanied by a decrease in DCX (migratory early neurons), TUBB3 (early-neural marker) and GAD67 (GABAergic neurons).

Conclusion
This study shows that the fibers developed here have potential applications in neural tissue engineering, namely for in vitro platforms for drug screening and disease modelling, and ultimately for direct transplantation of mature and functional neurons into patients’ brains. The coaxial fibers are electroconductive, soft, hydrophilic, able to swell up to two times their weight. These are stable in PBS, being able to maintain significant electroconductivity for up to 28 days. In the presence of lipase, PGS/PCL-PANI core layer PGS degrades completely after 7 days, but the shell layer (electroconductive) degrades slower. iPSCs, after neural induction, were successfully differentiated into neurons on PGS/PCL-PANI coaxial fibers. The electrical stimulation results suggest a shift from an inhibitory to an excitatory neural cell profile during the 30 days of culture. More studies are required to further explain the changes observed on neural differentiation and the mechanisms involved.

Melt Electrowriting of Polymers beyond Poly(caprolactone) with Focus on Electroactive Materials

Juliane C. Kade¹, Paul Otto¹, Biranche Tandon¹², Dario Pisignano³⁴, Luana Persano³, Robert Luxenhofer⁵⁶, Paul D. Dalton¹²

¹ University Hospital Würzburg, Department of Functional Materials in Medicine and Dentistry and Bavarian Polymer Institute, Würzburg, DE; ² University of Oregon, Phil and Penny Knight Campus for Accelerating Scientific Impact, Eugene, US; ³ NEST, Istituto Nanoscienze-CNR and Scuola Normale Superiore, Pisa, IT; ⁴ Università di Pisa, Dipartimento di Fisica, Pisa, IT; ⁵ Julius-Maximilians-University Würzburg, Polymer Functional Materials, Chair for Advanced Materials Synthesis, Department of Chemistry and Pharmacy, Würzburg, DE; ⁶ Faculty of Science University of Helsinki, Soft Matter Chemistry, Department Chemistry, and Helsinki Institute of Sustainability Science, Helsinki, FI

Introduction
Additive manufacturing techniques are increasingly used for tissue engineering and regenerative medicine (TERM). Melt Electrowriting (MEW) is an additive manufacturing technique to fabricate scaffolds with fiber diameters in the lower micron range with a need to expand the range beyond the current gold standard poly(caprolactone) [1,2]. We established MEW of electroactive scaffolds based on poly(vinylidene difluoride) (PVDF) [3] and a copolymer (PVDF-Trifluoroethylene; PVDF-TrFE) [4]. These polymers are known for their piezoelectric properties [5], which can be used for stimulating in TERM applications and wearable sensors.

Experimental Methods
A custom-built MEW printer was used to process the PVDF at 190°C and PVDF-TrFE at 170°C with an N₂-pressure of 3.0 and 0.5 bar, respectively. The distance between the print head and collector was set to 4.0±0.4 mm with an applied potential difference of +3.0 - 3.7 kV. The collector temperature was varied between room temperature and 150°C. Processing of PVDF was possible with collector speeds of up to 4000 mm/min. In contrast, sufficient processing parameters of PVDF-TrFE resulted in remarkable low speeds below 100 mm/min. Furthermore, additional printing parameters, like novel nozzle designs, have been investigated.

Results and Discussion
To MEW-process PVDF using a heated collector helped to improve the layering, accuracy and stability of the printed constructs. Furthermore, printing at speeds of 4000 mm/min and heating the collector to temperatures above 100°C does reduce warping of the already processed construct and therefore, enables to print scaffolds with 20 layers at 110°C (Figure 1A). However, at collector temperatures of 120°C or higher, the deposited polymer agglomerates resulting in coalesced dots at the crossing points of the scaffolds (Figure 1B-C) inducing a reproduceable biomimetic design.

Furthermore, the additional parameter of a heated collector was necessary to MEW-process PVDF-TrFE [4]. Due to the rapid solidification of the polymer jet, only collector temperatures of at least 120°C enabled sufficient fiber adherence and resulting fibers (Figure 2) were straight at remarkable low printing speeds. Using XRD, the processed polymer showed an increase in the total crystallinity, as well as a shift from the α- to the piezoelectric β-phase. The electroactive nature of the processed fibers was proven by PFM measurements.

Conclusion
PVDF and PVDF-TrFE were shown to be MEW-processable resulting into scaffolds with relevance to applications where well-resolved 3D printed structures of piezoelectric polymers are of interest, such as biomedical products.

The Development and Characterisation of Electroconductive Biomaterial Scaffold for Spinal Cord Injury Repair

Aleksandra Serafin¹, Mario Culebras Rubio¹, Maurice Collins¹, Miguel Oliveira²,³, Aleksandra Serafin¹

¹ University of Limerick, School of Engineering, Limerick, IE; ² University of Minho, Research Institute on Biomaterials, Biodegradables and Biomimetics, Minho, PT; ³ PT Government Associate Laboratory, ICVS/3B’s, Braga, PT

Introduction
Spinal cord injury (SCI) is a debilitating disorder that often results in paralysis at or below the injury site due to the loss of motor and sensory function of the patient and is caused by a primary injury to the spinal cord by means of traumatic contusion or laceration. Annually, 12,000 new cases of SCI are reported in the United States. Due to a lack of effective medical treatments for SCI, the number of patients who suffer from this affliction rises every year [1, 2]. The scientific and medical communities have thus in turn begun to explore tissue engineering (TE) strategies to try and alleviate the medical conundrum that is SCI repair. Neural stem cells and biomolecules have been often been incorporated into the TE scaffolds for this purpose, though limited results have been achieved to date due to the hostile nature of the injured spinal cord environment. Recently, interest in materials that possess electroconductive properties has enabled the production of a new generation of scaffolding materials, which deliver more optimal results in terms of tissue repair than their non-conductive counterparts.

As with the development of any biomaterial, a number of factors must be met to achieve suitability for use in TE strategies, including excellent biocompatibility, biodegradability, and suitability for cells/bioactive factor incorporation whilst facilitating the regeneration of neuronal or axonal tracts in the spine. The physicochemical characterization of this biomaterial includes morphology, degradation profiles, compression tests, electroconductivity, rheology, and biocompatibility studies. In-vitro cytocompatibility studies include Alamar Blue assay and Immuno-fluorescence staining of protein markers on neural stem cells.

In this work, we present the development and subsequent characterization of a new electroconductive biomaterial. The basis of the electroconductive element in this novel biomaterial is conductive polymer nanoparticles (NPs) created by means of a novel mini-emulsion method. Due to its production method, the polypyrrole (PPy) NPs are water-soluble and have the potential to be functionalized in a myriad of ways.

Experimental Methods

Structural analysis: The morphology of the developed NPs was first analyzed using Scanning Electron Microscopy. The NPs were then incorporated into a hydrogel structure to create NP electroconductive scaffolds. Cross-sectional images of NP electroconductive scaffolds were analyzed to evaluate the changes in the morphology and porosity of the scaffolds.

Compression properties: The compression test carried out on the NP electroconductive scaffolds using an in-house compression test facility equipped with a 1 kN load cell. Circular discs, diameter 13.5 mm and thickness 4 mm, were used with a screw speed of 1 mm/min up to 60% strain. The Young’s Modulus of the samples was calculated as the slope in the linear region of normalized stress vs. strain graph.

Conductivity properties: The resistivity of the NP electroconductive scaffolds was measured using an Ohm meter. The conductivity was then calculated as follows:

\[ \sigma = \frac{RA}{l} \]  

Where \( \sigma \) is the conductivity, \( l \) is the sample length, \( A \) is the cross-sectional area and \( R \) is the resistance.

Biocompatibility: Developed NP electroconductive scaffolds were U.V. sterilized and incubated in complete cell...
culture medium (DMEM media supplemented with 1% penicillin-streptomycin, 2% L-Glutamine and 10% FBS) for 72 hr at 37 °C (5% CO₂ incubator) to allow for equilibrium, with the media changed regularly. Subsequently, the media was removed completely and seeded with 0.05x10⁶ cells/scaffold Neural Stem cells in 24-well plates, and incubated overnight to allow for cell attachment to the scaffold. The scaffolds were then incubated for a period of up to 72 hr to perform Alamar Blue and Immunofluorescence assay.

Results and Discussion
The development and characterization of the NP electroconductive scaffold were successfully accomplished. Figure 1 shows the round and stable morphology of the synthetized PPy NPs, while Figure 2 shows the PPy NPs embedded in a gelatin/hyaluronic acid hydrogel blend scaffold, with individual NPs present dispersed and embedded throughout. The developed NP electroconductive scaffold displays adequate mechanical strength comparable to that of the native spinal cord. The conductivity of the scaffolds ranged up to 10⁻⁷ S/cm. Biocompatibility shows that the developed NP electroconductive scaffold facilitates cell proliferation and growth.

Conclusion
From this work, it can be concluded that the developed NPs and subsequent incorporation into NP electroconductive scaffolds show promise as a TE strategy for SCI repair.

**Introduction**

The use of electricity in interaction with biological systems for therapeutic and diagnostic purposes become a prominent research topic. Electrodes are key components of electrical stimulation and recording devices for *in vivo* and *in vitro* usages. Bioelectrodes should present excellent *electroconductivity* to be able to transfer the electrical current efficiently (charge mobility inside the device). Moreover, they need to provide excellent *electroactivity* to convert electronic current to ionic current at the electrode/extracellular fluid (ECF) interphase. The use of nanostructures in fabrication of bioelectrodes is beneficial, since nanostructures offer superior effective surface area that decreases impedance (Z) and increases charge storage capacity (CSC) of the electrodes. Low Z prevents irreversible faradic reactions that are harmful for biological systems (safe stimulation), and decreases thermal noises that interfere recording bioelectrical signals. Higher CSC ensures effective charge transfer (effective stimulation)¹. Here we developed highly pure metallic nanostructured electrodes from Ti, Au and Pt and characterized their electrochemical properties. Electrical stimulation (ES) modes for both *in vitro* and *in vivo* applications were simulated. Finally, we present the design of an *in vitro* ES platform incorporating nanostructured electrodes.

**Experimental Methods**

Au, Pt and Ti nanocolumnar layers (NCs) (~250 nm thick) have been deposited on glass substrates by means of magnetron sputtering using the glancing angle deposition configuration (GLAD)². Continuous thin films (~30 nm) of the same metals were also grown on glass as control groups with the same technique but using the standard parallel configuration. The microstructure of the electrodes was determined using scanning electron microscopy (SEM) (Fig. 1A) and atomic force microscopy (AFM). Electrochemical characterization was performed using a potentiostat with FRA32M module in a three-electrode setup. A platinum mesh used as a counter electrode and Ag/AgCl was used as reference electrode. Measurements were performed in PBS with a sinusoidal excitation signal of 10 mV in the 0.1-10⁵ Hz range. Cyclic voltammetry (CV) has been performed within the water potential window recommended for Pt (−0.5 to 0.8 V), with 0.1 V/s sweep rate. CSC values were obtained from CV diagrams.

**Results and Discussion**

Electrical impedance spectroscopy revealed that Z values at 1 Hz for Ti and Pt NCs are one order of magnitude smaller than those for Ti and Pt thin films. In the case of Au, the Z of NCs is ~2 times smaller than that of the thin film (Fig. 1B). Generally, lower Z is a favourable characteristic for ES systems (both for *in vivo* implants and *in vitro* setups) because of the increase in safety and efficiency of stimulation and recording. Moreover, Z is also gaining importance recently due to its strong dependence on the size of electrodes. The common strategy for increasing ES resolution in biological systems is reducing the size of electrodes, that consequently increases Z. Reduced Z offers then the possibility of miniaturizing the electrodes without harmful side effects. CSC values are significantly improved when NCs are used: ~200% in case of Ti and Au and ~400% for Pt. We obtained CSC of 1.3 mC/cm² for PtNCs, 4 times higher than the value reported for similar Pt nanostructures fabricated by electrochemical deposition³. CSC is an indicator for the sum of the charges that can be introduced to ECF at the electrode interface. Although larger surface area significantly improves CSC, this electrochemical behaviour highly depends on the intrinsic properties of...
the material. Therefore, larger values are obtained for Pt compared to Au and Ti (Fig. 1C). Finally, when applying ES via voltage-controlled methods, the resultant voltage experienced by the ECF may not be the same as the applied voltage waveform after being filtered by the electrochemical double layer capacitance at the interface. Since the double layer capacitance of NCs electrodes is higher than the one for the thin film, the NCs provide a voltage drop across ECF ($V_{\text{medium}}$) that is much closer to the source signal (Fig. 1D). Considering all those benefits of nanostructures, we developed a miniaturized device\(^ 4\) for \textit{in vitro} ES application that provides safe and effective stimulation in a large voltage range (Fig. 1E).

\textbf{Conclusion}

We characterized electrochemical properties of metallic nanostructured electrodes. We showed a remarkable improvement in charge storage capacity and highly significant reduction in impedance by using nanostructures. Among the three metals we compared, Pt provide the best properties, thus we incorporate it in \textit{in vitro} electrical stimulation device.

Organic Piezoelectric Biomaterials for Electrostimulation: Poly-1-Lactide Films

Sofija Nikolic, Lea Udovc, Mihaela Apetrei, Matjaz Spreitzer, Marija Vukomanovic

Jozef Stefan Institute, Advanced Materials Department, Ljubljana, SI

Introduction
Due to the high perspective of implantable electro-stimulators in achieving reinforced post-operative regeneration their design is constantly being improved. The improvements are mainly associated with advancing materials used for their assembly. So far the highest progress has been achieved by using piezoelectric materials. Piezoelectric scaffolds can generate electrical pulses as a result of deformation caused by body motion (blood circulation, heart beating, muscle tension, migration of cells, etc.). Important advantage of their application for electro-stimulation is lack of electrodes with questionable biocompatibility or lack of external source of electricity, which can result in accumulation of potentially toxic product of electrolysis. However, selection of the piezoelectric material that will meet the biocompatibility requirements in combination with required piezoelectric coefficients is a big challenge.

Experimental Methods
Our work is focused to optimizing piezoelectric properties of poly-1-lactide (PLLA) films using several processing approaches (illustrated in Fig. 1). In thermal drawing pre-melted, amorphous film is clamped and mechanically stretched to specific drawing ratio. The approach enables thick, self-standing films usually formed out of parallel layers, oriented in the drawing direction. On the other hand, in template wetting, the pillar-shaped pores in AAO template membranes are filled with pre-melted polymer. Polymer is drawn by capillary forces during wetting the walls of the pores inside template. After removing the template, polymer forms PLLA tubes. For the case of electrospining, instead of melting, polymer is dissolved in selected solvent and deposited on conducting collector (stationary or rotational). In this case, polymer is stretched by using forces in electric field combined by forces from rotating collector. The polymer forms fibres which could be random of aligned (depend on the type of collector). The morphology of so-formed fibres depends strongly on selected solvents and enables forming largely porous, non-porous and smooth surfaces. Due to the applied stretching, all three approaches enable orientation of PLLA molecules within formed structures. In all there cases we preferentially detected formation of α crystal structure. In films formed by thermal drawing crystallization takes place along with mechanical stretching, while films formed by wetting template and electrospinning usually need additional annealing to crystallize. As a result of molecular orientation and crystallization, films were having piezoelectric nature and they were able to provide voltage signal either after compressing or twisting deformation.

Results and Discussion
Piezo-PLLA films formed in our lab are investigated for interactions with both prokaryote and eukaryote cells. Electro-stimulation of bacteria in presence of piezo-PLLA films (deformed using soft ultrasound), is observed to provide damages in bacterial cell wall. In sessile bacteria we observed both bacteriostatic and bactericidal effects, while bacteria adhered to film surface are intensively detached after stimulation. During interactions with non-adherent mammalian cells (red blood cells, RBCs, isolated from sheep blood), similar damages on cell membranes were not detected. Electro-stimulation did not provide cell haemolysis and morphologically RBCs were keeping innate morphology without showing signs of clotting. Testing interactions with adherent mammalian cells (human skin keratinocytes, HaCaT) revelled effect of electro-stimulation on cell migration, proliferation and defect recovery (Fig. 1).

Conclusion
Page 341 of 2028
Due to its biocompatibility and biodegradability, piezo-PLLA is one of the most perspective candidate for clinical application of organic piezoelectrics in electro-stimulated tissue regeneration and recovery. Different processing routes enable versatility of their applications either as bioactive coatings or as membrane scaffolds.

Microrobotics and Nanomedicine: Future Directions in Medical Robotics

Bradley J. Nelson

ETH ZURICH, Mechanical and Process Engineering, Zurich, CH

While the futuristic vision of micro and nanorobotics is of intelligent machines that navigate throughout our bodies searching for and destroying disease, we have a long way to go to get there. Progress is being made, though, and the past decade has seen impressive advances in the fabrication, powering, and control of tiny motile devices. Much of our work focuses on creating systems for controlling micro and nanorobots as well as pursuing applications of these devices. As systems such as these enter clinical trials, and as commercial applications of this new technology are realized, radically new therapies and uses will result that have yet to be envisioned.

Social Activity 2 | YSF Night Out

This years’ YSF night out is unfortunately not taking place face to face in a beautiful bar near the Atlantic Ocean, as we wished for. But that should not prevent us from social gathering and meeting new and old friends from our scientific community!!!

We challenge young researchers (under 40!) to join our online event, where participants will be gathered into groups and play each other, letting us know how much you know about Portugal, the World, and… ESB!

As in any YSF night out, drinks should be a requirement! Due to restrictions in many countries we were not able to send you our famous Port Wine, but we invite you to grab a beer, glass of wine, or any cocktail of your choice (or a mocktail, if you really must…), so that we better feel the informal environment!

The event is free, but registration is required.

NANOSTEM Satellite Symposium

Title: New nanomaterials for neural stem cells drug delivery

Brain conditions such as neurodegenerative diseases, stroke and traumatic injuries are a major burden in modern society. Because neural stem cells (NSCs) can differentiate into new neural cells, including neurons, the regulation of their proliferation, differentiation and migration represents a promising regenerative/therapeutic strategy. The hypothesis of NANOSTEM project is that novel nanoparticles (NPs) combined with recent developed pharmaceuticals can be an efficient approach to control the biological activity of NSCs.

During this multidisciplinary symposium 14 Early-Stage Researchers will present their recent findings and advancements within the frame of the NANOSTEM European Project. The topics covered will be ranging from organic and polymer chemistry, biochemistry, molecular biology, neuroscience, and computational science, with particular emphasis on:
1) synthesis of nanomaterials and uploading of the therapeutics
2) evaluation of the permeation and efficacy of the formulations against neural stem cells
3) in vivo studies to assess the toxicity of the formulations developed and their ability to tackle the brain.

About NANOSTEM:

NANOSTEM is a Marie Skłodowska-Curie Innovative Training Network (ITN) funded by the European Commission through the Horizon 2020 Research and Innovation programme (H2020-MSCA-ITN-2017 G.A. 764958). The network is coordinated by Prof Marina Resmini at QMUL and comprises 9 beneficiary teams and 3 associated partners, from 6 different European countries, both from academia and industry.

The Coil-Globule Transition: Thermosensitive Hydration of Acrylamide-based Polymers
Patrick K. Quoika, Monica L. Fernández-Quintero, Anna S. Kamenik, Maren Podewitz, Klaus R. Liedl
University of Innsbruck, Department of General, Inorganic and Theoretical Chemistry University of Innsbruck, Innsbruck, AT

Introduction
Counterintuitively, thermosensitive polymers undergo a phase-transition with a lower critical solution temperature. Accordingly, they form a gel above a certain temperature, while they exist in liquid mixture with the solvent below this temperature. The macroscopic phase behaviour is linked to a conformational change of the polymers: the so-called Coil-Globule transition. To understand their extraordinary phase behaviour, we investigated the conformational dynamics of a selection of acrylamide-based polymers – including thermosensitive and non-thermosensitive ones.

Experimental Methods
We performed molecular dynamics simulations of linear polymer chains with atomistic detail at a wide range of temperatures. With regards to their potential thermosensitivity, we analyzed the conformational ensembles with respect to the Coil-Globule transition and quantified thermodynamics and kinetics of the process. To this end, we computed the equilibrium constants and energetic contributions to the free energy of the transition, such as e.g. the conformational entropy of the polymers, and characterized the conformational ensembles with polymer-specific descriptors. Therewith, we were able to build markov state models of the conformational dynamics, which yield an accurate reconstruction of the kinetics at different temperatures.
Results and Discussion
We succeeded in distinguishing between thermosensitive from non-thermosensitive polymers based on our simulation results. Further, we report distinct hydration profiles for these two classes of polymers and identified the polymer-solvent interactions to be essential for the energetic balance of the transition. We report a clear trend between the lifetime of the hydrogen bonds between the polymer-surface and water and the thermosensitive character of the polymers. Moreover, we were able to resolve the conformational space of the polymers by means of the freely jointed chain model and obtained consistent results with respect to thermodynamics and kinetics of the thermosensitive Coil-Globule transition.

Conclusion
We identified conformational substates that suggest that the thermosensitive Coil-Globule transitions may be a multi-step process. Furthermore, we found that the radius of gyration of these polymers is not an optimal coordinate to resolve the kinetics of this transition, despite it being a valid descriptor in experiments. Ultimately, we conclude that the solvation entropy is decisive for the thermosensitivity of these substances.

Nanogels for drug delivery: effect of synthetic methodology on the structure of pNIPAm and drug loading

Alena Vdovchenko¹, Amanda Pearce², Mark Freeley¹, Rachel O’Reilly², Marina Resmini¹

¹ Queen Mary University of London, School of Biological and Chemical Sciences, London, GB; ² University of Birmingham, School of Chemistry, Birmingham, GB

Introduction
The proximity of the volume phase transition temperature (VPTT) of poly-N-isopropylacrylamide (pNIPAm) nanogels to physiological temperature governs interest for their use as a drug delivery system.¹ At temperatures below VPTT, pNIPAm exists in a swollen state in an aqueous solution, while an increase in temperature above VPTT leads to the expulsion of water molecules from the polymer matrix. This thermoresponsive behaviour of pNIPAm can be used to control drug release. At the same time, thermostresponsiveness of pNIPAm leads to the possibility of switching the nature of polymerization from homogeneous, conducted below VPTT, to heterogeneous above VPTT.²

Experimental Methods
In the following study, we analysed how synthetic methodology, whether homogeneous or heterogeneous polymerisation, affects the morphology and properties of pNIPAm nanogels.

Results and Discussion
A number of experimental parameters were altered, such as the temperature of polymerisation and the choice of initiator. The obtained nanoparticles were then characterised with a range of techniques, such as dynamic and electrophoretic light scattering, UV-Vis spectroscopy, surface tensiometry, as well as liquid-phase atomic force and transmission electron microscopy.

Conclusion
The morphology and thermal behaviour of nanogels were rationalised to identify potential link with the polymerisation conditions.

Protein corona of nanogels and its impact on the air/water interface

Federico Traldi, Marina Resmini

Queen Mary University London, School of Biological and Chemical Sciences, London, GB

Introduction
In the last few decades, nanomaterials have emerged as attracting platforms for drug delivery and imaging. Despite the great potential of nanoparticles in nanomedicine, their application in clinical settings is hindered by the limited knowledge of their interaction with bio-interfaces. When dispersed in biological media, nanomaterials may be coated with proteins in solution and form a "protein corona". Extensive research has undeniably proven that the formation of a protein corona can deeply affect the behaviour of nanoparticles in biological systems. However, the relative limited knowledge of how the properties of nanomaterials drive the formation of the corona poses a serious obstacle to their rational design. New methods to characterise the nanoparticle corona in its biologically relevant environment are hence required to bridge this knowledge gap.

Experimental Methods
In this work we aimed at developing a novel approach towards the characterisation of protein corona of polymeric nanogels based on dynamic surface tensiometry. Nanogels' characteristics, such as low toxic profile, high colloidal stability and potential stimuli-responsive behaviour make them ideal candidates for drug delivery applications. A series of nanogels based on backbone monomer acrylamide (AM) and crosslinker methylenebisacrylamide (MBA) were synthesised via high dilution radical polymerization. To investigate the effect of electrostatic forces on the affinity of nanogels for model proteins, either negative or positive charged co-monomers were incorporated in the polymer matrix. Evaluation of protein corona formation was carried out using dynamic light scattering and surface tensiometry. The latter provides an attractive novel tool for the identification and characterisation of protein corona of nanogels.

Results and Discussion
We showed that dynamic surface tension could be used as a sensitive technique to characterise protein corona, by detecting in situ nanogel-protein interactions. Moreover, impact of protein corona formation on the properties of nanogels in the bulk of the solution as well as at the air/water interface was investigated with the complementary use of dynamic surface tension, dynamic light scattering, and circular dichroism.

Conclusion
These data advance the understanding of the impact of protein corona on the physico-chemical properties of nanoparticles and enable a more effective rational design of nanomaterials for drug delivery application.

Comparison of release profile of nanocapsules measured with dialysis and an innovative sample and separate technique, the NanoDis system

Sonia M. Lombardo¹², Akif E. Türelı¹, Nazende Günday-Türelı¹, Marc Schneider²

¹ MyBiotech GmbH, R&D Pharma, Überherrn, DE; ² Saarland University, Department of Pharmacy, Biopharmaceutics and Pharmaceutical Technology, Saarbrücken, DE

Introduction
Poly(lactic co-glycolic acid) (PLGA) nanoparticles have been of particular interest the last decades due to their good biocompatibility and their reported extended release properties. However, these nanoparticles often suffer from burst release, where a large amount of the encapsulated drug is released after the first hours in release medium [1]. As burst release can lead to sever adverse effects, its good characterization is essential. Nowadays, there is still no standard release tests for nanoformulations. Dialysis techniques are the most used methods in the literature as they are easy to set up. However, these methods suffer from sever drawbacks as the measured release might depend on the permeation kinetic of the drug through the dialysis membrane. If the release is faster than the permeation kinetic, which is often the case for nanoparticles suffering from burst release, the measured release profile is not representative of the actual release happening inside the dialysis bag. The burst release might then be hidden and the release profile easily misinterpreted as an extended release [2].

Experimental Methods
In this study, an innovative sample and separate technique, the NanoDis system, was used to assess the release of PLGA nanocapsules. With this technique, a USP II (paddle) dissolution apparatus coupled with an autosampler, was connected to hollow fiber filters. The nanocapsule formulations were diluted in different release media in sink conditions. At specific time points, the nanocapsules were automatically filtered by tangential flow filtration to efficiently separate the released drug from the nanocapsules. The same formulation was also tested using dialysis, in the same release media.

Results and Discussion
A high burst release could be observed with the NanoDis system after 1 hour, while the release profile measured with dialysis was limited by the permeation kinetic of the free drug. Thus, the NanoDis system showed clear superiority over the dialysis method for the measurement of burst release of our nanocapsule formulation. Next, the release profile of different nanocapsule formulations, prepared with various surfactants and polymeric coatings, were tested using the NanoDis system. Depending on the formulations, different burst release profiles were observed, showing the ability of the NanoDis system to discriminate between formulations.

Conclusion
Page 352 of 2028
In conclusion, the NanoDis system showed to be an interesting technique for the release test of a variety of PLGA nanocapsules and was able to accurately measure their burst release.

Targeted drug delivery of Diblock copolymers and drug encapsulation efficiency for neural stem cell proliferation

Eirini Epitropaki, Sam Parkinson, Rachel O'Reilly

University of Birmingham, BIRMINGHAM, GB

Introduction
Neurodegenerative diseases such as ischemic stroke, Alzheimer’s and Parkinson’s can cause cellular loss, which can be tackled with the use of neural stem cells (NSCs). To promote stem cells differentiation into functional neurons, nanomedicine as a non-invasive method presents an opportunity to enable delivery of differentiating agents, while preserving the blood and brain barrier (BBB). The field of nanomedicine has evolved tremendously in the last decade and has contributed to the development of new medical applications. In order for nanoparticles to achieve efficient delivery to the central nervous system (CNS), numerous physico-chemical parameters must be examined. To avoid multiple-step procedures, addition of toxic surfactants, and extensive intermediate purification steps, nanoparticles were synthesized using polymerization induced self-assembly (PISA) in order to create small and functional particle sizes with various charges. Based on the above, the current work aimed to produce amphiphilic nanoparticles with various corona chemistries and different sizes to evaluate their permeation ability through the BBB. To effectively target the CNS, Transferrin was used as protein coating on the nanoparticles in order to increase the permeation rate. In order to promote neural regeneration retinoic acid (RA) was used as a drug and encapsulated with various methods into the nanoparticles and drug uploading and release were evaluated. As the particles are developed as an intravenous carrier, the interaction between the self-assemblies and protein models must be investigated. The effect of the surface charge was explored by introducing the nanoparticles in various biological environments such as cell culture medium and model protein solutions and monitor the interactions occurring.

Experimental Methods
As reported above, polymerization induced self-assembly (PISA) was utilized to create nanoparticles and they were characterized with multiple techniques. Transferrin was attached to the nanoparticles using click chemistry. Drug encapsulation studies entail emulsification with prepared nanoparticles in a solution, emulsification with freeze-dried nanoparticles, and drug uploading during the synthesis of the nanoparticles. Protein solutions were added to the already formed particles in a ratio of 4:1. The nanoparticles were dialyzed into a cell culture medium and explored by dynamic light scattering (DLS).

Results and Discussion
PISA has completely transformed the concept of block copolymer self-assembly by combining polymerization and self-assembly in a single step, eradicating the tedious synthetic procedures. The drug uploading studies exhibited a higher encapsulation ratio during the synthetic uploading approach but also changes the hydrophobicity of the environment and leads to gelation of the reaction and different morphologies. Protein corona evaluation showed only a hard corona formation around the nanoparticles even in higher concentrations for the particles that can form electrostatic interactions with negatively and positively charged proteins.

Conclusion
Small and well-defined nanoparticles were created through PISA and were explored through further experimentation. Protein corona studies exhibited only a hard corona formation and drug uploading of RA showed small efficiency and hydrophilic drug work better with this system.

Improved Uptake of Extracellular Vesicles in Ischemia

Inês Albino1,2, Miguel Lino1,2, Lino Ferreira1,2,3

1 University of Coimbra, CNC - Centre for Neuroscience and Cell Biology, CIBB-Centre for Innovative Biomedicine and Biotechnology, Coimbra, PT; 2 University of Coimbra, IIIUC-Institute of Interdisciplinary Research, Coimbra, PT; 3 University of Coimbra, Faculty of Medicine, Coimbra, PT

Introduction

Ischemic diseases, characterized by an insufficient blood flow that leads to low oxygen levels and nutrient uptake by cells are a major contributor to both disability and death worldwide. Cell-based therapies have shown promising results in ischemic diseases although the poor survival and/or engraftment hinder their clinical efficacy.1 Extracellular vesicles (EVs), collected from stem cells and their progenitors represent a significant component of their paracrine effect after transplantation in the context of therapeutic angiogenesis.2 However, most of the therapeutic effects reported in the context of ischemic diseases are likely indirect. Advances in engineering the surface of EVs to increase travelling distance and targeting specific cell surface epitopes are needed to maximize their local/direct effects. Here, we propose a therapy based on engineered EVs to improve their targeting to ischemic tissues and enhance their angiogenic potential.

Experimental Methods

EVs secreted by mesenchymal stem cells (MSCs) were isolated by filtration and purified by size exclusion chromatography. In order to increase the targeting ability of EVs, the EV surface was conjugated by click chemistry with a peptide that targets galectin-3, a β-galactosidase-binding lectin highly expressed after ischemia.3 The angiogenic activity of native and engineered EVs was evaluated in human umbilical vein endothelial cells (HUVECs) by a survival assay to hypoxic conditions and by a tube formation assay. Targeting and uptake was tested in HUVECs after preconditioning cells to hypoxia (0.1% O2) during 18h. Uptake was evaluated by high content microscopy and confocal microscopy after 3h and 24h incubation with EVs.

Results and Discussion

Our data supports that EVs can be conjugated with controlled amounts of peptides via click-chemistry without changing significantly the physicochemical properties of EVs. Furthermore, we showed that the conjugation with a targeting peptide promotes the interaction with endothelial cells subjected to hypoxic stimulus, increasing its uptake significantly relatively to native EVs (more than 2 times after 3h and 24h incubation).

Conclusion

In conclusion, the EV surface can be engineered by click-chemistry methods to allow controlled presentation of biomolecules to enhance targeting to ischemic tissues.

NANOSTEM 03 | Nanoparticles and blood-brain barrier - mechanisms of permeation and permeability for successful drug delivery

Chair
**Matteo Puglisi**
Ludwig-Maximilians-Universität München, Department of Physiological Genomics, Planegg, DE
In vitro and in vivo evaluation of fluorescent NIPAM-based nanogels as brain-targeting drug delivery systems

Roberta Bilardo¹, Eleonora Rizzi², Caroline Mysiorek², Marie-Pierre Dehouck², Caroline H. Brennan¹, Marina Resmini¹

¹ Queen Mary University of London, School of Biological and Chemical Sciences, London, GB; ² University of Artois, Faculty of Sciences Jean Perrin, Blood Brain Barrier Laboratory (UR 2465), Lens, FR

Introduction
The delivery of drugs to the brain represents a big challenge, given the efficiency of the blood brain barrier (BBB) in preventing permeation. The use of nanoparticles as drug delivery systems has attracted considerable interest, as their very small size is a significant advantage. Polymeric covalently cross-linked nanogels are considered very promising candidates because their physico-chemical properties can be easily tailored by using specific functional monomers. Moreover, the ability of these nanoparticles to form stable colloids, while retaining a high volume-to-surface ratio, allows remarkable loading capability. Fluorescent tags can be easily incorporated in the nanogels to track the nanoparticles within in vitro and in vivo systems to ensure that the target area is reached.

Experimental Methods
Fluorescent labelling of nanoparticles is a commonly used approach used to investigate their uptake and distribution within in vitro and in vivo models. In this study, the introduction of a fluorophore was performed via covalent binding in order to prevent its leakage from the polymeric matrix. A small library of N-isopropylacrylamide-based nanogels containing a benzofurazan derivative as fluorescent label was synthesised and investigated. Following optimisation of the polymerisation protocols and ¹H-NMR monomer conversion studies, the most promising fluorescent nanogels were studied via dynamic light scattering and UV-vis spectroscopy to determine their size and thermo responsive behaviour, respectively. Moreover, UV-Vis spectroscopy and fluorescence spectroscopy were used to investigate their optical properties and their suitability to be used for tracking purposes in vitro and in vivo. Then, toxicity studies and an evaluation of BBB-permeation were performed in vitro by using a human BBB model. Additionally, both the biocompatibility and the distribution of these nanoparticles were assessed in vivo, in zebrafish up to 7 days post fertilisation.

Results and Discussion
The introduction of up to 1 mol% of the selected fluorescent monomer did not significantly impact the main properties of the nanogels compared to their non-fluorescent counterparts, yet allowing the nanoparticle tracking within the in vitro and in vivo models. In vitro studies revealed that these nanoparticles were non-toxic up to 0.1 mg/mL and able to permeate the BBB, being finally internalised within cells. Finally, successful tracking of these fluorescent nanoparticles was observed also within zebrafish and allowed to evaluate the nanogel localisation different administration routes.

Conclusion
In conclusion, successful tracking of the fluorescent nanogels within the selected in vitro and in vivo models revealed the suitability of the adopted strategy and of the selected polymerisable fluorescent monomer.

Introduction

Because of the difficulty of drug penetration into the brain due to the blood–brain barrier (BBB), many CNS drug candidates fail in clinical trials. Hence, there is a need to develop effective CNS drugs following strategies for delivery to the brain, by better selecting them as early as possible during the drug discovery process. The use of \textit{in vitro} BBB models has proved useful to evaluate the impact of drugs/compounds toxicity, BBB permeation rates, and molecular transport mechanisms within the brain cells, in academic research, and early-stage drug discovery [1]. However, these studies that require biological material (animal brain or human cells), are time-consuming, involve costly amounts of materials and plastic wastes due to the format of the models. Hence, to adapt to the high yield needed in early stage drug discovery for compound screening, a patented well-established human \textit{in vitro} BBB model [2] developed in 12-well format Transwell (TW) inserts has been miniaturized and automatized in 96-well format. In addition, PLGA nanoparticles coated with surfactants, polysorbate 80 (PS80) and poloxamer 188 (P188), have been shown to be able to cross the BBB [3], and thus, are interesting formulations for brain drug delivery. Hence, these nanoparticles, labelled with a fluorescent dye, and produced with the MicroJet reactor\textsuperscript{®} technology were developed and tested using the \textit{in vitro} BBB models. Their transport and uptake mechanisms were studied.

Experimental Methods

The original BBB \textit{in vitro} model was developed as a co-culture using endothelial cells derived from CD34+ hemetopoietic stem cells in the inserts, and brain pericytes in the bottom wells. Miniaturization was done using 96 TW plates from Corning\textsuperscript{®} and Falcon\textsuperscript{®}. Concerning automation; the robot Multiflo, BioTek Instruments was used for the cell seeding; Caliper (Sciclone(R), Perkin-Elmer) for experimental assays (permeability and immunostainings); and microscope ImageXpress Micro Confocal High-Content Imaging System (Molecular Devices) for Immunostainings and fluorescence visualization.

Model BBB phenotype was analysed; Gene profile expression by qPCR; the expression of junctional protein by immunofluorescence; BBB model paracellular permeability with Sodium Fluorescein (NaF); Efflux pumps functionality; Receptor functionality using a target molecule and inhibitors of transport; Drug brain penetration was assessed for its correlation with human \textit{in vivo} data; Finally, BBB integrity evaluation towards different compounds depending on concentrations.

Moreover, by using the \textit{in vitro} models developed, the BBB impact of surfactants coated PLGA nanoparticles over different concentrations, as well as the endothelium mechanisms of transport by using a set of inhibitors and competitors.

Results and Discussion

Miniaturized and automated replicate was achieved by adapting cell seeding ratio densities to the 96 TW plates surface area. This replicate reproduced the BBB phenotype [4] as the original 12 TW patented model, with low paracellular permeability, presence of junctional proteins, efflux pumps and functional membrane receptors. The model presented high correlation with human \textit{in vivo} data [5] concerning the brain exposure to the drugs. PLGA nanoparticles showed transport through brain endothelium. PS80 and P188 NP uptake were active transport
dependent and their uptake were reduced with the presence of specific competitors and inhibitors for each formulation.

**Conclusion**

Miniaturized BBB *in vitro* model replicate has met all the BBB model reliability criteria [3] to get predictive results, being easier to handle and using automated technology. This offer the opportunity of a higher screening capacity to generate useful numerous BBB permeation data of many CNS compounds or conditions to test at a time, allowing a significant reduction in biological material, plastic-waste, for being extensively used during early-stage drug discovery studies. Moreover, the PLGA nanoparticles PS80 and P188 tested presented an active internalization mediated by receptors. The formulations seemed to have different uptake profiles and affinities depending on the surfactant coated.

Introduction
Secondly to the formation of a clot in a brain vessel leading to a shortage of blood flow in the downstream region, the ischemic stroke cause cell damage and death in an area of the brain. As the second leading cause of death and the first cause of long-term disabilities worldwide, ischemic stroke needs urgent treatment and new therapeutic strategies to reduce the infarcted area and decrease the pathological outcomes in the long term. Overall, treatment targeting brain diseases face a hurdle which is the access of brain parenchyma due to the Blood-Brain barrier (BBB)\textsuperscript{1}. The BBB, localized at the level of capillary endothelial cells forming the brain vessels, controls and restricts the passage of cells and molecules to the brain parenchyma to maintain a physiological environment for the correct brain function. In the frame of NANOSTEM, a Marie Curie Action project, we studied the capacity of new nano-formulations to cross the BBB in order to target the neural stem cells and stimulate their differentiation capabilities as a novel therapeutic approach to brain. Among the multiple possible nano-formulations as novel drug delivery systems, nanogels retain some promising characteristics\textsuperscript{2}.

Experimental Methods
Given the importance of cells communications and interactions, we developed a human BBB in vitro model consisting of the main cell types at the level of the BBB namely endothelial cells (ECs), pericytes (PCs) and astrocytes (ACs). Our human BBB \textit{in vitro} model was submitted to oxygen and glucose deprivation (OGD) followed by 24h of reoxygenation (R). The model has been characterized for viability and barrier tightness. Additionally, toxicity, crossing and intracellular accumulation of nanogels were evaluated.

Results and Discussion
The human BBB \textit{in vitro} model, developed in a triple culture setting, based on a patented and well-defined one\textsuperscript{3}, retained the key characteristics for a BBB model: enhanced barrier tightness, expression of tight junction proteins and efflux pumps. At the same time, the model submitted to OGD showed visual presence of discontinuity in the tight junction network, as well as lower cell viability and increased expression of genes related to damage. All these are then recovered after the 24 hours of R. Nanogels were found not toxic in the studied conditions and their rate of crossing was showed to increase proportionally with time.

Conclusion
Overall, in this study we have developed and characterised a human BBB \textit{in vitro} model submitted to OGD and R, mimicking the \textit{in vivo} environment during stroke and reperfusion. Moreover, preliminary data, concerning nanogels toxicity and BBB crossing showed promising results.

Blood-Brain barrier permeation using DNA nanotechnology

Georges Kiriako, Elena Ambrosetti, Joel Spratt, Ana Teixeira

Karolinska Institutet, Medical Biochemistry and Biophysics, Stockholm, SE

Introduction
Receptor-mediated transcytosis (RMT) across the blood-brain barrier (BBB) is a key component in delivering drugs to the brain. Avidity, the accumulated strength of multiple protein-protein interactions, is a major regulator of RMT and has become a key factor in drug design. Previous research has shown that an optimal BBB permeation could be achieved by varying the avidity of nanoparticles. For example, the selectivity of nanoparticles coated with transferrin has been shown to increase with increasing avidity (1). [A1] However, high levels of avidity have been shown to hamper the release of the nanoparticles into the brain parenchyma (2). These results suggest that avidity in ligand/receptor interactions is a key regulator of RMT. However, in these systems, only crude control of avidity levels could be achieved by changing the average surface density of ligands on the surface of nanoparticles.

Experimental Methods
In this study, we used DNA nanostructures as scaffolds to manipulate the avidity and nanoscale spatial distribution of aptamers against the transferrin receptor (TfR). This tool allows for control of nanocluster spatial configuration and composition in the length scale of 100 nm and is unique in its high precision in presentation of aptamer spatial distributions. We combined WAZ, an RNA aptamer specific for the TfR, with both flexible and rigid DNA nanostructures to produce aptamer nanoclusters with precise patterns and densities ranging from 1 to 24 aptamer per nanostructure. We assessed the proper folding of WAZ/DNA nanostructures using agarose gel electrophoresis (AGE) and then applied DNA-Paint, a super-resolution microscopy technique, to evaluate the density and the spatial distribution of WAZ on each design. Moreover, we studied the internalization of WAZ/DNA nanostructures and their subcellular localizations in human brain endothelial cells by confocal microscopy.

Results and Discussion
We verified that the DNA nanostructures are properly folded, purified, and hybridized to the WAZ aptamer. DNA-Paint analyses confirmed that the density and the spatial distribution of WAZ were in agreement with our theoretical designs. We also showed that the permeability of DNA nanostructures, flexible and rigid, correlated to WAZ densities. Higher WAZ densities lead to greater nanocluster internalization. In addition, we showed that WAZ/DNA nanostructures colocalize with endosomal markers and escape lysosomal degradation. Further experiments will determine the optimal density of WAZ needed to maximize cell permeability.

Conclusion
In conclusion, these results open the possibility of using DNA nanostructures in delivering therapeutics across the blood-brain barrier. The approach presented can be used to probe a multitude of ligand/receptor-mediated pathways and has the potential to provide new insights relevant for the development of new types of multimeric biological drugs.

Introduction
After ischemic stroke, the blood brain barrier (BBB) undergoes a disruption with a consequent increase in its permeability (BBBP).¹ This event follows a time-course progression through the distinct stroke phases with different underlaying mechanisms. Nonetheless, this marked time-sensitive heterogeneities in post-stroke BBBP hamper the use of a universal and standardized treatment.² BBBP has been reported to be open up until one, three and even five weeks post-stroke³ but its true dynamics, particularly beyond the acute phase, are yet unclear. Understanding post-stroke BBBP evolution could allow the design of personalized and targeted biomaterials aiming to either avoid BBB opening or to tackle neurorepair mechanisms using BBBP as a gate to the central nervous system. Quantitative permeability imaging through magnetic resonance imaging (MRI) can help evaluate these dynamics but the lack of longitudinal studies evaluating BBBP beyond the acute stage hamper the possibility of using delayed BBBP as delivery platform in stroke patients. We aim to study the dynamics of the BBBP in the later phases of stroke and thus we present a pilot cohort study on subacute and chronic BBBP of ischemic stroke patients.

Experimental Methods
We included consecutive patients with acute ischemic strokes in the territory of the middle cerebral artery, aged 18 to 80 years. Neuroimaging was performed at the subacute and chronic stages by MRI including BBB permeability assessment by dynamic contrast enhancement (DCE). We manually drew a region of interest (ROI) including the ischemic region (as defined by diffusion weighted imaging). A second ROI was drawn in the brain parenchyma contralateral to the ischemic area with similar shape and anatomical position and used as control for the analysis. Pharmacokinetic modeling was performed automatically for each ROI using the Tofts Model to obtain the volume transfer coefficient (Ktrans) as a surrogate for BBBP. The same ROIs for each patient were placed in the subsequent 3 months follow-up MRI. We performed a two-tailed paired Student’s t-test between the ipsilateral ischemic and contralateral non-ischemic Ktrans values within each group to evaluate permeability in the lesion area, and between the subacute and the chronic phases to evaluate changes over time. Statistical significance was set at p<0.05.

Results and Discussion
We included 10 patients (6 males, 4 females), mean age of 63.5 ± 16.50 years. Subacute imaging was performed at a mean time of 7 ± 8 days and chronic imaging at 90 ± 12 days. Median (IQR) NIHSS admission was of 9 (8). BBBP was significantly increased in the ischemic tissue when compared to the contralateral (0.011 min⁻¹ vs. 0.0085 min⁻¹ p<0.001) at the subacute stage while in the chronic stage (3 months post-stroke) there was no significant differences between ipsilateral and contralateral permeability (0.008 min⁻¹ vs. 0.007 min⁻¹ p=0.83). We found permeability to be significantly higher (0.011 min⁻¹ vs. 0.008 min⁻¹ p=0.008) in the ischemic tissue in the subacute phase when compared to the chronic phase. Recovery mechanisms such as angiogenesis have been reported to occur in the subacute
phase, being related with higher permeability. This will allow the delivery of novel biomaterials taking advantage of the increased BBBP or the potentially overexpressed receptors in the new forming vessels. Moreover, our preliminary data suggests that contrary to what happens at one-month post-stroke in which BBB is still permeable, at 3 months the BBB appears to be repaired and hence, poorly permeable. This situation will hamper the use of biomaterials that aim to use disrupted BBB as vehicle in this stage.

Conclusion
Our findings reinforce the quantitative and biological heterogeneity of the BBBP after stroke, allowing the design of strategies that aim to use the BBB and its permeability as a therapeutic vehicle or target. Our preliminary data shows that BBBP remains increased in the subacute phase allowing its use as a delivery platform while it progressively decreases over time to reach a repaired and poorly permeable BBB at 3 months.

Introduction
Neurological disorders represent the second cause of death and the first cause of disability globally [1]. Many drugs and nanoformulations have already been developed to treat brain diseases, but few of them reached the clinical application due to the poor blood-brain barrier (BBB) crossing ability. EVs are naturally released lipidic vesicles that carry a cocktail of bioactive molecules (microRNAs, mRNAs, proteins, lipids) from the parental cell and mediate cell-to-cell communication. It has been recently shown that EVs are able to regulate the integrity of the brain vasculature through specific microRNAs [2,3]. For example, neurons secrete exosomes enriched in miR-132, capable of being translocated to endothelial cells and regulate the expression of vascular endothelial cadherin. In addition, there are experimental evidences that EVs may mediate in vivo the transport of proteins through barriers. For example, it has been reported that EVs secreted by red blood cells from PD patients can transfer α-synuclein across the BBB via adsorption mediated transcytosis (AMT)[4]. Using wheat germ agglutinin (WGA), an inducer of AMT, the amount of radiolabeled EVs increased significantly in the brain after intravenous injection in the jugular vein of mice. Despite these progresses, it is relatively unknown what miRNAs in EVs can modulate in the BBB allowing the transport of the EVs through the BBB. Here, we have transfected EVs with a short list of miRNAs to study their influence in the permeability of the BBB. The selected miRNAs were inspired by their role in ageing.

Experimental Methods
In order to identify the possible miRNA candidates for our system, we elaborated information from literature data by combining the information between miRNA changes during aging and miRNAs affecting the BBB. We then loaded the miRNAs on EVs. The EVs were isolated from umbilical cord blood (UCB)-derived plasma through an ultracentrifugation protocol [5], and they were purified from proteins by size-exclusion chromatography (SEC). For the loading purpose, we used the commercially available Exo-Fect transfection reagent, and we purified the samples by Optiprep density gradient (ODG) centrifugation. In order to test our system, we developed a human BBB model in vitro, both in static and dynamic conditions. A co-culture system of human brain vascular pericytes and endothelial cells differentiated from CD34-positive cells of UCB was established. Four days after starting the co-culture, the miRNA-loaded EVs were incubated with the BBB model for 48 h and effects on the endothelial monolayer were assessed by measuring TEER, Pe, and cell viability. Moreover, immunocytochemistry (ICC) was performed to check the modulation of TJs proteins and RT-qPCR helped assessing the gene expression of BBB markers.

Results and Discussion
During the optimization of our BBB model, we saw that four days of co-culture were enough to obtain transendothelial electrical resistance (TEER) values and paracellular permeability coefficient (Pe) similar to the ones already reported in the literature. By performing the data collection and elaboration, we identified some possible miRNAs candidates for our final system, and we tested them in the above-mentioned BBB model. Even though the cell viability was not affected by the incubation with miRNAs-loaded EVs, ICC showed alterations in claudin 5 and zona occludens 1 (ZO-1) expression in terms of intensity of staining and organizations of the TJs.

Conclusion
Therefore, our system represents a promising strategy for temporary BBB opening, useful to increase the ability to reach the brain of therapeutics injected into the bloodstream.

Introduction
Acute brain injuries, neurodegenerative diseases and aging are brain pathologies with a great social burden and a shared feature: neuronal loss. In the last decades regenerative medicine came up with different strategies to replace lost neurons including the conversion of local reactive astrocytes into new neurons. A common method to achieve astrocyte reprogramming consists in the forced expression of neurogenic factors via lentiviral or adenoviral vectors. Even if effective, such approaches permanently introduce exogenous genetic material in the host cells, raising safety concerns and possibly preventing the complete maturation of the induced neurons.

Experimental Methods
To address these issues, we decided to develop a transgene-free method for the transient manipulation of gene expression. Particularly, we investigated the potential of the CRISPR activation system in the form of ribonucloproteins (CRISPRa-RNPs) for the activation of endogenous neurogenic genes. The functional unit of our system are synthetic Transcription Factors (sTFs) made by the combination of a custom-made dCas9-VPR protein with neurogenic gene-specific guide RNAs (gRNAs).

Results and Discussion
In a first round of screening, we lipofected murine P19 cells with sTFs to transcriptionally activate a pool of validated neurogenic factors. After selecting the most efficient ones, we proceeded with validation in primary murine astrocytes too, since they are relevant for neuronal replacement therapies.

Conclusion
In conclusion, our results provide a promising starting point for the development of a fast and versatile approach to readily screen and multiplex TFs. The future application of our methods to different cell types, including human ones, will allow its further development and will bring it towards even more clinically relevant applications.

Introduction
The incidence of age-related diseases has risen dramatically in the recent years, due to an increase in aging population. Several of these diseases are caused by genetic mutations leading to DNA damage and cell proliferation decrease. Gene editing approaches for these kinds of pathologies are limited due to the difficulty to transfect aged cells. CRISPR/cas9 system is a promising tool to find therapeutic strategies to correct gene mutations, due to its specificity and minor off target effects (1). Nevertheless, this technology is mainly delivered with viral vectors; however, these strategies have been described to induce immune reactivity and integration into the genome. Aged cells characteristics such cell cycle arrest and DNA instability make them more difficult to transfect, due to the low proliferation rate and smaller number of dividing cells. For example, Hutchinson-Gilford progeria syndrome (HGPS), a rare, accelerated premature aging disorder resulting from a de novo point mutation in the LMNA gene that leads to the generation and accumulation of progerin, an abnormal form of LMNA. The accumulation of progerin produces nuclear abnormalities that promote accelerated aging, cellular damage, and senescence (2, 3). HGPS is a good model to understand physiological aging (4). The aim of our work is to find strategies to improve transfection and gene editing of aged cells using non-viral formulations.

Experimental Methods
The first step is the validation of the plasmid that contains the sequence of interest to induce the knockout of the LMNA mutation. For that purpose, we validated the transfection strategy in human WT skin fibroblasts using electroporation with the neon transfection system testing different parameters to evaluate the cell viability, and the transfection efficiency, determined by the percentage of GFP positive cells. Subsequently, we did evaluate the best nucleofection parameters in aged cell: HGPS fibroblasts. Progerin decrease percentage was evaluated by immunofluorescence and cell number after treatment was also evaluated.

Results and Discussion
The results showed that physical parameters such as number of pulses, voltage and width have an impact in the cell viability and transfection efficiency. The optimal nucleofection parameters found in WT fibroblasts (voltage: 1400; width: 2 ms and pulses: 2) showed a transfection efficiency of 28.04% and 67.26% of cell viability. These validated conditions were then applied for the transfection of HGPS cells. The results in the aged cell model showed a transfection efficiency of 24.84% and a cell viability of 70.03%, among the GFP+ cells 11.55% were progerin positive, there was a slight tendency to decrease progerin levels with a 92.91% in cells without nucleofection and 83.36% in transfected cells. More experiments will be performed to clarify the gene editing effect.

Conclusion
Our results showed an optimized strategy to transfect cells with substantial viability, moreover aged cells with progerin accumulation can be effectively transfected. This is the first non-viral based system for gene editing strategies in aged cells. These studies will improve significantly age-related diseases therapies and treatment for translational applications.

Keep Learning: Advantages of Age in Science (KLAAS)

Mário A. Barbosa

1 Universidade do Porto, Inst Ciências Biomédicas Abel Salazar, Porto, PT; 2 i3S-Instituto de Investigação e Inovação em Saúde, Porto, PT; 3 INEB-Instituto de Eng Biomédica, Porto, PT

This presentation is a very personal perspective on a research career. Success and failure are intrinsic parts of it. However, the most fascinating aspects of a long-term career in research are related to the endless opportunities to learn. Normally, a professor is regarded as someone who has something important to teach. However, with the pace of new discoveries it is inevitable that most of the things we teach become rapidly outdated. Continuous learning is not only a demand of the profession but also a fascinating opportunity to feel ignorant. It is this feeling that drives new questions.

As a researcher ages, he/she is often confronted with duties that are essential for the running of institutions but which actually deviate the person from his/her passion (assuming that we do research for passion). Mentoring younger colleagues in a research laboratory is an opportunity to learn with them, both as a scientist and as a person. The one-to-one relationship that is established is incomparably richer and more rewarding than classes in a classroom.

In a society in which the percentage of aged citizens is rapidly increasing, the research environment is affected in the same manner as other work environments. More and more people of different ages work together outside and inside academia. Progressively, the concept of active aging appears inadequate to describe the role of older citizens. Productive aging makes a lot more sense. Some misconceptions about the dependence of scientific productivity on age, and the very strong competition for funds, space and research positions, has led to increasing signs of ageism. Age discrimination affects also the younger members of our community, who often have to face prejudices that stifle their talent. “Ageism towards younger and older people is prevalent, unrecognized, unchallenged and has far-reaching consequences for our economies and societies”[1]. A debate on ageing in research is as needed as for other professions[2].

**Driving complex and synthetic tissue development via volumetric biofabrication technologies**

Riccardo Levato\(^1\,2\,3\)

\(^1\) Utrecht University, Department of Clinical Sciences, 3584CT, NL; \(^2\) University Medical Center Utrecht, Department of Orthopaedics, 3584CT, NL; \(^3\) Regenerative Medicine Center Utrecht, 3584CT, NL

The function of living tissues is intimately linked to their complex architectures. Advances in biofabrication technologies offer unprecedented opportunities to capture salient features of tissue composition and thus guide the maturation of engineered constructs into mimicking functionalities of native organs. In this lecture, the design of novel biofabrication strategies and printable biomaterials to enable the reconstitution of complex 3D structures with precise heterocellular, multi-material and hierarchical composition is discussed. Architectures designed to stimulate the native interaction between multiple (stem) cell types and self-assembled organoids are introduced, with a particular focus on applications in musculoskeletal regeneration and liver tissue engineering. Layerwise hydrogel extrusion and bioprinting, different additive manufacturing technologies, such as melt electrowriting of polymeric microfibers, ceramic plotting and digital light processing lithographic printing, can be combined to create composite, cell-laden constructs that enable integration between engineered hydrogels and hard tissue scaffolds to generate osteochondral grafts. Albeit powerful and versatile, this approach poses relevant limitations on the scalability and production of constructs having clinically relevant size, as well as on the generation of free-form and support free overhanging, porous structures, typically of native anatomy. To overcome these challenges, custom-designed light responsive hydrogels can be sculpted into cell-laden convoluted 3D structures within tens of second, via the development of layerless, volumetric bioprinting approaches inspired by visible light computed tomography. With such nozzle and shear stress-free, highly rapid cell processing approach a variety of hydrogel-based constructs can be assembled into hydrogel-based actuators for potential applications in soft robotics, or as platforms to enhance cell viability and maturation post-printing, including the shaping of large networks of hepatic epithelial organoids into defined 3D perfusable structures which exhibit biosynthetic and metabolic functions. Altogether, the combination of the different
strengths of advanced bioprinting technologies offers new opportunities for the biofabrication of large, clinically-relevant multi-tissue constructs for regenerative medicine and tissue engineering.

Optical reduction and shaping of graphene-oxide for controlled bone tissue regeneration and bacterial killing

Massimiliano Papi

Università Cattolica del Sacro Cuore, Neuroscience section of Biophysics, Roma, IT

Graphene and graphene oxide (GO) are capable of inducing stem cells differentiation into bone tissue with variable efficacy depending on reductive state of the material. Thus, modulation of osteogenic process and of bone mineral density distribution is theoretically possible by controlling the GO oxidative state. In this study, we laser-printed GO surfaces in order to obtain both a local photo-thermal GO reduction and the formation of nano-wrinkles along precise geometric pattern. Initially, after cells adhered on the surface, stem cells migrated and accumulated on the reduced and wrinkled surface. When the local density of the stem cells on the reduced stripes was high, cells started to proliferate and occupy the oxidized/flat area. The designed surfaces morphology guided stem cell orientation and the reduction accelerated differentiation. Furthermore the reduced sharp nano-wrinkles were able to enhance the GO antibacterial activity against methicillin-resistant Staphylococcus aureus (MRSA), a common cause of prosthetic joints infections. This strategy can offer a revolution in present and future trends of scaffolds design for regenerative medicine. Interestingly, laser printing of graphene oxide can be also applied in GO-based hydrogels to design specific biomimetic patterns able to enhance the antimicrobial efficacy of graphene oxide [1, 2].

Introduction

Commonly used metallic-based electrodes used in neuro-prosthetic platforms, have ideal conductive properties, yet the disparity in physicochemical properties compared to neuronal tissues, leads to deleterious foreign body responses, such as scarring and inflammation \cite{1}. To overcome this, recent electrode designs look to incorporate materials mimicking more closely the physicochemical properties of neuronal tissue \cite{2}. Graphene-based materials show outstanding electroconductive (EC) features for bioelectronic applications \cite{3}. From several graphene forms, pristine graphene (pG) exhibits optimal performance across all physical properties. Despite this, its impact in neuronal tissues is still widely underexplored. Thus, this study builds upon previous work in our group on the development of collagen-pristine graphene (CpG) EC composite biomaterials \cite{4}, and investigates their ability to support neuronal cell growth, interrogate their cellular function through electrical stimuli, and promote neuronal regeneration.

Experimental Methods

Composite suspensions were created by homogenizing type I collagen with varying contents of pG (0 to 60%; m/m). Films were then prepared via room temperature evaporation and physically crosslinked through a dehydrothermal treatment. Characterization of bulk material properties were conducted using white light interferometry (Filmetrics Profilm), tensile tests (Zwick Roelle) (>n=3), and dynamic contact angle measurements. The electrical resistivity of dry composite samples was determined using four-point probe system (>n=3). \textit{In vitro} electrical stimulation was performed with a C-Pace system (IonOptix) with 4-8h pulse (200mV; 0.6-3ms) stimulations. The neuronal cell lineages used include human astrocytes (primary), microglial cells (N9), human neuroblastoma cells (SH-SY5Y) and mouse motor neuron-like cells (NSC34). These were assayed for metabolic activity (AlamarBlue, Invitrogen), immunoprofiled (ELISA, R&D Systems) and immunostained to appropriate antigens (>n=3).

Results and Discussion

Type I collagen/pristine graphene composites were successfully fabricated via dry casting followed by DHT crosslinking. Loading of pG did not impact CpG film thickness (≈32.6µm), when compared to the collagen control (30.7µm). Tensile tests with hydrated CpG films show a significantly reduction in elastic modulus (10%-30%pG; E=0.4MPa), ultimate tensile strength unchanged (UTS≈16MPa) and maximum strain (60%pG ≈ 41%) (Fig. 1A), compared to collagen films (E=0.73MPa; UTS=25.9MPa; MS=41%). Analysis of sheet conductivity shows a relatively high percolation threshold at 50% pG loading (Fig. 1B). The highest conductivity with physically stable films was achieved at 60% loading (1.47S/m), rendering the composite conductive to physiologically relevant levels. Next, assessment of surface contact angles revealed that higher pG loadings lead to significantly higher contact angles (≈74º) (Fig. 1C), denoting a decrease in surface hydrophilicity.

To assess the neurotrophic potential of CpG materials, metabolic activity (Fig 2A) and cellular morphology (Fig 2B) was tested over 3 days of culture with 4 different cell lines (NSC34, SH-SY5Y, N9, and human astrocytes). Generally,
metabolic viability is maintained across the different cell types, with a consistent decrease seen only on astrocytes grown in CpG 60% films. To determine the immunomodulatory potential of CpG films, levels of anti-inflammatory (IL-10) and pro-inflammatory markers (IL-6/IL-1 beta) produced by astrocytes and microglia cells were quantified during 3 days. Astrocytes showed a significant increase in IL-10 production over time, followed by a decrease in IL-6 levels. For microglial cells, similar results were seen with IL-10 levels, while the levels of IL-1β were maintained consistent over time. These results demonstrate that CpG films do not induce a consistent neuroinflammatory response from both immunogenic cell types.

Next, we aimed to demonstrate how CpG composites can harness the regenerative potential of electrical stimulation. Currently there are no standardized protocols to electrically stimulate neuronal growth and maturation in vitro [5], therefore, it is crucial to optimize stimulation patterns to better assess the functional impact of EC materials. Our initial data with neurons (SH-SY5Y) in a standardized electrostimulation system, showed that neurite outgrowth significant increases with higher frequencies (1Hz-x1.25; 10Hz-x1.20), with deleterious effects occurring solely at above 50Hz.

Conclusion
Commonly used materials for neuronal interfaces lack the necessary balance of electrical conductivity and biocompatibility. In response to this, we report a collagen/pristine graphene composite with physiologically relevant levels of conductivity, which is capable of supporting growth and polarizing neuronal cells towards neurotrophic phenotypes. Current project milestones aim in demonstrating the potential of CpG films in harnessing electric stimuli to drive neuronal function and regeneration.

Introduction

Bacterial adhesion to surfaces is the onset of biofilm formation and a hard problem to tackle, with antibiotics still being the major weapon to fight bacterial infections. The rise of antimicrobial resistance is however a growing concern and a threat to public health, translated into more than 500 000 deaths globally/yr [1]. Light-based approaches, such as photodynamic (PDT) and photothermal (PTT) therapies, offer promising solutions, where development of bacterial resistance is highly unlikely to occur [2]. Graphene-based materials (GBMs) show great potential to be used as antimicrobial agents [3, 4], especially as photosensitizers in light-based therapies, due to their high photothermal conversion efficiency and absorption ability of near-infra red (NIR), particularly in the first biological window (650-950 nm) [5]. Here, few-layer graphene (FLG) and few-layer graphene oxide (FLGO) were explored as stand-alone antibacterial NIR-responsive platforms towards the two major agents responsible for medical infections, S. epidermidis and methicillin-resistant S. aureus. Bacteria response to irradiation with safe low-power NIR LEDs was explored, considering, for the first time, the impact of the oxidation degree of these films made only of GBMs (without polymers or photosensitizers molecules). Surfaces’ mechanisms of action were hypothesized based on surface physicochemical features, changes in temperature, glutathione (GSH) oxidation, and reactive oxygen species (ROS) generation.

Experimental Methods

FLG (5 μm lateral size) was oxidized into FLGO by modified Hummers method, followed by morphological (TEM) and chemical (XPS) characterization. FLG and FLGO films were produced by vacuum filtration of powders’ aqueous suspensions, and characterized before and after NIR irradiation (LED-based source: ~810 nm, 0.150 W/cm²) regarding surface morphology (SEM), chemistry (XPS) and wettability (water contact angle). Films were incubated with S. epidermidis and methicillin-resistant S. aureus (10⁶ CFUs/mL) in medium supplemented with plasma proteins (to simulate in vivo scenario) for 2 h at 37 ºC. Samples were then either kept in the dark (NIR off) or NIR irradiated (NIR on) for 45 min. Polymethylsiloxane reference materials were used as control surfaces. Antimicrobial activity towards adherent bacteria was assessed by live/dead assay (Baclight™ Bacterial Viability Kit) and fluorescence microscopy, and planktonic bacteria were evaluated by CFU counting and metabolic activity (resazurin assay). The mechanism of action was explored considering NIR’s impact on photothermal properties (temperature measurement at surface and on supernatant with a thermocouple microprobe), GSH oxidation (oxidative potential, Ellman’s assay), and photodynamic properties (ROS generation, DCFH-DA assay).

Results and Discussion

Successful oxidation of FLG (3.5% O) into FLGO (~31% O) was achieved, and lateral size of 5 μm confirmed. Films’ surface morphology, chemistry and wettability are kept upon NIR stimulation, with FLG films maintaining the non-
oxidized character and sharp edges exposed, while FLGO films show graphene sheets fusion with a wrinkled-like morphology and similar oxidation degree (31%).

FLG and FLGO films exposure to NIR significantly boosted their bactericidal performance, efficiently killing 90% and 99% of planktonic bacteria (S. epidermidis and methicillin-resistant S. aureus), respectively, and causing the death of 65% and 85% of adherent bacteria, respectively.

Upon irradiation, FLG films act through a combined action of high surface temperature (51.3 °C), ROS overproduction and elevated GSH depletion (92%), with the action of sharp edges contributing positively to the overall antibacterial effect. With higher bactericidal action than FLG but lower production of ROS, FLGO films induce higher surface temperatures (56.0 °C) and GSH depletion (94%) that lead to increased membrane destabilization. The low temperatures reached in the supernatants (39.3 °C for FLG and 42.0 °C for FLGO films) suggest ROS as the major contributor of planktonic bacteria death. Reference materials validate that the observed effects are specific and associated with the presence of the GBMs films.

As such, both surfaces act through a synergistic and interdependent combination of PTT and PDT, with PDT efficacy being enhanced by the films’ ability to oxidize GSH. FLG films are hypothesized to act predominantly through ROS-dependent oxidative stress pathway, while FLGO through a ROS-independent pathway.

**Conclusion**

Stand-alone FLGO films can thus be used as light-activated platforms for the effective killing of bacteria (~99% planktonic bacteria) under low power NIR light exposure (0.150 W/cm²), and through a synergistic photothermal and photodynamic effect. These NIR-activated graphene-based platforms arise as simple and economical disinfection surfaces/systems, with widespread use in medical and non-medical applications, representing an effective and sustainable solution against antimicrobial resistant infections.

Graphene oxide, an incentive for ectopic osteoinduction in biopolymer blend composites

George M. Vlasceanu¹,², Mariana Ionita¹

¹ University Politehnica of Bucharest, Faculty of Medical Engineering, Bucharest, RO; ² University Politehnica of Bucharest, Advanced Polymer Materials Group, Bucharest, RO

Introduction
Herein, the synthesis and characterization of novel chitosan-gelatin highly porous scaffold reinforced with graphene oxide, crosslinked with genipin was targeted. This study addresses the potential boost of mineral-independent osteoinduction and osteodifferentiation featured by fish gelatin/chitosan (GCs) hybrids per graphene oxide (GO) reinforcement. Standard GCs formulation was referenced against genipin (Gp) crosslinked blend and 0.5 wt.% loaded GO composite (GCsGp/GO 0.5 wt%).

Experimental Methods
Suitable GO dispersion was ascertained within the biopolymer mix as nanolayers specific signals lack in both FTIR and XRD spectra and the specific spectral features of the polymers persisted with GO load enhancement. Overall, correlations between the GO induced material structuration, crystallinity variations and chemical interaction of the compounds can be correlated with the physical features and bioactivity of each composite formulation.

Results and Discussion
Exploratory mechanical investigations were performed before assessing in vitro osteodifferentiation (against MC 3T3-E1 pre-osteoblasts) and materials' osteoinductivity in vivo (CD1 mice). Specific biological staining revealed collagen formation and Ca²⁺ deposits, validated by µCT. runx2 and opn markers determination stressed on the osteogenic phenotype of the cells populating the implanted materials. The aftereffects of implantation in ex vivo materials were studied from the angle of in situ biomineralization and morphology alterations. X-ray diffraction and Fourier-transform infrared spectroscopy underlined the novel material structuration in the mineralized extracellular matrix.

Conclusion
This data supports the GO bioactivity in osteogenesis mechanisms as being self-sufficient to boost osteoblast differentiation and bone formation in ectopic sites. Hence, the synthesis route of a natural polymer blend/graphene oxide composite material is anticipated to emerge as influential formulation in bone tissue engineering.

Introduction
Stem cell-based therapies have attracted considerable attention to treat the injured or diseased nervous system [1]. A major challenge in utilizing stem cells for regenerative therapies is the poor control over the survival, differentiation and functional integration of the transplanted cells. The combination of stem cells with scaffolds has been proposed to overcome this problem. In the present work, graphene-based hydrogels were developed as a substrate for neural stem cells (NSCs). These hydrogels were further functionalized with cerium oxide nanoparticles, thus providing a multifunctional platform for cells that combines the intrinsic physico-chemical, electrical and mechanical cues provided by graphene derivatives [2, 3] with the antioxidant and cytoprotective properties from cerium oxide [4].

Experimental Methods
The graphene/cerium oxide hydrogels were fabricated via the self-assembly of graphene oxide (GO) in the presence of ascorbic acid. Briefly, GO and cerium oxide nanoparticles were mixed in a bath sonicator for 30 min. Afterwards, ascorbic acid (AsA) at various ratios (GO:AsA ratios: 1:1; 1:4 and 1:10) was added and kept at 37 °C for two hours to allow the self-organization of the hybrid systems into hydrogels (Figure 1A). The resulting hydrogels were fully characterized in terms of mechanical properties (rheology), electrical conductivity, antioxidant capacity, morphology (scanning electron microscopy-SEM) and physico-chemical properties (Raman spectroscopy and X-ray diffraction). NSCs were isolated and cultured as previously described [1]. They were subsequently seeded on the hydrogels and fixed for immunostaining at different time-points (1, 3, 7 and 14 days). Several markers (NeuN, DCX, S100B, GFAP, Olig2, Nestin, etc.) were used to distinguish between the various populations found in the central nervous system.

Results and Discussion
The different GO:AsA ratios, as well as the amount of cerium oxide nanoparticles in the hydrogel, allowed us to adjust the morphology and mechanical and electrical properties of the resulting hydrogels, giving rise to a plethora of substrates for cell attachment with tunable features. Increasing the amount of AsA, which acted as a reducing agent, resulted in a more collapsed structure (smaller pore size—Figure 1B) and higher shear modulus and electrical conductivity (data not shown). The incorporation of cerium oxide nanoparticles endow the hydrogels with antioxidant properties but reduced both their shear modulus and electrical conductivity by an order of magnitude (Figure 1C). The studied hydrogels allowed the attachment of NSCs without the need of any further coating of their surface with extracellular matrix adhesion proteins (e.g., laminin). NSCs were able to differentiate towards cells from the nervous system (neurons, astrocytes and oligodendrocytes) when seeded on the hydrogels and a different expression profile was observed depending on the properties of the substrate (Figure 1D).

Conclusion
In this study, a simple and versatile method is presented for the fabrication of graphene-based hydrogels with tunable mechanical, electrical, physico-chemical and morphological properties. They also support cell adhesion and neurodifferentiation of NSCs. A more detailed analysis is being currently conducted to establish the exact parameters that determine the differentiation of NSCs. Accordingly, the formulated substrates constitute a promising tool for future cellular therapies including nerve tissue regeneration.

**Scaffolds based on decellularized extracellular matrix and graphene oxide: a route to repair the spinal cord injury?**

Daniela M. da Silva¹, Susana Cristina Pinto¹, Joana Patrícia M. Sousa¹, Lina Papadimitriou², Anthi Ranella², Paula Alexandrina A.P. Marques¹, Nathalie B. Barroca¹

¹ University of Aveiro, Department of Mechanical Engineering - Centre for Mechanical Technology and Automation, Aveiro, PT; ² Institute of Electronic Structure and Laser, Foundation for Research and Technology-Hellas (FORTH/IESL), Heraklion, GR

**Introduction**

Each year, 250,000 to 500,000 people suffer from a spinal cord injury (SCI).[1] Due to the limited ability of the central nervous system to repair itself, most of the devastating consequences on mobility and essential physiological functions last for a lifetime. While surgical and rehabilitation measures have improved functional outcomes at a clinical level, a strategy repair that can cure SCI is still inexistent.

At a research level, progresses in the understanding of axon regeneration,[2] cell engraftment [3] and spontaneous circuit reorganization [4] are leading to tantalizing regenerative routes, currently targeted via biological approaches or neuroprosthetics. Biological approaches often rely on proteins-based platforms, owing to their tissue-like mechanics and a remarkable flexibility in designing their chemical and physical properties. Neuroprosthetics, in its turn, intent to restore voluntary motor impulses using epidural or transcutaneous electrical stimulation.[4] Our group aims to design the coming generation of electronic neural interfaces for the electrical neuromodulation to treat the SCI, via an electroconductive platform coupled with an electrical stimulation system. This platform is formed by two building blocks. The first is decellularized extracellular matrix from porcine adipose tissue, that translates into a microenvironment with natural bioactive cues that can both attract and induce cell differentiation required for tissue repair. The second building block is reduced graphene oxide (rGO) used as the electroconductive filler. Seminal work on the in vivo use of rGO for the SCI has shown remarkable effects. When used as a standalone scaffold, it promoted several regenerative features at the injured spinal cord such as axonal and vascular growth after 4 months of implantation.[5]

Before coupling with the electrical stimulation system, these electroconductive platforms must prove cytocompatibility towards neuronal cells.

**Experimental Methods**

To promote electrical conductivity, graphene oxide was thermally reduced prior its incorporation to the decellularized extracellular matrix (adECM). adECM/rGO scaffolds were produced by solid-liquid phase separation followed by freeze-drying varying the rGO content (7.5, 15, 30 and 50 wt %). Cross-linking with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and N-hydroxysuccinimide (NHS) (1:1 molar ratio) was performed using 0.0033mM of EDC per mg of adECM. Morphological analysis of the scaffolds was performed using scanning electron microscopy and microcomputed tomography. Mechanical characterization was assessed via compressive tests on the hydrated scaffolds. The crosslinking efficiency was quantified by spectrophotometry using 2,4,6-trinitrobenzenesulfonic acid (TNBS) assay that quantifies the free primary amine groups. For the cytocompatibility study the embryonic neural stem cells (NE-4C) was cultured on the adECM/rGO scaffolds. The NE-4C cell line was derived from anterior brain vesicles of p53-deficient early (E9) mouse embryos and can differentiate into both neurons and astrocytes. Differentiation towards neurons and astrocytes was assessed by confocal microscopy. In conjunction with differentiation, synaptogenesis, as a critical aspect of the nervous system...
function, was evaluated. To determine synapse formation, differentiated cells were stained for synaptophysin, an integral membrane glycoprotein that occurs in presynaptic vesicles of neurons.

Results and Discussion

Traditional solid-liquid phase separation followed by freeze-drying successfully led to porous and mechanically compliant scaffolds based on adECM with up to 50 % wt of rGO. Cross-linking via EDC/NHS was effective, particularly for the scaffolds with less rGO (7.5 % wt), wherein a decrease in free amine groups up to 27% was observed.

In culture, all the scaffolds supported the adhesion, survival, and proliferation of cells. Although more cells were initially observed on the scaffolds with more adECM, the differentiation assays on scaffolds with high loading of rGO revealed that the cells were more prone to differentiation when cultured on scaffolds with more rGO. Preliminary results indicated that neural stem cells cultured on these electroconductive platforms expressed synaptophysin, pointing to the possibility of a functional neuronal network forming inside the adECM/rGO scaffolds.

Conclusion

This work demonstrated the use of a simple technology to produce highly elastic and electroconductive scaffolds based on adECM from the adipose tissue and rGO. Cell culture on the porous and mechanically compliant scaffolds revealed the presence of a fully developed complex network of neurons, wherein synaptogenesis is taking place. These adECM/rGO scaffolds appear as a promising route to be further coupled with electrical stimulation to treat the spinal cord injury.

Engineering Graphene-based Nanocomposites for Optical Brain Stimulation

Artur Filipe Rodrigues1, Bruno Figueiredo2, Lino Ferreira1,3

1 Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, PT; 2 Graphenest SA, Paradela do Vouga, PT; 3 Faculty of Medicine, University of Coimbra, Coimbra, PT

Introduction
Neurological disorders are one of the world’s leading medical and societal challenges, affecting approximately 2.6 billion people worldwide. The failure of pharmacological therapies has prompted the investigation of alternative treatments such as electrical stimulation to improve brain function in a range of disorders including stroke, epilepsy, migraines, dementia, Alzheimer’s and Parkinson’s diseases [1]. However, significant adverse effects related to device operation and long-term biocompatibility have encouraged the investigation of novel materials and stimulation modalities [2]. Graphene-based materials (GBMs) reunite promising attributes for brain interfaces, including their biocompatibility, flexibility, and high capacitive charge conduction [3]. GBM electrodes were recently shown to generate an electrical response upon light exposure [4], which could capitalize the enhanced spatiotemporal precision of light for deep brain stimulation. In order to circumvent the use of visible light, which poorly penetrates biological tissue, we propose the incorporation of upconversion nanoparticles (UCNP) for wireless transcranial activation using near-infrared (NIR) radiation [5]. We hypothesize that UCNPs will enhance optical activation of graphene-based electrodes with NIR radiation for stimulation of cells, minimizing photothermal effects which could cause cytotoxicity.

Experimental Methods
Graphene nanoplatelets (Graphenest) were screen-printed onto PET substrates and characterised their electrical response to radiation applied at different wavelengths (405, 785, 980 nm) and power densities (0-2 W/cm²) by cyclic voltammetry and electrochemical impedance spectroscopy. Based on these results, a library of UCNPs was generated using Design of Experiments (DoE) to investigate the influence of different host matrices (NaYF4, NaGdF4) and dopants (Yb, Nd, Tm, Er, Sm) in the electrical response of graphene. The optimal UCNP formulation was then covalently attached to graphene nanoplatelets following selective hydroxyl derivatization. This nanocomposite was then characterized with respect to its optoelectronic performance and in vitro biocompatibility.

Results and Discussion
First, we have demonstrated that graphene nanoplatelets responded to different wavelengths of light (UV-Vis-NIR) according to their energy. These results supported the rational design of UCNPs using a DoE approach, in order to improve optical activation by NIR radiation. This approach enabled the optimization of dopant concentrations in order to adjust the optical properties necessary to maximise the electrical response from graphene nanoplatelets. Covalent functionalisation was essential to maintain long-term stability of the composite in physiological milieu.

Conclusion
Graphene-based nanocomposites are biocompatible options for brain interfaces, providing a variety of strategies for cell stimulation. Our results pave the way for minimally invasive optical stimulation of cells, enabled by transcranial NIR radiation.

Track02

S06 | Hybrid Cell-Microbiomaterial 3D Assemblies

Chairs
Zeinab Niloofar Tahmasebi Birgani
MERLN Institute, Maastricht University, Instructive Biomaterials Engineering, Maastricht, NL
Roman Truckenmüller
Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL
Max von Witzleben (YSF)
TU Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE

At this symposium, the participants will learn how to:
– identify the main criteria for designing instructive designer microbiomaterials.
– analyze and interpret the advanced interactions between progenitor cells and therapeutic micron-scale biomaterials.
– apply these principles in developing 3D hybrid microtissues for regenerative medicine applications.
Designing (almost) all-cellular living materials

Mariana B. Oliveira

University of Aveiro, Department of Chemistry, CICECO - Aveiro Institute of Materials, Aveiro, PT

Relevant regenerative therapies are often directed towards the use of biomaterials as main supporting matrices and cue-providers to cells. However, the passage of new biomaterials to the marketplace is subjected to time consuming and costly regulatory processes. Although scaffolding materials are designed to mimic aspects of native extracellular matrix (ECM), cellular presentation and assembly in these structures is mostly man-induced. Scaffold-free strategies allow cells to naturally assemble and form stand-alone structures through cell-cell contact and deposition of their own ECM. Cell sheets are the most widely reported scaffold-free constructs for tissue engineering. Despite having shown outstanding clinical results in the treatment of thin and poorly vascularized tissues, the scaling of these structures into long-term functional constructs capable of filling large three-dimensional (3D) defects is challenging. Multicellular microtissues, mostly with spherical geometry, have also been suggested as building blocks to generate higher order tissues. However, the construction of such constructs often depends on mobility confinement strategies and/or the multistep deposition of multicellular micrometric units, hampering the complete free-form and direct fabrication of versatile shapes.

The use of long cell fibers may allow using knitting/textile, printing and even stitching techniques to position cellular constructs prepared in vitro in favorable architectural configurations, and to build macrometric tissues with spatially controlled compositions. We recently reported the rapid one-step fabrication of centimeter-long cellular fibers made of human mesenchymal stem cells derived from the adipose tissue (hASCs) [1]. Previously reported techniques for the fabrication of scaffold-free cellular fibers consistently required the use of exogenous proteins and sacrificial biomaterials templates. Instead, we described the fabrication of centimeter-long cell-only monotypic and heterotypic fibers, using human hASCs and their combination with endothelial cells. hASCs were seeded onto wettable channels patterned on superhydrophobic surfaces, generating a hanging column setup after upside-down rotation. The self-assembly of cells into fiber-shaped constructs rendered highly malleable structures, able to adapt to complex-shaped defects. Those also exhibited high viability and homogenous thickness distribution. After 7 days of culture into a simplistic ECM-mimetic in vitro model, hASCs fibers were able to sprout and secrete pro-angiogenic, trophic and immunomodulatory factors. The integration of cell fibroids into an ex ovo matrix (CAM assay) was also confirmed, and heterotypic fibers (hASCs+HUVECs) showed pro-angiogenic properties. Such micro-to-macrotissues may be enabling platforms for regenerative medicine, and may find broader application as in vitro screening devices.

Although architectural features of cell-rich structures may be crucial to enable ease of processing into higher-order structures, as well as their in vivo applicability and ease of handling, the functionality of living structures based on mesenchymal stem cells has benefited from cellular conditioning. Mostly, these strategies rely on the administration of soluble factors to boost cellular pro-regenerative function, or to trigger their differentiation into organotypic cell phenotypes. The biophysical guidance of cell response by direct contact with biomaterials has proven promising for the local modulation of adherent stem cells’ response. Nonetheless, the introduction of high masses of biomaterials into cell aggregates may lead to the loss of their extremely cell-rich character and associated advantages. Also, regulatory approval of such structures may be hampered or delayed, especially if materials that have not been previously tested in clinical settings are introduced. We recently demonstrated the fabrication of sheet-like microparticles (~200 nm thickness) made of polymers previously approved by the FDA for implantation purposes, encompassing a vast array of geometries with high fidelity to original patterns (e.g., circles, triangles, squares, hexagons), using a straightforward and scalable method based on platforms showcasing wettability contrast [2].
These structures showed cell-mediated pliability, and their integration in gravity-enforced human adipose-derived stem cells aggregates led to enhanced metabolic activity and prolonged secretion of a relevant pro-angiogenic factor (VEGF). These geometrically controlled ultrathin microparticles may act as valuable elements in the design of “low-biomaterial” living structures with improved therapeutic purposes. Different strategies resorting to scaffold-free and low-biomaterial approaches targeting the design of highly functional cell-dense constructs as regenerative devices will be presented, considering crucial steps towards their ease of manufacturing and (pre-)clinical translation.

Introduction

Stem cells are one of the most rising and promising research lines in Tissue Engineering and Cell Therapies due to their properties of self-renewal and potency. The available solutions usually involve stem cells in vitro expansion followed by their administration through systemic and local injection. However, most of the failure attempts are related with the cell handling and manipulation processes, thus the optimization of these therapies is a great necessity due to the low rates of cell survival and efficacy of treatment. New strategies are being explored to extend the period of cell survival in suspension conditions. These approaches mostly consist of giving mammalian cells a better support against external stresses for instance by functionalizing the cells to improve the targeting, integrate cells on 3D scaffolds, coating cells to improve their mechanical resistance and protection or by encapsulating them. In fact, single cell encapsulation seems to be one of the most interesting approaches by allowing a better control and programming of cells while improving their viability. It offers a tougher and durable support for cells which is very important regarding cell therapies and the harsh processes they must go through. Inspiration from nature has been leading a variety of fields from science to architecture to study, mimic and find new strategies and materials. Biomineralization is a natural process by which living organisms form minerals from bioorganic molecules and inorganic solids. Silica, as biomaterial, possess a range of characteristics like mechanical strength, chemical inertness, hydrophilic character and biocompatibility that make this material appealing to biomedical applications. Furthermore, silica has an important role in the bone and connective tissue formation, and it can also be easily manipulated using sol-gel methods under mild conditions to obtain new materials with different properties.[1] Fully encapsulated cells using silica were already achieved with promising results against enzymatic attacks although during long time applications cells start to die.[2] Such can be caused by the processing of the materials that can be quite toxic and disruptive for the cell membrane along with cell full entrapment which limits their normal functions. We report an innovative concept and strategy, where silica-based partial coatings (silica backpacks) are formed at the surface of individual stem cells. Based on electrostatic interactions and sol-gel process under mild conditions, only a part of cell surface was successfully engineered with a silica backpack.

Experimental Methods

A 2-step procedure was performed in isolated human adipose derived stem cells (hASCs) while adhered to a petri dish as previously described.[3] After washing, cells were incubated with a new modified chitosan with carnitine prepared in a PBS solution to be used as a primer coating material. Then, a silica-based solution was prepared under mild conditions. The obtained partial-coated cells were characterized by flow cytometry and confocal microscopy. Cell viability was evaluated by the Live/Dead and Apoptosis/Necrosis assay for 21 days while the cells were in suspension during the assay. To prove their potential for injection therapies an assay was carried out using partially coated cells and uncoated (control) cells. They were resuspended in a filtered 2% w/v alginate solution dissolved in PBS solution (pH = 7.4). By using a 1 mL syringe fitted with a 30 G needle and a flow rate of 30 mL h⁻¹, cells were
injected at the same time. Then, they were incubated with Live/Dead solution and their viability was assessed through fluorescence microscopy.

Results and Discussion
Partial coated cells were achieved by a straightforward 2 step procedure under mild conditions and using a new type of primer not toxic for cells (Fig. 1). It is important to highlight that from hASCs used on this study, 57% of cellular population present silica backpacks. These cells can survive longer than 21 days forming larger aggregates compared to pristine cells, which suggests prolonged cell survival and functionality. Injection assays results showed that partially coated cells possess higher viability after extrusion than the uncoated ones, revealing its potential for bioprinting applications and injecting therapies (Fig. 2).

Conclusion
By using a minimal material approach, we developed a new hybrid material: cells partial coated with an inorganic material with potential to overcome viability issues on applications when used in suspension conditions. This minimal material approach can positively influence cell survival at longer term without compromising cell functions. The use of silica in this strategy can also be explored as drug carrier for cell differentiation or drug delivery.

Hyaluronic acid-mediated active targeting: cell uptake is ruled by the interplay between polysaccharide molecular weight and nanoparticle production technique

Francesca Della Sala¹, Assunta Borzacchiello¹, Teresa Silvestri², Laura Mayol², Marco Biondi², Luigi Ambrosio¹

¹ National Research Council, Institute of Polymers, Composites & Biomaterials, Naples, IT; ² Università di Napoli Federico II, Dipartimento di Farmacia, Naples, IT

Introduction
Hyaluronic acid (HA) is an anionic naturally occurring polysaccharide, main constituent of the extracellular matrix, able to bind specifically CD44 receptor, which is overexpressed in a wide array of cancer cells. HA, due to its outstanding characteristics, aroused a noteworthy research interest for the engineering of nanoplatforms endowed with active targeting features. HA has been chemically anchored onto many drug-loaded nanodevices, and their enhanced tumor targeting ability assessed. Nevertheless, the need for a chemical reaction poses serious regulatory challenges for FDA approval. Moreover, HA rearrangement and conformation play a cornerstone role in dictating the specific interaction and binding proneness to CD44 receptor, which in turn strongly depends on HA size and molecular weight (MW). In this study, nanoparticles (NPs) based on poly(lactic-co-glycolic acid) (PLGA) have been produced by a modified nanoprecipitation technique. Specifically, NPs were decorated with HA by exploiting polymer self-aggregation driven by a lipophilicity gradient between oil and water phases. NPs were coated with HA at 200, 800 and 1435 kDa, and named HA2, HA8 and H14 correspondingly. The influence of HA MW on uptake was assessed by kinetic internalization studies on CD44-overexpressing breast carcinoma (HS578T) and healthy mouse fibroblast (L929) cells. Furthermore, the results were compared with the numerical simulations obtained with a kinetic internalization model based on a cell membrane adsorption-desorption balance.

Experimental Methods
NPs were produced by nanoprecipitation, forcing a PLGA/F68/F127 solution in acetone (1:0.5:0.5 weight ratio; 5 mL, 3% w/v) through a syringe at 333 µL/min flow rate by a Syringe Pump [1]. The solution was precipitated in an aqueous phase, containing poloxamers as surfactants (1:1 weight ratio) and different amounts of HA, depending on the specific MW. HA NPs were characterised by TEM, PCS, DLS and DSC. Cellular uptake kinetics of fluorescent NPs were obtained by performing, at scheduled time points, cell lysis followed by a spectrofluorimetric assay on the lysate to quantify NP-associated fluorescence. NPs internalization has been modelled a pseudo-chemical equilibrium relation at cell membrane, as mathematical model described previously [2].

Results and Discussion
Spherical NPs with a < 200 nm mean size were obtained (Fig 1A). ZP was < -50 mV in all cases, thereby indicating HA arrangement on NP surface. DSC thermograms run on poloxamers showed endothermic peaks, associated to the melting temperature (Tm), at about 54.9°C, 56.0°C and 55.2°C for F68 and F127 and their 50:50 w/w mixture (Fig 1B), respectively. Endothermic peaks attributable to poloxamers were also identified in all NPs formulations, but at lower temperatures, comprised between 46.1 and 48.3°C. This has been associated to a plasticizing effect of PLGA and HA toward poloxamers. Furthermore, the heat generated during the melting of poloxamers (∆Hm) within NP bulk was drastically lower than the ∆Hm of the raw materials. This suggests the loss of most of poloxamers crystalline regions within the rubbery phase of the PLGA, which is completely amorphous. HA NPs uptake kinetic experiment, compared with the results of numerical simulations, revealed a higher internalization for HA8 compared the other two formulations (Fig 2A). In particular, the HA14 showed, within 72 hours of exposure, a significantly lower uptake...
uptake than the other two formulations. Uptake by cancer cells was promoted for all three formulations, with an increase of approximately 2, 2.3 and 1.3 times for HA2, HA8 and HA14, respectively. Fig 2 B shows \( N_{\text{MAX}} \) values, which expresses the number of NPs that can be internalized by cells after a virtually infinite time, indicating that the uptake of HA2 and HA8 by HS578T cells is 2.5+3.6-fold higher than \( N_{\text{MAX}} \) calculated with L929 cells. In contrast, in the case of HA14, the calculated values of \( N_{\text{MAX}} \) were similar in both cell populations. Cell uptake experiments and model simulations indicated a significant tropism of HA-decorated NPs towards tumour cells and, more interestingly NPs uptake were higher for NPs HA 8, compared HA 2 and HA 14. HA exposure on NP surface is intimately connected to the NPs production technique used, because HA is physically linked, and HA is actually engaged in the interaction with the hydrophilic poloxamer segments. This indicated that segment of HA chain that actually protrudes from a single NP (influenced by NP production technique) and its different arrangement conformation (influence by HA MW) on particle surface affected the cell internalization.

**Conclusion**

Overall, results obtained in this work point at how HA MW, despite being a pivotal project parameter in NP formulation, cannot dictate NP internalization amount and kinetics per se. Rather, cellular uptake outcomes plainly emphasize the importance of the technique used for NP production in dictating the biological interplay between NPs and CD44-overexpressing cells.

Injectable, self-healing colloidal gels for mRNA delivery to stimulate bone regeneration

Lea Andrée1, Rik Oude Egberink2, Marije Heitmeijer1, Fang Yang1, Roland Brock2, Sander C.G. Leeuwenburgh1

1 Radboudumc, Department of Dentistry – Regenerative Biomaterials, Radboud Institute for Molecular Life Sciences, Nijmegen, NL; 2 Radboudumc, Department of Biochemistry, Radboud Institute for Molecular Life Sciences, Nijmegen, NL

Introduction
Bone can be damaged or lost due to a wide variety of factors such as trauma, disease or congenital malformations [1]. Biomaterials, often in combination with proteinaceous growth factors (GFs), are used to stimulate regeneration of damaged bone tissue. Yet, these growth factors need to be administered in supraphysiological amounts due to their rapid clearance, and they are costly to produce [2].

Messenger ribonucleic acid (mRNA) has evolved into a promising new class of bioactive compounds. In contrast to classical GF delivery, mRNA therapy harnesses the cell’s translation machinery to stimulate endogenous protein production. So far, research has mostly focused on complexation of these oligonucleotides for systemic delivery. By comparison, the development of suitable biomaterial carriers for local delivery of osteogenic mRNA has only received little attention. Injectable biomaterials hold great promises for dental applications since they can be administered via minimally invasive procedures and can fill irregularly shaped bone defects. In this research, we focus on colloidal hydrogels based on gelatin nanoparticles (GNPs) as injectable carrier materials for mRNA-nanocomplexes and investigate their mechanical properties and self-healing behaviour in respect to their composition (solid content, GNP type) along with release characteristics and transfection efficiency of mRNA-polyplexes (mRNA-PPs).

Experimental Methods
Oppositely charged GNPs were prepared by coacervation of type A or type B Rousselot gelatin, and characterized by scanning electron microscopy (SEM), dynamic light scattering (DLS) and zeta potential measurement. To investigate gel formation of GNP-based colloidal gels and their self-healing behaviour after shear-induced destruction, we performed rheological time and amplitude sweep measurements. For mRNA delivery we employed non-covalent complexation with the polypeptide PepFect14. Fluorescently labelled mRNA coding for enhanced green fluorescent protein (EGFP) was complexed with PepFect14 into mRNA-polyplexes (mRNA-PPs) and characterized by DLS and zeta potential measurement. Transfection efficiency of mRNA-PPs was assessed in mouse pre-osteoblasts (MC-3T3) by confocal live cell imaging.

Results and Discussion
SEM showed spherical particles with a diameter of 145 ± 10 nm (type A) and 161 ± 14 nm (type B) in dry state. In swollen state diameters were 473 ± 107 nm (type A) and 313 ± 44 nm (type B). Zeta potential measurement of GNPs revealed a surface charge of 18.3 ± 1.3 mV and -12.6 ± 0.8 mV for type A and type B GNPs, respectively. Rheological time sweep measurements confirmed the formation of GNP-based colloidal gels, which displayed a higher storage modulus (G’) with increasing gelatin content (1.2 ± 0.2 kPa, 8.3 ± 0.8 Pa, 31.2 ± 2.1 Pa for 5 w/v%, 10 w/v% and 15 w/v%, respectively). Furthermore, the self-healing behaviour of gels after shear-induced destruction was shown, with up to 84 ± 5 % immediate recovery of G’ for 10 w/v% gels (Fig. 1). Additionally, colloidal gels with a solid content up to 10 w/v% and 15 w/v% could be extruded through needles of 22G and 16G, respectively. mRNA-PPs of mRNA complexed with PepFect14 had a diameter of 84.2 ± 9.7 nm and a Zeta potential of 26.4 ± 5.3 mV. These mRNA-PPs could transfect mouse pre-osteoblasts within two hours as seen by the intracellular
localization of labelled mRNA (Fig. 2A). Furthermore, successful cell transfection and subsequent translation of mRNA was confirmed by cellular expression of EGFP after 24h (Fig. 2B).

**Conclusion**

GNPs are suitable building blocks for the assembly of colloidal gels with favourable self-healing behaviour for application as an injectable carrier material. Using PepFect14, mRNA can be complexed into nanosized mRNA-PPs which get internalized by pre-osteoblastic cells. Moreover, PepFect14 effectively protects mRNA from premature degradation, leading to strong expression of the encoded protein. In the future, we aim to combine these two components to form an injectable gel stimulating endogenous protein expression through mRNA-PP release. We expect the colloidal gel to facilitate controlled release while maintaining the bioactivity of mRNA-PPs. Moreover, the bottom-up assembly of this colloidal gel will allow to tune the properties of the final biomaterial for clinical application.

Proteomic Characterization and Inter-Donor Variability Evaluation of Human Cell-Assembled Extracellular Matrices

Fabien Kawecki¹, Maude Gluais¹, Stéphane Claverol², Nathalie Dusserre¹, Todd McAllister³, Nicolas L’Heureux¹

¹ University of Bordeaux, BIOTIS U1026 INSERM, Bordeaux, FR; ² University of Bordeaux, Centre de Génomique Fonctionnelle, Plateforme Protéome, Bordeaux, FR; ³ Fountain Therapeutics, Cluver City, US

Introduction

Synthetic scaffolds can be easily produced at a low cost with great control over their geometry and structure. Nevertheless, they can be associated with limitations, such as foreign body reaction and chronic inflammation resulting in material degradation [1,2]. Interestingly, natural materials, such as collagen or fibrin gel, exhibit several advantages at a biological level by facilitating cell-to-matrix interactions [3]. Our research group focuses on a tissue engineering approach that uses Cell-Assembled extracellular Matrix (CAM) sheets for vascular applications. This approach uses the capacity of mesenchymal cells, such as fibroblasts, to assemble in vitro their completely biological endogenously-secreted extracellular matrix (ECM) in the presence of ascorbate and serum [4]. We have been the pioneers to graft this CAM in humans for autologous and allogeneic vascular applications [5]. This CAM has been rolled and fused to produce tissue-engineered blood vessel under a good manufacturing process (GMP) for hemodialysis access. Clinical results demonstrated that the CAM biomaterial could integrate into the native tissue, be remodeled by the host’s cells, and limit infections [5]. The data allowed us to develop an allogeneic strategy of large-scale production for the CAM, which is more adapted for industrial transfer and/or clinical applications. This study aimed to evaluate this variability as well as the three main parameters (the strength, the thickness, and the quantity of hydroxyproline) that drive CAM production in a clinical manufacturing context.

Experimental Methods

To this end, human CAM sheets were produced under GMP condition using different primary dermal fibroblast populations obtained from 21 patients requiring arteriovenous shunt for hemodialysis. The strength, the thickness, and the hydroxyproline content of the CAM sheets were evaluated for each donor. Also, a detailed inventory of the CAM matrisome composition was realized using mass spectrometry. Then, correlations between the CAM parameters and the proteins detected within the CAMs were assessed by computing two-tailed Pearson correlation coefficients.

Results and Discussion

Results demonstrated that the strength, the thickness, and the hydroxyproline content of the CAM sheets varied between donors by 33% (coefficient of variation), 19%, and 24%, respectively. Another objective was to characterize the CAM matrisome to better understand its relation with the CAM properties. The CAM sheet strength showed moderate and strong positive correlations with the CAM thickness and hydroxyproline quantity, respectively. A detailed CAM matrisome characterization was performed by mass spectrometry and confirmed the inter-donor variability in term of CAM protein composition. Data also revealed that the CAM strength correlates with collagen alpha-1(I) chain abundance. The CAM thickness showed strong correlations with fibrillin-1, dermatopontin, and peroxidasin, which are involved in collagen fibril formation and stabilization. In addition, the CAM hydroxyproline quantity intensely correlated with proteoglycans (e.g. decorin) and ECM regulators (e.g. serpin H1) involved in collagen fibril biosynthesis.
Conclusion
Finally, this study formally evaluates the CAM inter-donor variability in a clinical manufacturing context and suggests that the CAM properties are driven by the fibril formation rate of the collagen and its stabilization. Furthermore, the detailed CAM composition characterization identified molecular predictor of the CAM properties and possible targets for improving CAM properties.

Control of dynamic hydrogels via supramolecular engineering: 1,3,5 Benzene tricarboxamide hydrogels as extracellular matrix mimics

Shahzad Hafeez¹, Agustina Aldana¹, Hans Duimel², Clemens V. Blitterswijk¹, Lorenzo Moroni¹, Matthew B. Baker¹

¹ Institute for Technology-Inspired Regenerative Medicine, Department of Complex Tissue Regeneration, Maastricht, NL; ² Maastricht MultiModal Molecular Imaging Institute, M4I, Microscopy Corelab, Maastricht, NL

Introduction
Supramolecular hydrogels provide a biomimetic way to create artificial extracellular matrices for cell culture and biofabrication applications [1][2][3]. Via supramolecular polymerization, we can create fibrous, dynamic, and stimuli-responsive materials [1][4][5]; however, the rational design and control over the properties of the material remain a challenge. Control of the mechanical properties (both static and dynamic) are paramount to the success of supramolecular hydrogels in applications from simple cell culture to injectability and 3D printing. Herein, we develop a series of hydrogelators based on telechelic 1,3,5-benzene tricarboxamide (BTA) polymers, with systematic variations on the hydrophobic sidearms on the self-assembling unit. We hypothesized that the alterations in the hydrophobic domain of the BTA could provide a convenient handle to control the viscoelastic properties of the hydrogels. We then investigated the resultant supramolecular structures, the mechanical properties, and the utility in applications from injectability to 3D printing enabled by these small alterations in the molecular structure.

Experimental Methods
The telechelically functionalized BTA polymers (PEG-20K, variation in side arms from C₆ to C₁₂) were synthesized according to a novel desymmetrization route developed in the lab. The polymers were fully characterized with NMR and GPC, and gel properties were determined via oscillatory rheology. The supramolecular structures of these polymers were probed with a Nile Red fluorescence assay in combination with cryo-SEM and TEM. Cell viability was investigated using ATDC5 chondrocytes, and 3D printing was performed using a CellInk BioX printer and quantified using image analysis.

Results and Discussion
All target polymers were synthesized in good yield and purity, and all systems formed hydrogels with different critical gelation concentrations. We found that the stiffness of the hydrogels produced was not dependent on the side arm substitution, while the viscoelastic properties were highly dependent. By only changing a few atoms, we could tune stress relaxation from 0.2 to 2500 seconds. The relationship between molecular structure and hydrogel properties could be linked to known theory for the polymer physics of worm-like micelles. All samples formed fibrous aggregates in solution, with a tunable hydrophobic pocket upon self-assembly. The hydrogels were capable of self-healing, injectibility, and 3D bioprinting. Their performance as a bioink was tightly linked to the hydrophobic substitution of the BTA. High cell viability (>85%) was found before and after printing.

Conclusion
We have shown a novel approach to controlling the properties of supramolecular hydrogels based on simple molecular engineering. These hydrogels exhibit high cell viability and rationally tunable mechanical properties. By tuning of the hydrogel properties, we were able to create a 3D printable bioink from this system, with biomimetic mechanical properties and fibrous structure. These results enable further rational design of supramolecular biomaterials and show their potential in advanced applications like 3D bioprinting.

In situ mineralization of MnO₂ on layer-by-layer polymer capsules to limit the accumulation of cytotoxic by-products resulting from enzymatic reactions

Edurne Marin¹, Juan F. Cadavid-Vargas², Jose R. Sarasua¹, Aitor Larrañaga¹

¹University of the Basque Country (UPV/EHU), Department of Mining-Metallurgy Engineering and Materials Science, POLYMAT, Faculty of Engineering in Bilbao, Bilbao, ES; ²Universidad Nacional de la Plata, INIFTA-CONICET-UNLP, La Plata, AR

Introduction

The use of enzymes has emerged as an attractive strategy in the fabrication of biomedical systems for therapeutic applications thanks to their specificity and efficacy. However, considering their susceptibility to undergo protease degradation and denaturation in body fluids, several encapsulation strategies have been considered to protect them from harsh environmental conditions and maintain their structural integrity [1]. Glucose oxidase (GOx) catalyzes the reaction of the environmental glucose to yield gluconic acid and hydrogen peroxide (H₂O₂). Based on this reaction, a plethora of biomedical systems have been developed including insulin delivery capsules [2], glucose sensors [3], cancer cell targeting capsules [4] or antimicrobial capsules [1]. The cytotoxic H₂O₂ produced in the reaction has been exploited to combat cancerous cells and bacteria (Fig. 1a) [1,4]. However, in many other strategies, the accumulation of H₂O₂ can have a detrimental effect on the surrounding cells/tissues, as well as in the catalytic activity of the enzyme, thus limiting its biomedical applications (Fig. 1b) [2,3].

To scavenge the produced H₂O₂, the use of MnO₂ as antioxidant synthetic enzyme (nanozyme) has been placed in the spotlight of many investigations owing to its unique enzyme mimetic activity and stability.

In this work, inspired by the compartmentalization strategies found at the cellular and subcellular level, we encapsulate GOx into layer-by-layer (LbL) polymer capsules. Their outer layer was further functionalized with an in situ created MnO₂ shell to simultaneously regulate glucose levels and reduce the undesired production of H₂O₂ from the microenvironment (Fig. 1b).

Experimental Methods

Microcapsules were fabricated via the LbL approach following a well-established protocol [5]. GOx was preloaded in the inner cavity of the capsule through a co-precipitation method, to obtain GOx-loaded CaCO₃ spherical microparticles. After the LbL process, using as polyelectrolytes poly (sodium 4-styrenesulfonate) (PSS) and poly(allylamine hydrochloride) (PAH), the MnO₂ layer was created in situ via a mineralization process incubating different KMnO₄ solutions (i.e., 2.5, 5, 10, 20, 50 and 100 mM) with the microparticle. After a morphological and physicochemical analysis of the fabricated capsules by means of scanning electron microscopy (SEM), ζ-potential, UV-vis and X-ray diffraction (XRD), the antioxidant capacity of the MnO₂ layer and the glucose reduction capacity of the GOx was assessed. Finally, the protective effect of the capsules was studied in an in vitro model of human lung fibroblast cells (MRC-5).

Results and Discussion

Capsules loaded with GOx and functionalized with the MnO₂ shell were satisfactorily fabricated via the LbL approach and displayed a spherical morphology with sizes in the range of 3-5 microns (Fig. 2a). The alternate deposition of the layers was confirmed with ζ-potential measurements in which a charge reversal was observed as different polyelectrolytes were incorporated (Fig. 2b). The capsules efficiently scavenged H₂O₂ from solution at biologically relevant concentrations (10-50 µM H₂O₂) (Fig. 2c), particularly at the highest KMnO₄ concentrations studied (i.e., 20, 50 and 100 mM). The activity of the encapsulated enzyme was preserved, as demonstrated by its ability to...
successfully reduce glucose from solution. The presence of naked (i.e., without the external MnO\textsubscript{2} shell) capsules promoted H\textsubscript{2}O\textsubscript{2}-induced cell death at increasing glucose concentrations in the culture media. In contrast, the external MnO\textsubscript{2} shell scavenged the overproduced H\textsubscript{2}O\textsubscript{2}, thus ensuring the survival of MRC-5 cells.

Conclusion
In this work we fabricated polymer capsules via the LbL approach, which were able to reduce the glucose levels from the cellular microenvironment and simultaneously scavenge the undesired H\textsubscript{2}O\textsubscript{2} created from the GOx reaction. These polymer capsules represent a promising strategy to protect enzymes from harsh environmental conditions maintaining their activity, while avoiding cell damage by reducing the effect of undesirable by-product accumulation.

S07 | Biomaterials: The Roadmap Towards Personalised Strategies in Musculoskeletal Tissue Engineering

Chairs
Nicola Baldini
University of Bologna & Istituto Ortopedico Rizzoli, Bologna, IT
Maurice Collins
University of Limerick, Limerick, IE
Gabriela Graziani
Rizzoli Orthopaedic Institute, Bologna, IT

Participants will have a comprehensive understanding of the latest advances in musculoskeletal engineering which are underpinning advances at the frontiers of materials, biological and medical science. These include new trends in 3D printing/bioprinting for regenerative medicine and tissue models, combination of 3DP and nanoscale materials, vascularization of 3D constructs.

3D Bioprinting has tended to focus on the production of increasingly intricate architectures. However, in achieving this, many concessions are being made regarding the biological aspects of printed materials. Therefore, there is a pressing need for novel engineering approaches to obtain biomimetic inks for future musculoskeletal engineering strategies.

3D Bioprinting Strategies to Bioengineer Skeletal Muscle Constructs that Accelerate Muscle Function Restoration

Sang Jin Lee

Wake Forest School of Medicine, Wake Forest Institute for Regenerative Medicine, Winston-Salem, US

To achieve rapid skeletal muscle function restoration, many attempts have been made to bioengineer functional muscle constructs by employing physical, biochemical, or biological cues. Currently, 3D bioprinting technologies combined with tissue engineering principles have been developed to offer the creation of biological tissue constructs that mimic the structural, anatomical, and functional features of native tissues or organs. Hence, these technologies have been applied to fabricate an implantable, bioengineered skeletal muscle tissues composed of human primary muscle cells. The bioprinted muscle constructs showed a highly organized multi-layered muscle bundle made by viable, densely packed, and aligned myofiber-like structures. More importantly, these constructs have been implanted in animal models and showed muscle regeneration with the vascularization and host nerve integrity, resulting in the restoration of muscle function. These 3D bioprinted skeletal muscle constructs present a possibility for therapeutic effects to treat the muscle defect injuries and have implications for future translation.

Biomimetic 3D scaffold-based model for in vitro investigation of bone pathologies

Silvia Fare
Politecnico di Milano, Dept. of Chemistry, Materials and Chemical Engineering, Milan, IT

Among the adults, 0.2% of the total amount of malignant tumors are primary bone tumors, while among children (<15 years old) they make up 5% [1].

Bone microenvironment, built up by stromal tissue, extracellular matrix (ECM), cells and molecules, is influenced and it influences, itself, the tumor development. In particular, the tumor is characterized by a vicious cycle, in which tumor cells, stimulated by bone environmental factors, causes an increase in osteoclastic activity through osteoblastic activity modulation [2]. Consequences consist in a higher bone tissue resorption and in the development of a tumor niche, which should be perfectly reproduced in vitro, in order to identify anti-neoplastic therapies, which remove oncogenic tumor stimuli.

For decades, tumor research is based on 2D in vitro tumor models and animal models to reproduce what happens in the human body to identify and verify new anti-neoplastic therapies’ effectiveness [3]. However, both have intrinsic limitations: 2D in vitro tumor models do not reproduce the microenvironment (3D architecture, cell-cell, and cell-matrix interactions), while animal models have ethical and economic problems and, in addition, they are not so reproducible. Due to these limitations, only 5% of anti-neoplastic drugs, which demonstrated good results during 2D in vitro and in vivo studies, confirmed these results during clinical trials.

For all these reasons, during the last years, 3D in vitro tumor models have been developed to reproduce mechanical, biochemical, and structural bone microenvironment elements, allowing cells to behave as in vivo. The present talk is aimed at describing different approaches for the design of 3D in vitro models based on various polymeric porous scaffolds, in order to mimic structural, physical and mechanical properties of bone tissue. In vitro biological characterization provides appropriate information on the performance of the produced scaffold-based models in mimicking bone tumors.

Introduction
Articular cartilage lacks the ability to regenerate once damaged. Tissue engineering approaches have shown some promise to overcome this limitation by combining appropriate biomaterials, biochemical cues, and stem cells to facilitate environments capable of producing healthy de-novo cartilage. Our group has had success using freeze dried collagen and hyaluronic acid (CHyA) scaffolds to recapitulate the native cellular environment of cartilage.¹,² Combining this scaffold with bone-marrow derived mesenchymal stromal cells (BM-MSC) has shown production of cartilage like tissue that shows an increase in sulphated glycoaminoglycans (sGAG) and other chondrogenic markers over time.¹,² These scaffolds have shown potential in a number of animal models and in human patients but their mechanical properties restrict their use to small joint defects. To overcome the weak compressive modulus of CHyA scaffolds, this study focussed on developing a biomimetic, bioabsorbable scaffold with both mechanical and biochemical properties tailored to the specific requirements of the complex native tissue

Experimental Methods
PCL was extruded through a bioprinter (Allevi USA) to produce a macro-porous scaffold with mechanical properties tailored specifically to mimic articular cartilage. Two different scaffold designs, rectilinear and gyroid were selected for their ideal printability (continuous, non-intersecting toolpaths) and brought forward for mechanical testing. Aqueous CHyA was combined with PCL scaffolds and freeze dried together at -20C. Uniaxial compressive strain was applied cyclically at 0.15mm/s to 20% strain on a Zwick Roell mechanical tester (Zwick Roel, Germany) to determine Young’s compressive modulus. A 3 point bend test was used to determine how much force is required to bend CHyA-PCL scaffolds to the contour of a femoral condyle. This information was used to determine what fixation methods were strong enough to hold CHyA-PCL to the subchondral bone. 3 different osteochondral suture anchors were tested, two cylindrical scaffolds were 3D printed in-house (4, 6mm diameter) and a commercially available option (Twin Fix Ti, Smith and Nephew) were investigated. For in-vitro studies, scaffolds were seeded with BM-MSCs (5X10⁵ per scaffold) on their 5th passage and placed in complete chondrogenic media (CCM). sGAG production, DNA quantification, and histological analysis was performed on samples after 1, 14, and 28 days in culture. Prism software (GraphPad, USA) was used for one-way analysis of variance (ANOVA) of data or a two-tailed T test when appropriate.

Results and Discussion
Both the Rectilinear and Gyroid toolpath designs (Fig 1A) were able to increase the compressive modulus of CHyA scaffolds (Fig 1B) by 3 orders of magnitude which mimics the native mechanical property of articular cartilage. The Gyroid scaffold was more flexible than the Rectilinear scaffold (Fig 1C) which required an additional 6.9N to bend. All anchor systems tested (Fig 1D) were strong enough to hold a Gyroid scaffold in place, but only the commercial option was able to hold the rectilinear scaffold in place. CHyA matrix was successfully incorporated into PCL reinforced scaffolds (Fig 1E) without affecting the mean pore size (Fig 1F). Since the Gyroid was more flexible, and could be paired with numerous fixation options, it was brought forward for in vitro testing.
PCL reinforcement did not inhibit sGAG production on CHyA scaffolds. Cells seeded on PCL-CHyA scaffolds showed an increase in sGAG accumulation over time (Fig 2A) with a significant increase compared to non-reinforced CHyA 28 days after seeding. GAG production was normalized to DNA content to account for variation in cellular proliferation rates (Fig 2D). Only PCL-CHyA scaffolds were able to show an increase in GAG/DNA production overtime. Histological sections stained with Alcian Blue pH 1 (Fig 2B,C,E,F) show successful production of sulphated GAG (sGAG) signifying a high quality extracellular matrix production for the use in cartilage regeneration.

**Conclusion**

In conclusion, the addition of a PCL framework into a CHyA scaffold was able to significantly increase the compressive modulus the CHyA scaffold to more accurately mimic the native mechanical properties of articular cartilage while maintaining biological functionality as seen by cells attaching and depositing sGAG. Preventing the microporous architecture of CHyA from being flattened under physiological loads has previously been a limitation that restricts the effective area size that can be treated in cartilage defects. Reinforcement with a bioabsorbable material allows autologous BM-MSCs to migrate into the scaffold while also serving as a potential attachment point to fix the CHyA scaffold in place to the subchondral bone when implanted in joint defects. Taken all together, these PCL-CHyA reinforced scaffolds show great potential to be used as an off the shelf treatment for large area cartilage defects when combined with micro-fracture surgical technique.

Complex designs for tissue regeneration: Melt Electrowriting of gradient scaffolds

Małgorzata Włodarczyk-Biegun1,2, Piotr Zieliński1, Magdalena Gladysz1, Anno Hofman1, Timo Rikmanspoel1, Xixi Wu1, Maria Villiou2, Marcus Koch2, Aranzazu del Campo2, Marleen Kamperman1

Introduction
Melt electrowriting (MEW) is an additive manufacturing technique that uses a high voltage to deposit with unprecedented precision fibers with diameters in the micrometer range. High control over printed structures and flexibility in the designs makes MEW a promising tool to recapitulate the complexity of native hierarchical structures. Therefore, using MEW we attempted to recreate the original architecture of the Human Trabecular Meshwork (HTM). HTM is a network located in the eye which is responsible for maintaining proper pressure in the ocular chamber, and its dysfunctions lead to glaucoma, one of the leading causes of blindness worldwide. HTM is ca. 600 μm thick and is composed of 3 geometrically different layers with pore dimensions between 0.1μm to 25μm.

We are also employing our approach to mimic the stratified structure of the skin and gradients of hard-soft tissue interfaces. The interfacial tissues, such as bone-tendon or bone-ligament connections, are characterized by gradual change of the architecture, accompanied by the gradients in chemical, mechanical, and biological properties, typically occurring over less than 1 mm length.

Experimental Methods
Printing of medical-grade Polycaprolactone (PURASORB PC 12, Mw ~55,000,) and high Mw Polycaprolactone (Sigma, Mw ~ 80,000) was performed with Melt Eletrowriting printer (Spraybase, Ireland and RegenHu, Switzerland). Scaffolds with different designs (varied pore shapes and sizes, different number of layers) were printed and visualized with scanning electron microscopy (SEM) to assess the accuracy of fabrication. The dependency of mechanical properties (in tensile and compression modes) on the scaffold's architecture was investigated. Biological response of fibroblasts and primary HTM cells seeded on different scaffolds was analysed based on SEM imaging and immunofluorescent staining.

Results and Discussion
Four different designs, inspired by the architecture of the native HTM and its three distinctive layers, were successfully printed (see Figure 1). The thickness of the scaffolds, depending on the design, varied between 70 and 500 μm, the average strand size was ca. 10-12 μm, and scaffolds overall porosity was in the range of 70-90%. These geometrical features closely mimic the native architecture of HTM. Mechanical testing revealed the subtle influence of the design on the mechanical properties of the scaffolds.

Primary HTM cells attached to the scaffolds proliferated to form a confluent layer within 7 days of culture and maintained their phenotype throughout the whole time of the cell study. Additionally, the first attempts to obtain scaffolds mimicking different zones in native skin and hard-soft tissue interfaces were made and different bioinspired structures were designed, printed, and visualized.

Conclusion
In conclusion, we have shown that MEW technique is a powerful tool to obtain high precision, small scale biomimetic scaffolds tailored into specific applications. MEW enabled the reconstruction of the multilayer structure of native HTM. Scaffolds permeability to liquid and response of the HTM cells to specific drugs, are currently under investigation. MEW is also a suitable technique to printed hard-soft tissue interfaces and skin models with varying mechanical and biological performance.
We envision that small-scale hierarchical structures printed with high precision will serve in the future as implantable systems or an in-vitro testing model.

Significance of Geometry in Biomimetic Eardrum Scaffolds

Shivesh Anand¹, Thomas Stoppe², Marcus Neudert², Serena Danti³, Lorenzo Moroni¹, Carlos Mota¹

¹ Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; ² Technische Universität Dresden, Carl Gustav Carus Faculty of Medicine, Otorhinolaryngology, Dresden, DE; ³ University of Pisa, Department of Civil and Industrial Engineering, Research Unit of INSTM, Pisa, IT

Introduction

The human eardrum is a thin, concave membrane located at the end of the outer ear canal. It is responsible for capturing sound waves from the environment and transforming them into mechanical motion [1]. Perforated eardrums are one of the most common ear injuries, resulting in a partial or severe hearing loss due to inept sound conduction. Microsurgical placement of autologous tissue grafts from temporalis fascia or perichondrium have been the conventional approach to repair a damaged eardrum [2]. However, the incongruent tissue properties may impair an optimal hearing restoration. This has often been attributed to the lack of an appropriate geometry and mechano-acoustical characteristics in the recovered membrane [3]. The concurrent sound transmission and stability of a healthy eardrum is facilitated by its unique three-dimensional (3D) architecture comprising radially and circumferentially distributed collagen fibers [4, 5], although a limited knowledge is available on the contribution of these discrete micro-anatomical features. Therefore, this work presents a combination of theoretical and experimental approaches toward understanding the significance of geometry in biomimetic eardrum scaffolds (Figure 1).

Experimental Methods

A Python script was developed for modelling the anatomical architecture of the human eardrum. Three test designs (case I, II and III) along with a plain control were chosen to decouple some of its dominant structural attributes. Theoretical comparisons were performed on COMSOL Multiphysics by simulating the appropriate mechanical and acoustical interaction of the selected cases (Figure 2 (i)). A dual scale strategy combining electrospinning and additive manufacturing was implemented for manufacturing hierarchical scaffolds. A block copolymer of poly(ethylene oxide terephthalate) (PEOT) and poly(butylene terephthalate) (PBT) was employed as the suitable biomaterial. Parametric optimization of the fabrication steps were conducted, following which the constructed scaffolds were characterized mechanically, acoustically and biologically. The mechanical and acoustical responses were evaluated by applying the techniques of macroscopic indentation and laser Doppler vibrometry (LDV), respectively. For the biological assessments, human dermal fibroblasts (NHDFs) and human mesenchymal stromal cells (hMSCs) were seeded independently on the eardrum constructs. The cultured samples were assessed based on their ability to steer the cell distribution and alignment, along with an effective extracellular collagen production.

Results and Discussion

The Python script served as a versatile and robust tool for generating eardrum models with diverse anatomical features. In silico investigation of the chosen designs suggested a geometrical dependency of their mechanical and acoustical responses, where the presence of radially aligned fibers was observed to have a more prominent effect as compared to their circumferential counterparts. The hybrid fabrication strategy was carefully optimized to manufacture biomimetic scaffolds within the dimensions of the native eardrum. The macro-indentation results corroborated the findings of the theoretical simulations, where radially aligned scaffolds were noted to show a Young’s modulus closer to that of the human eardrum (Figure 2 (iii)). The circumferential filaments, on the other hand, were deemed critical for maintaining an optimal resilience and structural integrity. In addition, the LDV measurements demonstrated all the fabricated constructs to be acoustically comparable to the native tissue (Figure...
Finally, the biological studies performed with NHDFs and hMSCs, revealed a favorable influence of 3D hierarchy on cellular alignment and subsequent deposition of extracellular collagen. A higher orientation coherency and collagen production was obtained along the additive manufactured fibers (Figure 2 (ii)).

**Conclusion**

This study highlights the relevance of scaffold geometry for eardrum reconstruction. A radical improvement in the previously reported limits for manufacturing alloplastic eardrum replacements was achieved [4, 5]. Among the investigated micro-anatomical features, the radially-aligned fibers were observed to have a more prominent effect over stiffness, whereas the circumferentially-aligned ones were deemed critical for maintaining the structural integrity of the constructs. Cellular quantifications demonstrated the role of additive manufactured fibers in steering the distribution and alignment of collagen production on electrospun meshes. In conclusion, desirable mechanical, acoustical and biological behavior, analogous to that of the native tissue, can be achieved by manipulating the 3D geometry of eardrum scaffolds.

Nanoactuators for Therapy and Diagnosis

Jesús M. de la Fuente

CSIC-Universidad de Zaragoza & CIBER-BBN, Instituto de Nanociencia y Materiales de Aragón, Zaragoza, ES

In the last decades, inorganic nanoparticles have been steadily gaining more attention from scientists from a wide variety of fields such as material science, engineering, physics, or chemistry. The very different properties compared to that of the respective bulk, and thus intriguing characteristics of materials in the nanometre scale, have driven nanoscience to be the centre of many basic and applied research topics. Moreover, a wide variety of recently developed methodologies for their surface functionalization provide these materials with very specific properties such as drug delivery and circulating cancer biomarkers detection. In this talk we describe the synthesis and functionalization of magnetic and gold nanoparticles as therapeutic and diagnosis tools against cancer. Gold nanoprisms (NPRs) have been functionalized with PEG, glucose, cell penetrating peptides, antibodies and/or fluorescent dyes, aiming to enhance NPRs stability, cellular uptake, and imaging capabilities, respectively. Cellular uptake and impact were assayed by a multiparametric investigation on the impact of surface modified NPRs on mice and human primary and transform cell lines. Under NIR illumination, these nanoprobes can cause apoptosis. Moreover, these nanoparticles have also been used for optoacoustic imaging, as well as for tumoral marker detection using a novel type of thermal ELISA and LFIA nanobiosensor using a thermosensitive support.
Tumor-Targeted Nanomedicine Approaches for Enhanced Immunotherapy

Horacio Cabral¹,²,³

¹ The University of Tokyo, Department of Bioengineering, Tokyo, JP; ² The University of Tokyo, Department of Materials Engineering, Tokyo, JP; ³ Innovation Center of Nanomedicine, Kawasaki, JP

Immunotherapy has revolutionized cancer treatment. However, despite the outstanding benefits, the proportion of patients responding to immunotherapies is still low. Nanomedicine has the potential to improve immunotherapy through spatiotemporal control of drug activity and promotion of effective antitumor immunity [1]. Nevertheless, only a few nanomedicines formulations have reached human clinical studies so far, and even fewer systems are being used in the clinic. Among translatable nanomedicines, self-assembled polymeric micelles have shown unique characteristics for dealing with tumor heterogeneity, such as the possibility to control their size in the sub-100 nm range and the possibility to install ligands on their surface to promote tissue and cellular targeting. Polymeric micelles can be designed to enhance antitumor immune responses by various immunopotentiating functions, such as the induction of immunogenic damage to cancer cells, the alteration of the tumor immune microenvironment through the delivery of immunomodulators, the reprogramming or elimination of immunosuppressive cells, and the improvement of the infiltration of antitumor immune cells. Polymeric micelles can be engineered to sense intratumoral stimuli for activating specific immune responses. For example, epirubicin-loaded polymer micelles can induce immunogenic cell death (ICD) to generate a strong immune response against murine models of glioblastoma [3]. The epirubicin-loaded micelles delivered more than 100-fold more drug into brain tumors than free epirubicin for promoting antitumor immunity. The micelles increased the infiltration of cytotoxic CD8+ T cells and M1-like macrophages, turning immunosuppressive glioblastoma into inflammed tumors. Thus, their cytotoxic effects synergized with immune checkpoint blockade elicited by anti-PD1 antibodies, allowing to overcome glioblastoma's resistance to immune checkpoint blockade. Polymeric micelles installed with ligands can be applied for increasing drug levels in tumors to enhance immune signals [4]. We have recently showed that glucose installation on the surface of polymeric micelles facilitated the accumulation into solid tumors by targeting the glucose transporters expressed on the tumor vasculature, which allowed the vascular translocation of the nanomedicines into the tumors [5]. Based on this approach, we designed glucose-installed nanocarriers loaded with anti-PD-L1 antibodies for enhancing the delivery to tumors. The anti-PD-L1 antibody-loaded nanocarriers achieved more than 10-fold higher accumulation in brain tumors compared to native anti-PD-L1 antibodies. Moreover, they eradicated intracranial glioblastoma models after a single intravenous injection. These results indicate that by fostering the intratumoral access of immunomodulating drugs it is possible to sensitize brain tumors to antitumor immunity. Thus, the capability of nanomedicines to exert immunomodulatory functions selectively in tumor and tumor-associated tissues increases the efficiency of the treatments, while avoiding systemic immunosuppressive toxicities and the exacerbation of adverse immune responses.

Tunable drug release from electrospun scaffolds for tympanic membrane regeneration

**Shivesh Anand**¹, Cemre Günday², Sara Munafò¹,³, Nazende G. Türel³, Serena Danti³, Lorenzo Moroni¹, Carlos Mota¹

¹ Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; ² MyBiotech GmbH, Überherrn, DE; ³ University of Pisa, Department of Civil and Industrial Engineering, Research Unit of INSTM, Pisa, IT

**Introduction**

The human tympanic membrane (TM) is a thin tissue lying at the intersection of outer and middle ear. Its main function is to receive sound vibrations from the outer air and transmit them to the adjoining ossicular chain [1]. TM perforations are the most common damage to the human eardrum, where typical etiologies include microbial infections and acoustic traumas [2]. Among them chronic otitis media, a bacterial inflammation of the middle ear has been reported to be the leading cause for TM injuries in children. Majority of the acute perforations heal without an external stimulus, owing to the inherent regenerative capacity of the native tissue [3]. However, in case of larger chronic injuries induced by recurrent infections, the absence of a tangible support limits the requisite cell migration and proliferation for a self-recovery. Several tissue engineered grafts have been reported to treat the damaged eardrums, although not much attention has been directed towards preventing on-site microbial infections upon transplantation [4]. In this work, we investigate the integration of biofabrication with targeted drug delivery to create antibacterial scaffolds for TM.

**Experimental Methods**

Ciprofloxacin-encapsulated poly(D,L-lactide-co-glycolide) (PLGA) nanoparticles were synthesized with two distinct approaches, namely double-emulsion and nanoprecipitation, by applying an automated microjet reactor technology. A co-electrospinning/electrospraying strategy was implemented to incorporate the drug-loaded nanoparticles within the electrospun mesh of poly(ethylene oxide terephthalate)/poly(butylene terephthalate) (PEOT/PBT) (Figure 1). The resultant scaffolds were evaluated with respect to a simple immersion approach where pre-fabricated PEOT/PBT electrospun meshes were soaked in the nanoparticle colloidal suspension. Furthermore, additional electrospinning modalities were investigated by including the ciprofloxacin in the precursor polymeric blend. This was performed to entrap the drug within the PEOT/PBT nanofibers, which in combination with the simultaneous electrospraying of PLGA nanoparticles allowed the manufacturing of dual loaded TM scaffolds. The chosen modalities were compared based on the surface properties, drug release kinetics, and mechanical response of their corresponding constructs. Preliminary cytocompatibility assessments of ciprofloxacin and PLGA nanoparticles were carried out with human mesenchymal stromal cells (hMSCs).

**Results and Discussion**

Among the two nanoparticle synthesis routes, nanoprecipitation was found more suitable for the applied co-electrospinning/electrospraying strategy [5]. Moreover, unlike the immersion approach, it resulted in a more homogeneous distribution of the deposited nanoparticles (Figure 1). The successful adhesion of the electrosprayed nanoparticles to the PEOT/PBT nanofibers was confirmed using scanning electron microscopy (Figure 2A) and fluorescent labeled PLGA (Figure 2C). Following an initial burst release, the PLGA nanoparticles ensured a controlled delivery of ciprofloxacin for the next 48 hours. On the other hand, the inclusion of ciprofloxacin within the electrospun fibers demonstrated an enhanced release kinetics between day 1 and 7. Therefore, a combination of the two modalities is being optimized to manufacture TM scaffolds with a tunable release profile up to 7 days. Cytocompatibility studies performed with hMSCs revealed no noticeable effect of the antibiotic-encapsulated...
nanoparticles on cellular attachment and proliferation (Figure 2B). Finally, a detrimental influence of ciprofloxacin over the cell viability and metabolic activity assays was noted only for concentrations exceeding 33 µg/mL (Figure 2D).

Conclusion
This work introduces a combination of electrospinning strategies for manufacturing TM scaffolds with a tunable antibacterial response. The implemented modalities have been found more efficient for targeted drug delivery as compared to conventional immersion techniques [5]. Electrospun meshes capable of releasing ciprofloxacin within its minimum inhibitory concentration (0.23 – 1.16 µg/mL) have been fabricated. Preliminary biological studies conducted with hMSCs have shown promising results. Further characterizations of the TM scaffolds along with the validation of their antibacterial activities is currently under investigation.

Introduction

Bacterial biofilms are nowadays a major health concern due to the escalating figures of antimicrobial resistance. Conventional therapy for implant-associated biofilms usually fails since it is solely focused on the administration of antibiotics. However, the biofilm matrix represents a biological barrier against these drugs, leading to antimicrobial resistance phenomena. A combinatorial therapy that focus on both bacterial cells and the matrix is urgently needed. In this work we developed lipid nanoparticles (LNPs) to encapsulate N-acetyl-cysteine (NAC), which is a mucolytic agent with potential to disrupt the matrix of mature biofilms, promoting the break of this protective barrier [1].

Experimental Methods

The LNPs were produced by the double emulsion technique and optimized by a rational design. The nanoparticles were characterized regarding their hydrodynamic diameter, polydispersity index, and zeta potential. Their biocompatibility was assessed through a hemolysis assay and an in vitro cytotoxicity assay against the L929 fibroblasts cell line. The in vitro antibiofilm efficacy of the developed LNPs was tested against Staphylococcus epidermidis (Gram-positive) and Pseudomonas aeruginosa (Gram-negative) biofilms.

Results and Discussion

The LNPs showed suitable characteristics for intravenous administration and biocompatibility. At the tested concentration, the LNPs were more efficient against Pseudomonas aeruginosa biofilms, with a 50% reduction of biofilm biomass. These results were further confirmed by a biofilm viability assay and by scanning electron microscopy. In a more complex approach, the LNPs were combined with a well-known antibiotic, moxifloxacin. This combination showed a potential synergistic effect between the LNPs and the antibiotic on the reduction of bacterial viability within the biofilms.

Conclusion

Overall, the developed LNPs have a potential therapeutic effect on Pseudomonas aeruginosa biofilms, alone or in combination with antibiotics.

Chitosan-hybrid micelles loaded with camptothecin inhibit colorectal cancer progression \textit{in vivo}

Andreia Almeida$^{1,2}$, Flávia Castro$^1$, Marlene Lúcio$^3$, Simo Schwartz Jr.$^4$, Bruno Sarmento$^{1,5}$

$^1$ Institute for Research and Innovation in Health, University of Porto, Porto, PT; $^2$ Institute of Biomedical Sciences Abel Salazar, University of Porto, Porto, PT; $^3$ Centre of Physics of University of Minho and Porto, University of Minho, Braga, PT; $^4$ Vall d’Hebron Institut de Recerca, Universitat Autònoma de Barcelona, Barcelona, ES; $^5$ Institute for Research and Advanced Training in Health Sciences and Technologies, Porto, PT

Introduction

Colorectal cancer (CRC) is among the cancers with highest prevalence and mortality worldwide. Conventional CRC chemotherapy is hindered by poor local drug bioavailability and solubility, resulting in a reduced therapeutic outcome. To address this inadequacy, we design polymeric micelles, based on a new synthesized chitosan derivative (mPEG-CS-OA), for delivery of camptothecin (CPT), a chemotherapeutic agent [1].

Experimental Methods

Methoxypolyethylene glycol (mPEG) and oleic acid (OA) was grafted on chitosan backbone by carbodiimide reactions, resulting in an amphiphilic copolymer with ability to produce micelles. Copolymer characterization included $^1$H NMR, FTIR, GPC, DSC/TGA, and XRD. Moreover, micelles were prepared by dialysis and characterized by the size, zeta potential and morphology (DLS, ELS, and TEM, respectively). The association efficiency of CPT was determined by HPLC. The cytocompatibility of empty micelles was study in PBMCs, Caco-2, HT29, HCT116 tumor intestinal cell lines as well was the anticancer efficacy of CPT-micelles. The intestinal permeability was studied on Caco-2 model and on a 3D intestinal model developed by our group [2]. The effect of micelles on the metabolic activity and tumor size reduction was studied on a CRC triple co-culture spheroid model [3] and the anticancer therapeutic potential on a HCT116 xenograft model.

Results and Discussion

While empty micelles presented a safe profile during 72 h of incubation with PBMCs, CPT-loaded micelles decreased their metabolic activity at the highest concentration (250 µg/mL). However, free CPT presented a significative reduction on the metabolic activity after 24 h, highlighting the advantage of micelles for CPT delivery to avoid off-target toxicity. Regarding the anticancer efficacy, CPT-loaded micelles were able to significantly decrease the cellular viability, more evidently after 48 and 72 h. Further, CPT-loaded micelles significantly improved CPT permeability across a 3D intestinal model about a 2-fold increase as compared to free drug. CPT-loaded micelles were able to significantly decrease the spheroids’ metabolic activity and their size, demonstrating an active effect on the reductions of an \textit{in vitro} ‘tumor-like structure’. Finally, pharmacodynamic studies using HCT116 xenograft animal model showed a tumor reduction of 45% as compared with the control group (without treatment) and an area under the curve (AUC) significantly lower as compared with all the tested groups (saline, empty micelles and free CPT).

Conclusion

Overall, this study suggests that CPT-loaded micelles improved the CPT intestinal permeability and may be a promising system for chemotherapy, capable of inhibit tumor progression \textit{in vivo}.

In vivo efficacy of CPT-loaded micelles

CBA nude mice injected with $1 \times 10^6$ HCT116 cells on the right flank were subcutaneously treated with CPT-loaded micelles, empty micelles, free CPT, CPT i.v. and saline. Animals treated with saline solution were used as control. (A) The values presented were normalized to each tumor values at the first treatment and represented the tumor growth during 30 days; (B) The AUC for all the treatments used, where CPT-loaded micelles presented a lower value; (C) Tumor volume after treatment finished and a 45% tumor reduction was observed for CPT-loaded micelles; (D) Survival rate of animals during 60 days.

With Keynote lecture by Prof. Luigi Ambrosio in homage to Pr Charles Baquey – a great biomaterials scientist and friend of the ESB society, passed away at the end of December 2020, this symposium will present the relevant strategies for the development and the design of the future tissue engineered products according to the clinical requirements.
Nano-biocomposites: from tissue repair/regeneration to therapeutic behaviour

Luigi Ambrosio

National Research Council, Institute of Polymers, Composites and Biomaterials, Pozzuoli, IT

The implementation of a personalised therapy together a less invasive surgery for the restoration of human tissues is becoming an appropriate strategy to mitigate costs of the modern health care system and the maintenance of health and quality of life. The current challenge is to design material at the site of surgery with specific behaviours for mimicking the natural structures and delivering appropriate signals to cells promoting tissue repair/regeneration. Selection of a suitable injectable is often based on material characteristics (including mechanical properties, drug release kinetics and degradation) that serve for the specific treatment function. Micro or nano-structured materials in the form of gels, nanoparticles, nano-fibers and nano-composites have gained increasing interest in regenerative medicine because they are able to mimic the physical features of natural extracellular matrix (ECM) at the sub-micro and nano-scale levels. By a careful selection of materials and processing conditions it is possible to finely control characteristic shapes and sizes from micro to sub-micrometric scale and to incorporate bioactive molecules such as proteins or growth factor to develop active platforms to support the repair/regeneration of different tissues. It has been shown that the use of minimally invasive approach such as for bone cement to treat vertebral fracture has significant clinical potential. To achieve the ideal properties of bone filler efforts have been paid to optimize injectable calcium phosphate cements (CPC) which have been recognized as excellent alloplastic material for osseous augmentation/regeneration. The sol-gel synthesis approach appears to be the most suitable route towards performing injectable CPC. Furthermore, injectable hybrid material based on graphene oxide nanosheets and hydroxyapatite prepared by sol-gel approach is described. The presence of GO increases the bioactive and osteogenic properties of materials [1,2]. Within the class of 2D materials, exfoliated black Phosphorus is investigated to evaluate proliferation and the osteogenic differentiation of human pre-osteoblast cells (HOb) and mesenchymal stem (hMSC) cells. In vitro analysis demonstrated that 2D bP induced the proliferation and the osteogenic differentiation of human pre-osteoblast cells (HOb) and mesenchymal stem (hMSC) cells while inhibited the metabolic activity of osteosarcoma cells (SAOS-2) [3].

One more approach is based on the use of antimicrobial injectable materials [4]. It has been demonstrated that some imidazolium, pyridinium and quaternary ammonium ionic liquids (IL) have antimicrobial activity against some different clinically significant bacterial and fungal pathogens. Here, several systems based on IL at different alkyl-chain length incorporated in Hydroxyapatite (HA) through the sol-gel process to obtain an injectable material with simultaneous osteoinductive and antimicrobial behaviours.

Furthermore, as example of technology transfer activity, cellulose superabsorbent hydrogels are discussed as material intended to allow safe and effective weight loss and improvement of glycemic control in overweight and obese people [5]. The hydrogels are designed to mimic the structure and the viscoelastic properties of ingested dietary fibers, while being partially degraded in the last part of the gastrointestinal tract (colon).

Mesenchymal stem cell response to disordered bioactive patterns

Yujie Zhang, Christel Chanseau, Emilie Prouve, Murielle Remy, Marie C. Durrieu

University of Bordeaux.fr, CBMN, 33400 Talence, BORDEAUX, FR

Introduction
Stem cells are a major focus in regenerative medicine since they promise to provide unlimited amounts of cells for transplantation. Stem cells within their natural niches in vivo maintain through the lifetime and retain the ability to serve regenerative purposes by making choices for survival, self-renewal, differentiation, quiescence, or apoptosis in a regulated manner. Stem cell behavior patterns are guided by the external signals that a stem cell receives from its local niche. Such cues include soluble growth factors and hormones, contacts from neighboring cells, and also cues from the local extracellular matrix (ECM)\(^1\). In vivo, the cellular microenvironment has a crucial impact on the regulation of cell behavior and functions such as cellular differentiation, proliferation, and migration. One of the challenges confronting cell biologists is to mimic this microenvironment in vitro in order to more efficiently study living cells and model diseases. Adhesion ligands (density, distribution of ligands, sizes of the bioactive patterns) and mechanical properties of extracellular matrix (ECM) play significant roles in directing mesenchymal stem cells (MSCs) behaviors. Patterning of ligands with high degrees of density and spatial control has become a powerful approach for applications in tissue engineering.

Experimental Methods
In this study, we investigate the effects of adhesion and differentiation ligand density and distribution on osteoblastic differentiation of MSCs. Polyethylene terephthalate (PET) substrates were used as a model material to geometrically defined regions of RGD + BMP-2 mimetic peptides. These ECM-derived ligands are under research for the regulation of mesenchymal stem cells’ osteogenic differentiation in a synergistic manner. Briefly, PET was hydrolyzed and oxidized in order to create carboxyl groups on the surface (labeled as “PET-COOH” (Fig.1)). Then, the surfaces were immersed in a solution of EDC (0.2M) + NHS (0.1M) + MES (0.1M) in MilliQ water for activation\(^3\).

Results and Discussion
A smart technique for micropatterning surfaces for cell growth support is described and characterized. This technique allows covering of 2D or 3D surfaces at low cost with controllable size and shape of micropatterns and with a very low time-consuming. This method takes advantage of the random properties of aerosols and the principles of liquid atomization. Parameters of interest were the pressure of atomization air, the flow rate and volume of the atomized liquid, and the distance between the spray nozzle and the surface of the sample. The experimental setup permitted to obtain diameters of spots between 0 μm and 100 μm microns with a maximum surface coverage of 30%.

Conclusion
Bioactive molecular patterns with different densities, different shapes, and sizes were obtained on the PET surface (Fig 1). Different surface coverages of bioactive peptides on PET were obtained(Table 1). Fluorescence microscope and image J were used to evaluate the density of biological peptides (BMP-2=3.1±1 pmol/mm\(^2\) and RGD=2.83±0.6 pmol/mm\(^2\)) (Fig 1e iii). When they were randomly co-distributed on the surface, they promote cell adhesion and osteogenic differentiation, respectively, and further enhance the osteogenic effect (Fig 1e-f). Further works include the investigation of different patterned surfaces (pattern size, surface coverage, pattern shape, and surface grafted with different peptides) impact on the differentiation yield of hMSCs toward osteoblast lineage.

Nitric oxide-scavenging hydrogels as therapeutics for inhibiting angiogenesis in triple-negative breast cancer

Amir Abdo¹, Sharon Glynn², Pau Farràs³, Abhay Pandit¹

¹ National University of Ireland Galway, CÚRAM, SFI Research Centre for Medical Devices, Galway, IE; ² National University of Ireland Galway, Discipline of Pathology, Lambe Institute for Translational Medicine, School of Medicine, Galway, IE; ³ National University of Ireland Galway, School of Chemistry, Ryan Institute, Galway, IE

Introduction

Triple-negative breast cancer is a highly aggressive malignancy constituting around 10-20 % of breast cancers, with a limited number of treatment options [1]. Within the tumour microenvironment, nitric oxide (NO) orchestrates the angiogenesis and lymphangiogenesis processes, depending on its concentration, duration of exposure and the surrounding tissue [2,3]. More importantly, the surrounding cells' sensitivity to NO varies with its concentrations [2,3], making NO scavenging a potential strategy to bring in homeostasis in these cells. According to its molecular weight (MW), hyaluronic acid (HA) may have pro-or-anti-inflammatory roles in breast cancer. For instance, specific low MW-HA fragments are pro-inflammatory by inducing the production of specific inflammatory cytokines and proteases by tumour-associated macrophages [4]. The specific objectives of this study were: (i) to construct HA hydrogels loaded with different hemin conjugates; (ii) to test their NO-scavenging potential and (iii) to evaluate the cytotoxicity of the hydrogels and assess the downstream effects of NO-scavenging.

Experimental Methods

Hydrogel fabrication: Following the synthesis of several hemin derivatives proved to act as potential NO-scavengers, each type was loaded to 4-arm polyethylene glycol (PEG)-crosslinked HA hydrogel with investigating their physicochemical properties.

NO-scavenging potential: This was evaluated using NO-sensor and luminol/H₂O₂-luminescence reaction in phosphate buffer and culture media for choosing the formulations with optimum functionality and injectibility properties. In vitro testing: The hydrogels' cytotoxicity was tested by measuring the metabolic activity of the triple-negative breast cancer cell line (MDA-MB-231), human umbilical vein endothelial cells and microvascular endothelial cells using alamarBlue™ cell viability assay. Next, NO secreted intracellular levels from 300 μM Diethylenetriamine-NONOate (DETA-NONOate) were measured over 24 hours using Diaminofluorescein-FM diacetate and fluorescence microscopy following the cell culture with different hydrogels. Next, the effects of NO-scavenging by the hydrogels on cell migration were evaluated using wound healing assay and measuring the levels of the secreted Vascular Endothelial Growth Factor A and C using Enzyme-Linked Immunosorbent Assay (ELISA).

Results and Discussion

Hydrogel fabrication: The enhanced activation of HA chains for the crosslinking resulted in more activation of the loaded hemin/hemin conjugate alongside the formation of hydrogels with high storage modulus. This allows further covalent bonding of hemin with the cross-linker to be more protected within the hydrogel matrix. The loading of hemin was confirmed using SEM/EDX (fig. 1).

NO-scavenging potential: Some hydrogel formulations were proven to have different abilities to scavenge NO, depending on the degree of crosslinking within and the loaded compounds’ availability to react with NO (fig. 2a). Moreover, some formulations were able to protect the loaded compounds within the hydrogel matrix against the degrading effects of H₂O₂ (fig. 2b).

In-vitro testing: The hydrogel formulations characterized to be injectable, slowly degrading with the highest efficiency to bind NO, while loaded with the lowest concentrations of the different hemin compounds, were selected for further in vitro testing. Herein, specific formulations loaded with hemin or a hemin conjugate up-to 30 μM were
tested. The loaded hydrogels that maintained the cells' metabolic activity above 80% were chosen for further evaluation against the candidate hydrogels. Next, the intracellular NO was measured over 24 hours following the treatment of cells with DETA-NONOate and culturing with hydrogels loaded with 3.83, 7.66 or 15 μM. The in vitro experiments revealed that specific HA hydrogel formulations could protect the loaded NO-scavenging compounds without influencing their functions on inhibiting the cancer cell migration and quenching the intracellular NO levels while maintaining the injectability of the hydrogel.

**Conclusion**

Injectable hydrogels loaded with different hemin conjugates have been fabricated. The hydrogel formulation can be tuned to maintain the NO-scavenging efficiency by loading the lowest possible NO-scavenger concentrations, mechanical properties and degradability.

Allysine-mediated cross-linking for the development of elastin-like biomaterials

Tobias Hedtke1,2, Wolfgang Hoehenwarter3, Matthias Menzel1, Jürgen Brinckmann4, Thomas Groth2, Christian E.H. Schmelzer1

1 Fraunhofer Institute for Microstructure of Materials and Systems IMWS, Biological and Macromolecular Materials, Halle (Saale), DE; 2 Martin Luther University Halle-Wittenberg, Biomedical Materials Group, Institute of Pharmacy, Halle (Saale), DE; 3 Leibniz Institute of Plant Biochemistry, Proteome Analytics Research Group, Halle (Saale), DE; 4 University of Lübeck, Institute of Virology and Cell Biology, Lübeck, DE

Introduction

Elastin is a highly cross-linked biopolymer and the main component of elastic fibers in the extracellular matrix. Thus, it is essential for force-bearing connective tissues and organs including large blood vessels, tendons, skin and lung, which it provides with elasticity and resilience. The biosynthesis of elastic fibers is referred to as elastogenesis, a complex multi-step process, in which elastin is assembled from its monomeric precursor tropoelastin by covalent cross-linking involving lysine residues. This step requires their oxidative deamination to α-aminoadipic-δ-semialdehyde by lysyl oxidase (LOX) or LOX-like (LOXL) enzymes. Since elastin production dramatically drops in the early neonatal period and the biopolymer is not renewed throughout life, it is subject to degeneration associated with functional losses of the respective tissues. The development of close-to-native elastin-like biomaterials offers promising treatment options for severe pathological conditions. To comprehend the molecular structure behind its properties, we thoroughly investigated the crosslinking pattern of elastin. These findings helped us to develop elastin-like biomaterials based on its precursor by using enzymatic and non-enzymatic methods to induce allysine-mediated cross-linking in vitro.

Experimental Methods

Mature elastin was isolated from human aorta and skin as published by Schmelzer et al. [1]. Multi-enzyme digestion and subsequent HPLC-MS/MS analyses were used to study the cross-linking pattern on a molecular level using an untargeted bottom-up proteomics approach. Tropoelastin-based biomaterials were obtained by incubating recombinant human tropoelastin with lysyl-oxidase like 2 (LOXL2). Due to the limited availability of this enzyme, we further developed and applied an alternative non-enzymatic approach based on pyrroloquinoline quinone (PQQ). The resulting biomaterials were characterized by HPLC-MS/MS and amino acid analysis for cross-linking structures. Atomic force microscopy, scanning electron microscopy and enzymatic degradation assays were applied to study mechanical properties, microstructure and stability, respectively.

Results and Discussion

In human elastin, several bi- and tetrafucntional cross-linked peptides were identified and revealed an overall randomized cross-linking pattern with respect to the involvement of distinct cross-linking sites. This means that across single tropoelastin monomers distinct lysine residues were cross-linked by different cross-linking entities to different other lysine residues or were not cross-linked at all [2].

The cross-linking of recombinant tropoelastin by LOXL2 resulted in a stable elastic polymer with elastin-like mechanical properties. Cross-linking structures identified by mass spectrometry and a decrease of free lysine found by amino acid analysis indicate a successful transformation of lysine to allysine in vitro. Although the material showed elevated resistance against trypsin, the lysine modification rate was only 13% with respect to mature elastin [3]. PQQ, a soluble cofactor of bacterial oxidoreductases, comprises an ortho-quinone structure like the native cofactor of LOX/LOXL enzymes. The incubation of recombinant tropoelastin with PQQ and divalent copper in solution led to
the formation of a stable and trypsin-resistant biomaterial with a lysine modification rate of 56% with respect to mature elastin. The detection of free allysine and α-aminoadipic acid as well as cross-linked peptides indicate a high efficiency of lysine modification. Amino acid analysis and quantification of cross-linking amino acids gave proof to the PQQ-mediated activation of the cross-linking cascade known from mature elastin. The mean elastic modulus of the resulting biomaterial was in the range of 1-2 MPa and thus comparable to mature elastin.

**Conclusion**

PQQ is a well-suited alternative for the oxidative deamination and subsequent cross-linking of lysine residues for the fabrication of elastin-like biomaterials. With recombinant tropoelastin, a stable biomaterial with close-to-native mechanical properties and an elastin-like cross-linking pattern can be achieved. Beyond that, PQQ may also be considered as a promising alternative over toxic agents for the cross-linking of other protein-based biomaterials.

**Acknowledgement**

The work was supported by the Fraunhofer Internal Programs under Grant No. Attract 069-608203. Prof. Markus Pietzsch (Martin Luther University Halle-Wittenberg) is thanked for providing recombinant human tropoelastin. Dr. Laurent Muller (Collège de France) is thanked for providing recombinant human LOXL2. James McConnell (University of Manchester) is thanked for the assistance with atomic force microscopy and nanoindentation of LOXL2 cross-linked tropoelastin.

Amino acid analysis

This figure indicates the reduction of free lysine residues through the action of PQQ in cross-linked tropoelastin (cTE) when compared to untreated tropoelastin (TE). The highest modification rate with respect to mature human aortic elastin (hAE) was found at an incubation temperature of 50 °C.
The Young’s modulus of three cTE specimens and elastin isolated from bovine ligamentum nuchae were analyzed by atomic force microscopy. The mean modulus of cTE is between 1.0-1.9 MPa and therefore comparable to the Young’s modulus of elastin that was determined to be 1.8 ± 0.3 MPa.

Development of a curcumin loaded-NLCs hydrogel system for topical applications

**Rosa Calderon-Jacinto**, Pietro Matricardi, Violeta Rodriguez-Ruiz, Emmanuel Pauthe

1 CY Cergy-Paris University, ERRMECe Laboratory, Biomaterials for Health group, Maison Internationale de la Recherche I MAT, Neuville sur Oise, FR; 2 Sapienza University of Rome, Department of Drug Chemistry and Technologies, Rome, IT

**Introduction**

The balance of prooxidant-antioxidant reactions plays a crucial role in the regulation of skin physiological processes, especially during wound-healing. In standard conditions acute wounds heal in few weeks. However, an uncontrolled oxidative stress may hinder the normal wound-healing process by perpetuating tissue damage. Curcumin is a natural active ingredient known by its capacity to efficiently act at the wound site by controlling the toxicity of radicals and through the activation of cytoprotective signaling pathways in dermal cells, thus contributing to the regeneration of the skin barrier function [1]. However, the efficient topical application of active curcumin at cutaneous tissues is hindered by its low solubility in aqueous systems and the need to avoid its degradation (especially by heat and light) during its formulation.

In this work, Nanostructured Lipid Carriers (NLCs) [2] were developed as an encapsulating drug system aimed to prevent the drawbacks of curcumin stability and to favor its delivery to the skin. This would allow its topical application at the wound site by being incorporated into a dynamic hydrogel matrix.

**Experimental Methods**

NLCs were prepared by the hot homogenization method. Particle size and polydispersity index were determined by Dynamic Light Scattering. Zeta potential was calculated from the electrophoretic mobility obtained from Laser Doppler Micro-electrophoresis.

The amount of loaded curcumin was indirectly and directly determined by HPLC and UV-VIS spectrophotometry. In addition, the antioxidant properties of the formulation were assessed by the ABTS assay. The cytocompatibility of the developed nanocarriers towards human fibroblasts and keratinocytes was studied by the MTT assay and by the Trypan Blue staining method. Moreover, the amount of curcumin released from NLCs was evaluated at different time points after incubation at 37°C in culture media and in PBS.

After the incorporation of the system in a carbopol gel, the flow behaviour of the new composite system was analysed by rheology.

**Results and Discussion**

A stable NLCs formulation composed of negatively charged particles of an average size of about 300 nm was obtained. The curcumin encapsulation efficiency was more than 80% and the preservation of the antioxidant properties during the preparation process was demonstrated.

The viability of dermal cells involved in the wound-healing process was assessed after 24 hours of contact. Curcumin cytotoxicity was decreased while being encapsulated in the NLCs. Developed NLCs were found to be non toxic to fibroblasts and keratinocytes at concentrations below 0.54 mg/mL (containing 10 µM of curcumin) and 1.1 mg/mL (containing 20 µM), respectively. Furthermore, the formulation showed a prolonged curcumin release profile in biological media, reaching a maximum of 75 % in 72 hours.

Finally, NLCs were successfully incorporated into a carbopol hydrogel. Rheological analysis revealed that the mechanical properties of the gel matrix were not disturbed by the addition of NLCs.
Overall, our results show the feasibility of combining a natural compound-loaded NLCs and a hydrogel support into a multiscale platform in order to modify the release of the natural compound.

**Conclusion**

The developed system is highly compatible and promising for a topical application. Most of all, it preserves the antioxidant properties of curcumin and controls its release towards dermal cells. Such behavior has been demonstrated to be a key feature in order to achieve pro wound-healing effects [3]. Currently, the ability to promote cell migration and proliferation in *in-vitro* wound-healing tests is under assessment.

On the development of new composite hydrogels mimicking vocal-fold histological and mechanical features

Daniel Ferri\textsuperscript{4}, Hamid Yousefi-Mashouf\textsuperscript{2,3}, Lucie Bailly\textsuperscript{2}, Laurent Orgéas\textsuperscript{2}, Jerome Sohier\textsuperscript{1}

\textsuperscript{1} CNRS, UMR 5305 - Laboratoire de biologie tissulaire et ingénierie thérapeutique, Lyon, FR; \textsuperscript{2} University Grenoble Alpes, CNRS, Grenoble INP, 3SR, Grenoble, FR; \textsuperscript{3} University Grenoble Alpes, CNRS, Grenoble INP, GIPSA-lab, Grenoble, FR; \textsuperscript{4} CNRS, UMR5510 MATEIS, Villeurbanne, FR

Introduction

Human vocal folds are soft laryngeal structures able to endure very large and reversible deformations (up to 50\% stretching), despite the stresses they are subjected to during voice production. These outstanding properties are related to their multi-layered structure (epithelium, lamina propria and vocalis muscle) and fibrous microstructures\textsuperscript{1}. Vocal folds can accommodate with many traumas, but severe or cancerous lesions require microsurgical intervention that may induce dysfunctional scarring lesions. Few biomaterials have been envisaged to treat vocal folds’ lesions, mainly because their unique mechanical properties are not clearly understood. A way to better comprehend these properties and pave the way to future clinical applications would be to mimic the fibrillar and elastomeric structure of vocal folds. In this respect, a tailorable mimetic hydrogel (poly-lysine dendrimers (DGL) and polyethylene glycol (PEG-NHS)) could be of interest\textsuperscript{2}. Its association with polycaprolactone (PCL) nanofibers could provide composites of modular mechanical and vibratory properties, close to native tissues. Thus, this work aims at (i) characterizing the organization of collagen and elastin of the human vocal folds, and (ii) reproducing it through the design and mechanical evaluation of different nanofibres/hydrogels composites (nFHC) with tuned hydrogel elasticity, nanofibrillar orientation and mono/multi-layered organization, (iii) comparing their mechanical response with those of native human tissues.

Experimental Methods

Microstructural organization of vocal folds excised from donated bodies was assessed with biphotonic microscopy for collagen and elastin fibres (Zeiss® LSM 780). PCL nanofibres of adjustable orientations (iso- and anisotropic) were processed using a jet-spraying method\textsuperscript{3}. Diameter distribution and orientation of collagen, elastin and PCL fibres (SEM FEI quanta) were analysed using Fiji®. Hydrogels of varying mechanical properties were obtained by mixing DGL (Colcom®) and PEG-NHS aqueous solutions of various concentrations, PEG molecular weights (2 k, 10 k or 40 kDa) and geometry. Different nFHC were prepared by percolation of hydrogel solutions through the nanofibers. Swelling of hydrogels and composites was measured over 48 h. Their mechanical properties were characterized in cyclic tension upon finite strains (BOSE® EF3200). Similar experiments carried out previously with Human vocal folds were used as reference data\textsuperscript{4}.

Results and Discussion

The microstructural analysis of human vocal folds revealed specific organizations of collagen and elastin fibres in the different anatomical layers. Epithelium was devoid of either, few were present in the muscle layer while the lamina propria was rich in both. Within the latter, both elastin and collagen wavy fibers were arranged in an entangled network of antero-posterior orientation, showing density gradients from superficial to deep layers (Fig 1A). Collagen fibers were thicker than elastin ones.

PCL nanofibers in the processed mats were of orientations and diameters similar to collagen and elastin fibers (Fig 1B). Thanks to the very high porosity of nanofibrillar networks (more than 96\%), nanofibers could be impregnated in a continuous DGL/PEG hydrogels matrix to create composites. (Fig 2A). Nanofibers incorporation reduced their swelling, revealing a coherent integration and the effect of stronger PCL fibres on composite properties (Fig 2B).
Mechanically, DGL/PEG hydrogels showed a quasi-linear reversible behavior with negligible residual strains and hysteresis (Fig 2C). Increasing the PEG/DGL ratio augmented elastic modulus (10 to 75kPa in PEG2k at 5% strain), while increase of $\text{PEG}_{\text{MW}}$ resulted in improved elongation at break (from 35% to <90%). Incorporating PCL nanofibers into the hydrogels systematically yielded to non-linear stress-strain responses characterized by a J-shape strain hardening, due to the progressive recruitment and/or reorientation of nanofibers during tension. A typical stress hysteresis was also observed with residual strains during unloading, potentially due to nanofiber rearrangements and plastic deformation. Therefore, through initial fiber orientation and hydrogel composition, it was possible to modulate the composites mechanical properties in terms of stress levels (up to 120 kPa at 10% peak strain), tangent moduli (up to 3 MPa), residual strains (up to 3.5%) and dissipated energy (up to 0.2 J/m$^3$). This parametric adjustability of the nFHC allowed us to conform with the corridor of human vocal folds mechanical properties (Fig 2C), indicating the potential of our approach.

**Conclusion**

Through the design of nFHC, it was possible to provide simple, efficient and highly versatile tools to mimic the structure and mechanical properties of human vocal folds, in view of modelling and better understanding their unique mechano-biological properties. Future work focuses on resulting vibro-mechanical properties of the composites.

Development of 3D-printed hydrogel scaffolds for liver tissue engineering

Nathan Carpentier¹, Lana Van Damme¹, Louis Van der Meeren², Andre Skirtach², Lindsey Devisscher³, Hans Van Vlierberghe⁴, Peter Dubruel¹, Sandra Van Vlierberghe¹

¹ Ghent University, Polymer Chemistry & Biomaterials Group, Centre of Macromolecular Chemistry, Ghent, BE; ² Ghent University, Nano-biotechnology Laboratory, Department of Biotechnology, Faculty of Bioscience Engineering, Ghent, BE; ³ Ghent University, Gut-Liver Immunopharmacology Unit, Dpt Basic and Applied Medical Sciences, Liver Research Center Ghent, Ghent, BE; ⁴ Ghent University, Hepatology Research Unit, Dpt Internal Medicine and Paediatrics, Liver Research Center Ghent, Ghent, BE

Introduction

Annually, millions of people die because of liver failure, while the waiting duration for a donor liver is around 12 months.[1] Herein, we target hybrid indirect 3D-printed scaffolds to serve liver tissue engineering (LTE) applications. The starting materials gelatin and dextran were selected as mimics for the liver extracellular matrix (ECM) and crosslinked using two different chemical crosslinking approaches to explore their effect on the cell response. Methacrylated gelatin (GelMA) served as benchmark. The hydrogel materials were characterized on 2D- as well as on 3D-level.

HepG2 cells were used to assess the in vitro biocompatibility of the developed hydrogels.

Experimental Methods

Thiolated gelatin (GelSH)[2] was combined with norbornene-functionalized dextran (DexNB) followed by a radical step-growth thiol-NB crosslinking. In parallel, oxidized dextran with a degree of oxidation of 80 (Dexox80) and gelatin were crosslinked using a Schiff-base mechanism.

Both materials were characterized on 2D-level to assess the physico-chemical properties such as the swelling, gel fraction and mechanical properties. HepG2 cells were seeded onto 2D-disks to perform an in vitro biocompatibility study based on the metabolic activity using an MTS assay.

3D-hydrogel scaffolds of both materials were developed by indirect 3D-printing[3]. These scaffolds were characterized assessing their gel fraction, swelling ratio, compressive modulus and in vitro biocompatibility. The biocompatibility was assessed using HepG2 cells seeded onto these 3D-scaffolds and an MTS assay and live-dead staining using a fluorescence microscope were performed.

Results and Discussion

On a 2D-level, GelMA and DexNB-GelISH were superior over Dexox80-gel as their crosslinking kinetics were significantly faster and they mimicked natural liver tissue (NLT) to a greater extent with respect to swelling and mechanical properties. The swelling ratio of GelMA and DexNB-GelISH were respectively 9.1 ± 0.5 and 9.6 ± 0.5, which is in line with the swelling of NLT (i.e. 10)[4]. The swelling of Dexox80-gel was significantly higher (16.6 ± 0.9).

Atomic Force Microscopy (AFM) measurements revealed superior microscale mechanical properties of the DexNB-GelISH hydrogel sheets compared to the other materials. DexNB-GelISH exhibited a stiffness of (196 ± 24) kPa, dexox80-gel of (6 ± 5) kPa and GelMA of (291 ± 11) kPa. Healthy NLT exhibits an average surface stiffness of (183 ± 48) kPa. The higher the stiffness, the more the material mimics the ECM of unhealthy cirrhotic liver ((411 ± 63) kPa)[5].

Because of the inferior physico-chemical properties, dexox80-gel was not taken further beyond the 2D-level.

On a 3D-level, DexNB-GelISH scaffolds exhibited a compressive modulus of (4.8 ± 1.6) kPa which is in excellent agreement with that of NLT (i.e. 1 – 5kPa)[7] as compared to GelMA which resulted in a modulus of (8.5 ± 1.9) kPa.
However, the *in vitro* biocompatibility of both materials was comparable based on the MTS assay. The live-dead staining showed that the cells grew more into clusters on the DexNB-GelSH scaffolds compared to the more spread morphology which the cells exhibited on the GelMA material.

**Conclusion**

DexNB-GelSH scaffolds are promising hybrid materials to support LTE as they exhibit similar physico-chemical properties compared to NLT (cfr. microscale stiffness, compressive modulus and swelling ratio), while cell viability and proliferation of the hepatocytes were preserved. Further analyses evaluating the preservation of cell functionality using PCR are ongoing.

In future research, different coating compounds such as laminin and fibronectin will be applied to the scaffolds in order to investigate the effect on cell interactivity. Furthermore, the influence of replacing dextran with the more cell-interactive glycosaminoglycan chondroitin sulfate will be investigated.

Introduction
Adoptive cellular therapy (ACT), a type of personalized cancer immunotherapy, is achieving long-term remissions in late-stage and refractory cancers, especially in haematological malignancies and melanoma.[1, 2] Nevertheless, there are still several limitations, such as producing the large amounts of therapeutic T cells needed for these therapies in a short period of time and in an economically viable manner, which would then persist in the human body. Previously, we presented three-dimensional (3D) poly(ethylene) glycol (PEG) hydrogels covalently combined with heparin to resemble the lymph nodes,[3] as the current expansion systems do not mimic them. In these hydrogels, PEG provided the needed structural and mechanical properties to imitate the lymphatic tissue, whereas heparin was used as an anchor for the cytokine CCL21, which is present in the lymph nodes, and can affect cell migration and proliferation. The 3D structure of the hydrogel in combination with its loading capacity resulted in an increased primary human CD4+ T cell proliferation compared to the state-of-the-art expansion systems consisting of using artificial antigen presenting cells in suspension, i.e. without the presence of a 3D scaffold. Here, we introduce novel 3D printed hydrogels with the objective to improve 3D cell cultures.[4]

Experimental Methods
Hydrogels of previously functionalized heparin with maleimide and thiolated4-arm PEG were printed with a 3D bioprinter Regenhu 3D-Discovery (RegenHu, Switzerland). Then, the 3D printed hydrogels were loaded with a cytokine cocktail and used to culture primary human CD4+ T cells of healthy adult donors. Cell proliferation and differentiation were studied by CFSE stainings and anti-CD45RO/CD62L expression, respectively, through flow cytometry.

Results and Discussion
Initially, the printing process was optimized to demonstrate the capacity of the hydrogels, consisting of covalently linked PEG and heparin to be used as ink material. Thus, we fabricated 3D printed constructs of a few layers (Figure 1), and evaluated them as 3D scaffolds for T cell culturing. Firstly, T cell proliferation was evaluated in cultures of unloaded 3D printed hydrogels with different layers of biomaterial, showing that all of them promoted higher proliferation rates than the standard cell culture suspensions. Moreover, we observed that the higher the layer number of the printed hydrogels, the higher the proliferation achieved. In addition, T cell differentiation was analysed, and we observed that the 3D printed hydrogels promoted phenotypes associated with better clinical outcomes when using T cells to treat certain malignancies through ACT.[5] Additionally, the hydrogels with the highest number of layers were loaded with a cytokine cocktail, which is known to promote T cell homing and proliferation. In this case, the highest proliferation rates were obtained in the cultures that included immobilized cytokines on the 3D printed hydrogels.

Conclusion
We present a new bioink consisting of PEG and heparin covalently linked, that is suitable to produce 3D hydrogels for cell culture. In this case, we observed higher T cell proliferation rates with the 3D printed hydrogels compared to the state-of-the-art culturing conditions in suspension. These results were further improved by the addition of a
cytokine cocktail. Additionally, the 3D printed hydrogels promoted T cell phenotypes that are desirable for ACT in the clinics.

Cartilage Tissue Engineering using Bioinspired Growth Factor Immobilization on Microfiber Scaffolds

Madison J. Ainsworth¹, Oliver Lotz²,³, Aaron Gilmour²,³, Mattie van Rijen¹, David R. McKenzie³, Marcela M.M. Bilek²,³, Jos Malda¹,⁴, Behnam Akhavan²,³, Miguel Castilho¹,⁵

Introduction

Osteoarthritis is one of the most common chronic diseases globally, with 10% and 13% of men and women affected, respectively [1]. Currently, there is no mechanically competent, biologically functional treatment for the end-stage cartilage degeneration it causes. In this study, we hypothesize that the fabrication of well-organized microfiber reinforcing scaffolds [2] with locally, covalently immobilized growth factors could support and guide the formation of new cartilaginous tissue. The addition of such biomolecular cues, particularly transforming growth factor beta 1 (TGFβ1), are crucial for the differentiation and maintenance of cartilage tissue [3]. To create a complex mechanical structure with the necessary biomolecular cues, we combined melt electrowriting (MEW) and atmospheric-pressure plasma jet (APPJ) treatment to produce well-organized microfiber scaffolds with selectively, covalently-immobilized TGFβ1.

Experimental Methods

Poly-ε-caprolactone melt electrowritten scaffolds were fabricated using a 3DDiscovey printer (regenHU), then functionalized using a computer-controlled APPJ device (4.5 kV discharge voltage, 1.9 L/min feed gas flow, 60 mm/s, 5 mm spaced-parallel line trajectory) [4], generating a controlled functionalization pattern (Figure 1i). TGFβ1 was then immobilized onto the MEW scaffolds using submersion in solution (0.01-2 µg/mL TGFβ1 in PBS, 24 hrs, 4°C). Detergent (Tween20/sodium dodecyl sulfate (SDS)) washing steps were undertaken to remove non-covalently bound protein molecules. Characterization of protein immobilization was performed using attenuated total reflection Fourier-transform Infrared (ATR-FTIR) spectroscopy and immunofluorescence detection. In vitro experiments were performed by seeding equine mesenchymal stromal cells (MSCs) (~16x10⁶ cells/mL) into the MEW scaffolds and were cultured for 28 days (Figure 1i). The culture groups consisted of (i) plasma-treated-scaffolds w/ immobilized TGFβ1, (ii) plasma-treated-scaffolds w/o TGFβ1, (iii) untreated-scaffolds w/ TGFβ1 in the culture medium, and (iv) untreated-scaffolds in basal medium. Neo-cartilage formation was quantified with dimethyl methylene blue/picogreen assays for glycosaminoglycan (GAG) production and confirmed with histological analysis.

Results and Discussion

Covalent immobilization of TGFβ1 was achieved using the APPJ-functionalization approach [4]. ATR-FTIR results confirmed a protein signature on the samples following intensive 5% SDS washing and immunofluorescently-labelled TGFβ1 was detected in microfiber scaffolds (following 0.1% Tween20 washing). In vitro analysis demonstrated that GAG production (DNA-normalized) was significantly enhanced in both the immobilized TGFβ1 (i) and TGFβ1 in medium groups (iii), compared to the control groups (ii & iv). This finding was further validated by the heightened production of GAGs and collagen type II, observed in histological sections (Figure 1ii). Additionally, this increase in matrix production was seen to become more pronounced as the concentration of immobilized TGFβ1 increased.

Conclusion
We have demonstrated that APPJ-facilitated covalent immobilization of TGFβ1 retains the growth factor's bioactivity and allows for cellular interactions that stimulate the differentiation of MSCs into the chondrogenic lineage. Our results also demonstrate that the new constructs with locally-immobilized TGFβ1 are able to support neo-cartilage formation. Furthermore, integrating MEW and plasma functionalization within a single printing platform will allow for functionalization during the MEW of microfiber scaffolds for gradient and patterned protein guidance for neo-cartilage formation.

Bridging the gap between the mechanical and metabolic activity in MSCs differentiation

Ana San Felix¹, Sara Trujillo², Matthew Dalby¹, Manuel Salmeron-Sanchez¹

¹ University of Glasgow, Glasgow, GB; ² Polytechnic University of Valencia, Centre for Biomaterials and Tissue Engineering, Valencia, ES

Introduction
Cells are in constant communication with their surroundings. Any stimulus coming from the extracellular matrix (ECM) is sensed by cells, having a direct impact in cell mechanical and metabolic activity [1]. This close relation between cells and the ECM is established by focal adhesions (FAs) through which cells sense the environment, exert forces, pull to deform the matrix and transmit these forces through the cytoskeleton[2]. We hypothesise that to create an adaptive response to ECM signals, cells undergo mechanical and metabolomic changes that lead to specific cell differentiation and traction force exertion [3]. This work aims to understand how cells test the environment from a mechanobiological perspective during their attachment, proliferation, migration and differentiation. This will provide a better understanding on how microenvironmental cues can be used to control cell fate, enhancing studies in multiple fields e.g. tissue regeneration.

Experimental Methods
The proposed system consists on a 2D full-length fibronectin (FN)-based polyethylene glycol (PEG) hydrogels model developed in our group [4]. This system allows to have full control of gel stiffness, varying the amount of PEG, and degradability, by adding protease-sensitive crosslinkers. For optimisation of the system, we used murine L929 fibroblast cultured for 24 hours. Then we started using mesenchymal stem cells (MSCs). To study the forces exerted by the cells we used traction force microscopy (TFM). In this technique the displacement of fluorescent microspheres embedded in the gels is tracked during cell attachment (fig.1 A-B). Using a plug-in of ImageJ these displacements were used to reconstruct the forces exerted (fig.1C) [5]. By adding a myosin II inhibitor (blebbistatin) we studied the implication of cytoskeletal tension in force generation. At the same time, we are using metabolomics to investigate cells metabolic activity during force exertion.

Results and Discussion
After 24 hours, cells pull more on degradable hydrogels compared to non-degradable ones when maintaining same bulk stiffness (8.1 kPa) (fig.2A). When we looked at force exertion on degradable gels with different stiffnesses (2.6 kPa, 8.1 kPa) for 24 hours, cells exerted higher forces on stiffer gels (8.1 kPa) (fig.2B). Also, cells spread more on stiffer surfaces compared with softer ones (fig. 2D). In all cases, when blebbistatin was added to the system, cells were unable to reach the same force magnitude as the control with no treatment (fig.2A-B). However, cells were still able to pull more on degradable gels compared with non-degradable ones (fig.2A). It was interesting to see that after 24 hours, YAP nuclear translocation was increased on stiffer surfaces (25. 7 kPa), even when myosin II was inhibited (fig.2C), what suggests that YAP might not be sensitive to blebbistatin. The metabolic profiles studied have shown different cell metabolic activity after 24 hours and 7 days on degradable gels with different stiffnesses (fig.2E). Cells showed higher metabolic activity in terms of metabolites production after 24 hours compared with time 0 and day 7, where similar metabolic activity was found. Within these first 24 hours, more metabolites were found on stiffer hydrogel. This pattern is not shown after 7 days, where higher metabolic activity was shown on softer surfaces (2.5 kPa).

Conclusion
Matrix degradability and stiffnesses have shown to have an effect in cell response. A direct evidence is through morphological changes, which indicate that further adaptive response might be taking place inside the cell. Furthermore, actin cytoskeleton contraction has great importance in force loading, as it has been shown after blebbistatin addition. Based on these results we can conclude that changes in the biophysical properties of the matrix alter how cells sense their surroundings and hence, their mechanobiological response and fate. Even though these results are promising, further studies need to be carried out to completely fulfill this gap in understanding how cell mechanics are linked to metabolic activity.

Synergizing topographical and chemical cues to control mesenchymal stem cell adhesion, migration and differentiation on biomaterials

Joaquim Minguela, Luís Llanes, Maria Pau Ginebra, Joan Josep Roa, Carles Mas-Moruno

Technical University of Catalonia, Barcelona, ES

Introduction
Topographical and biochemical surface modifications stand out as powerful strategies to direct cell behavior and improve the bioactivity of biomaterials, aiming at achieving better levels of tissue integration [1]. However, the combination of both approaches has rarely been investigated.

Thus, in this communication we report for the first time the combination of micro-patterning and chemical functionalization on the surface of yttria-stabilized tetragonal zirconia polycrystal (Y-TZP), a biomaterial widely used in dentistry, to explore potential synergisms between topographical and biochemical cues and their effects on fine-tuning cell behavior.

In detail, Y-TZP surfaces were treated with ultrashort pulsed direct laser interference patterning (DLIP) with a femtosecond laser to produce linear micro-patterns. Laser patterned surfaces were further functionalized with a novel hybrid peptide containing cell adhesive and osteogenic potential [2].

Experimental Methods
DLIP with a femtosecond Ti:Sapphire laser was employed to produce two periodic grooved patterns with a periodicity of 3 and 10 μm. A platform containing the cell-adhesive RGD and the osteogenic DWIVA peptides was synthesized using standard solid-phase peptide synthesis (SPPS) methods [2] and used to functionalize the grooved surfaces. Topography and surface damage were characterized by confocal laser scanning (CLSM), scanning electron and scanning transmission electron microscopy techniques. Accelerated tests in water steam were carried out to assess hydrothermal degradation resistance. The attachment of the molecule was analyzed through fluorescence CLSM and X-ray photoelectron spectroscopy. Finally, the biological properties of the surfaces were studied with human mesenchymal stem cells (MSCs) evaluating cell adhesion, morphology, migration and differentiation.

Results and Discussion
A dual approach employing peptidic biofunctionalization and laser micro-patterns on dental zirconia was explored, with the aim of providing a flexible tool to improve tissue integration of restorations.

DLIP produced two periodic grooved patterns with a periodicity of 3 and 10 μm. The surface patterns exhibited a high homogeneity and subsurface damage was found in the form of nano-cracks and nano-pores, at the bottom of the valleys. Accelerated tests in water steam showed a slight decrease in hydrothermal degradation resistance; however, the detrimental effects of the laser modification were reverted by a post-laser thermal treatment. The attachment of the molecule was achieved via chemisorption using two units of L-3,4-dihydroxyphenylalanine (L-DOPA) as anchoring units and verified through fluorescence CLSM and X-ray photoelectron spectroscopy, which indicated a higher attachment of the molecules on the micro-patterned surfaces.

MSCs on grooved surfaces displayed an elongated morphology and aligned along the patterns (Figure 1). On these surfaces, migration was greatly enhanced along the grooves, but also highly restricted in the perpendicular direction as compared to flat specimens. After biofunctionalization, cell number and cell area increased and well-developed cell cytoskeletons were observed. However, no effects on cell migration were found for the peptidic platform. Although some osteogenic potential was found in specimens grooved with a periodicity of 10 μm, the largest effects were observed from the biomolecule, which favored upregulation of several genes related to osteoblastic differentiation in all the surfaces.

Page 456 of 2028
Conclusion

In order to improve the tissue integration potential of zirconia surfaces, this work explored the combination of topographical and biochemical modifications. USP-DLIP was successful at producing defined micro-patterns on the surface of zirconia at a low cost in terms of surface damage. The patterns were combined with a dual RGD/DWIVA peptidic platform. Thanks to the L-DOPA anchoring molecule, the peptide-based platform successfully attached to the surface of zirconia in a single step process, avoiding the use of toxic solvents. The effects derived from the two surface modifications could be combined. Notably, the presence of the peptidic platform did not mask the effects derived from topography. While the grooves were mainly associated with contact guidance (cell alignment, elongation and migration) the peptidic platform improved cell adhesion (cell number and spreading) and introduced a certain osteogenic potential to the surface. The combination of surface topographical features obtained by laser patterning and biofunctionalization with organic molecules provides thus a flexible tool to improve MSC functions on Y-TZP surfaces.

Substrate-driven dynamics and biocues inducing the formation of human bone marrow mesenchymal stem cells spheroids

Valeria Perugini¹, Cheryl Collins¹, Sophia Khan², Matteo Santin¹

¹ University of Brighton, Centre for Regenerative Medicine and Devices/School of Applied Sciences, Brighton, GB;² Tissue Click Ltd, Brighton, GB

Introduction
In vivo, mesenchymal stem cells (MSCs) reside in what is known as the stem cell niche. They are preserved in this microenvironment in an undifferentiated state and prone to migrate towards tissues in response to signals such as growth factors and cytokines thus contributing to their remodelling or healing. It is recognised that the niche preserves the long-term maintenance of the MSC phenotype through the niche basement membrane and through cell-to-cell interactions [1]. However, the pathways of niche formation and MSC migration are not fully understood and it is worth suggesting that unveiling the interactions between the stem cell niche components and MSCs would be the first step towards the controlled handling of MSC in vitro as well as towards the development of suitable carriers for their transplantation.

Previous research has demonstrated the ability of PhenoDrive, a novel synthetic substrate mimicking the main features of the basement membrane, to induce the formation of human bone marrow MSC spheroidal structures similar to those observed in the MSC niche in vivo [2, 3].

The present study unveils, for the first time, the dynamics and biocues driving the migration of human bone marrow MSCs during the process of spheroid formation when cultivated on this basement membrane-mimicking substrate.

Experimental Methods
Phenodrive-Y (Tissue Click Ltd, UK) was used for the coating of tissue culture plates by reconstituting its powder in 75% ethanol at a concentration of 0.1mg/mL. The solution (200µL) was added to the wells of 24-well plates and left to cast in a sterile tissue culture hood overnight.

Frozen human bone marrow MSCs (Lonza), isolated from 2 donors (age: 19 and 24, gender: female and male), were resuspended in 1mL StemPro MSC SFM. Cells were drop-seeded at 4x10⁴/mL, at 37°C, 5% CO₂ and 90% humidity for 30 minutes to allow their adhesion to the substrates. Medium (1mL) was added to each well and MSC were monitored by time-lapse microscopy (Cytosmart, NL) to assess their migration patterns over 3 days with snapshots taken at an interval of 5 minutes. Each well was washed with 3x1mL Phosphate buffer saline (Sigma-Aldrich, UK). 1mL of 3.7% formaldehyde (Sigma-Aldrich,UK) was then added to each well for fixing and left in each well for 15 minutes at room temperature and washed with 3x3mL PBS (Fisher Scientific, UK). MSCs were stained for Integrin beta 1 and DAPI, by the addition of secondary Ab Alexa Fluora 488 and Alexa Fluora 555 (Fisher Scientific, UK). Cells were imaged using Leica SP5 confocal microscope at 20x with an additional 5x or 3x zoom on the control panel. Tissue culture plastic was used as control.

Results and Discussion
Time-lapse microscopy over 3 days showed the migration of MSC to form spheroids. These structures appeared to be in a constant phase of remodelling characterised by single cells joining a spheroid or leaving it to reach an adjacent one or bridging the merging of two spheroids into larger structures (Figures 1 a and b). This process appeared to be driven by a track-and-trace system led by fragments of cell membrane left deposited on to the substrate (Figure 2). These fragments were exploited by the migrating cells as well as by merging spheroids as adhesion cues through the anchoring of their philopodia (Figures 1 a and b, circles; Figure 2 black arrows). At the same time, the migrating cells showed an induced formation of extracellular vesicles by blebbing (Figure 2a, white arrow). These bi-rifrangent
structures were also found on the surface of PhenoDrive and in contact with the philopodia (Figures 2 a and be, black arrows). Immunostaining demonstrated the presence of integrins preferentially at the periphery of the spheroids and structured as clusters at the extremities of philopodia. Likewise, the released membrane vesicles appeared to be positive to integrin immunostaining confirming their plasmalemma origin and suggesting the hypothesis that they can enable the anchorage of these extracellular vesicles onto the substrate (data not shown). This dynamic process was gradually reduced with time as the spheroids became more established and distant from each other.

MSCs seeded on control tissue culture plastic formed typical fibroblast-like colony units where no significant migration process was observed (data not shown).

**Conclusion**

The data of this study show that the biomimetic substrate PhenoDrive, presenting both a nano-topography and bioligands similar to those of the stem cell niche basement membrane, is able to activate a process of migration of MSC through a track-and-trace system based on plasmalemma blebbing that leads to the formation of 3D cellular structures similar to those observed in the MSC niche in vivo. The unveiling of such pathways of morphogenesis also paves the way towards a controlled handling of MSC in vitro as well as towards the development of carriers for their transplantation in clinics.

**Introduction**

Magnesium (Mg) is the fourth most abundant element in the human body with important functions in mineral metabolism and osteoblast/osteoclast regulation. For bone substitution, titanium (Ti) is the most widely used material; however, its surface is relatively bioinert. Bioactive degradable coatings present an interesting possibility when added to Ti surfaces to stimulate early regeneration processes. In this way, coatings produced by the sol-gel technique allow the obtainment of materials with controlled release of biomolecules or ions with different biological functions already known. When applied to biomaterials, Mg ion can increase cell adhesion, reduce inflammation, and increase the osteogenic response. Upon implementation, protein adsorption is the first phenomenon to occur. This is dependent on several factors, such as material surface proprieties (e.g. ion incorporation), and it will affect the following biological response. Considering this, the purpose of this study was to develop Mg-doped coatings to be applied on Ti surfaces, characterize the protein layer formed upon exposure to human serum and correlate it with *in vitro* cell responses. The results showed a higher absorption of proteins related to cell adhesion, inflammatory regulation, and bone regeneration on the Mg coatings. It was possible to establish a correlation with *in vitro* results that showed an anti-inflammatory potential as well as an increment in the osteogenic potential and cell adhesion.

**Experimental Methods**

The coatings were obtained employing the sol-gel route using the precursors MTMOS and TEOS (molar ratio of 7:3) and increasing MgCl₂ concentrations (0, 0.5, 1, and 1.5%). The sol-gels were applied to grade 4-Ti substrates (10 mm diameter, 1-mm thick) by dip-coating. The materials were characterized with FT-IR, ²⁹Si-NMR, XRD, and SEM.

The coating degradation was studied by mass loss and the amount of Mg²⁺ released was measured by ICP. Cell adhesion, ALP activity, and gene expression (ALP, TGF-β, OSX, RUNX2, ITGA5, and ITGB1) were measured in MC3T3-E1 osteoblastic cells to evaluate the osteogenic potential. Gene expression (IL-6, TNF-α, TGF-β, and IL-4) and ELISA (TNF-α and TGF-β) to RAW264.7 macrophages were used to understand the inflammatory potential. Surface protein adsorption was evaluated after incubation with human serum for 3h and characterize by nLC-MS/MS.

**Results and Discussion**

The materials were successfully synthesized and the incorporation of Mg did not affect the crosslinking of the sol-gel network and MgCl₂ did not precipitate and formed crystalline structures, indicating that Mg ions are trapped through hydrogen bonding, Van der Waals, or electrostatic forces. However, the material did not present adverse effects on the cells. A controlled release of Mg was observed and as more MgCl₂ was incorporated into the sol-gel network, more the coating degraded, and more Mg²⁺ was liberated. The Mg-doped coatings preferentially adsorbed proteins related to inflammatory responses, cell adhesion, tissue regeneration, and coagulation. In what concerns the inflammatory responses, the reduction in TNF α secretion and the increase in TGF-β and IL-4 gene expression indicates the materials the anti-inflammatory potential of the materials. This was consistent with the increased adsorption of immune-system regulatory proteins (CLUS, CFAH, IC1, and VNTC). Moreover, the Mg-doped materials
showed an increased affinity to the proteins related to cell adhesion (DESP, FILA2, and DSG1) and VTNC, which is correlated with the increment in cell surface area and rearrangement of the cytoskeleton arrangement, and gene expression of integrins (ITGA5 and ITGB1). For osteogenic responses, ALP activity as well as TGF-β, OSX, and RUNX2 gene expression were augmented in Mg-doped materials. Additionally, the preferential adsorption of proteins related to tissue regeneration (CYTA and VTNC) indicates the regenerative potential of these materials. These results allow us to hypothesize that the effects observed on the materials with Mg can not only be dependent on the ion itself as well as in the proteins adsorbed onto the surface.

**Conclusion**
The overall results obtained show that the Mg-doped coatings present anti-inflammatory properties as well as increased cell adhesion and osteogenic responses. It was possible to establish a correlation between the proteins adsorbed onto the materials with the *in vitro* cell responses. The Mg-doped coatings adsorbed more proteins related to inflammatory response regulation, cell adhesion, and tissue regeneration, while decreased the cell inflammatory response and promoted osteogenesis and cell adhesion. Further studies are needed to better understand the way the adsorbed proteins affect well-known responses of materials with Mg.

Active biomaterials for the ex-vivo expansion of Hematopoietic Stem Cells: from biointerfaces to functionalised hydrogels

Michaela Petaroudi, Aleixandre Rodrigo-Navarro, Matthew J. Dalby, Manuel Salmeron-Sanchez

University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB

Introduction
Hematopoietic Stem Cells (HSCs) constitute a rare cellular population residing in the bone marrow (BM) and have recently gained traction in research due to their significant clinical potential. These multipotent, self-renewing cells have the unique capacity to regenerate the whole hematopoietic system in the event of hematological disorders. This particular property has placed HSCs in the spotlight of experimental hematology, making ex-vivo HSC expansion a significant challenge for the research community. Such an achievement would produce clinically relevant numbers from a small sample of cells that could be used for BM transplantation and other clinical applications. Inspired by the huge clinical significance of HSC transplants, we aim to develop a synthetic platform to support their ex-vivo expansion. To achieve this, our system is designed to mimic both the Mesenchymal Stem Cell (MSC) and HSC compartments of the BM by providing the soluble and mechanical cues to maintain MSCs in a naïve state in long term cultures and support HSC expansion ex-vivo. Our system is based on a biointerface between human MSCs, HSCs, the non-pathogenic genetically engineered bacterial species Lactococcus lactis (L. lactis)¹ NZ9020, and synthetic polyethylene glycol (PEG) hydrogels that can be used in different setups as shown in figure 1. This platform mimics the chemical and mechanical properties of the bone marrow by providing both stem cell types with soluble and adhesion recombinant proteins produced by the bacteria, and structural support presented by the hydrogels. We report a notable HSC expansion in co-cultures with the biofilms and inside the hydrogels. We also show that the biofilms can retain the MSCs in a stem-like, BM-resembling state. Our final goal is to encapsulate the HSCs in the hydrogels and culture them in contact with the biofilm and MSCs to provide a close bone marrow analogue.

Experimental Methods
We genetically engineered non-pathogenic bacterial biofilms (Lactococcus lactis)¹, to produce key human BM niche factors (CXCL12, TPO, VCAM1, and the FN fragment III7−10)². Bacterial engineering was conducted using PCR and Gibson Assembly and was based on the pT2NX plasmid. We also fabricated synthetic PEG hydrogels, crosslinked with Laminin and Fibronectin to mimic the mechanical and architectural properties of the BM. MSCs and HSCs were cultured directly on the biofilms or in hydrogels for phenotype studies. MSC phenotype evaluation was conducted after 14 days of culture on the biofilms and was assessed by staining for Nestin, Stro1, ALCAM, Osteopontin, and Osterix using In Cell Western analysis. The expanded HSC population was measured after 5 days of co-cultures with the bacteria and was compared to the initially seeded number of HSCs, using the HSC markers CD34, CD38 and CD90, by flow cytometry analysis.

Results and Discussion
Our co-cultures of the biointerface and MSCs and HSCs with and without the presence of hydrogels showed no negative effect of the biofilm on either stem cell viability. Our data shows that MSCs cultured on different biofilms retain a naive, BM-resembling phenotype after 14 days of culture with and without the use of hydrogels. At the same time, we show no MSC commitment towards osteogenic differentiation, suggesting that our platform can be used to maintain MSCs in a stem-like state in long-term cultures. Furthermore, our HSC population analysis suggests that the L. lactis-CD34+ cell co-culture system supports HSC phenotype maintenance and can achieve up to 19-fold HSC expansion in 2D experiments compared to Day 0. Finally, we show that the biophysical properties of the hydrogels

Page 462 of 2028
can be tuned to maintain and encourage HSC proliferation. Combined, these results suggest that the bacteria can maintain MSCs in a BM-like state, while also providing HSCs with the necessary signals for their maintenance and expansion. Additionally, the hydrogels are shown to contribute to HSC maintenance. Together, these platforms could be combined to create a representative BM analogue, with bacteria and MSCs supporting HSC maintenance and proliferation, and the hydrogels adding mechanical support. To our knowledge, this is the first attempt to combine a living biointerface and mechanical support provided by hydrogels for BM and HSC niche engineering.

**Conclusion**

Our data suggest that this novel system has a promising potential to control MSC behaviour and induce HSC expansion *ex-vivo*. The tunable growth factor-producing biointerface, MSC layer and hydrogels can be tailored to produce a close analogue of the BM and more accurately mimic the native conditions that support HSC maintenance and expansion.

**Acknowledgement**

This research was supported by UKRI. The authors would like to thank Dr. Oana Dobre for her invaluable contribution to sharing her expertise on the fabrication of the hydrogels used in this work.

**Figure 1.** Overview of the system and the various platforms we can create for different applications. *L. lactis* NZ9002 biofilms have been engineered to produce recombinant CXCL12, TPO, VCAM1 and FN. Human MSCs and HSCs can be seeded on top of the biofilm in order to study changes or maintenance of their phenotype. We aim to closely mimic the BM conditions by encapsulating the HSCs in hydrogels and ultimately add an MSC feeder layer to create a representative BM analogue that presents the appropriate biochemical and mechanical stimuli in order to induce HSC maintenance and expansion.

Engineering ligand mobility in the adhesive crosstalk to control stem cell differentiation

Eva Barcelona-Estaje¹, Matthew J. Dalby¹, Pere Roca-Cusachs², Marco Cantini¹, Manuel Salmeron-Sanchez¹

¹ University of Glasgow, Glasgow, GB; ² Institute for Bioengineering of Catalonia, Barcelona, ES

Introduction

Cell behaviour is influenced by mechanochemical signals, which are largely mediated by interactions with the extracellular matrix (ECM) via integrins, and by interactions between cells through cadherins. Both of these receptors are in contact with the actin cytoskeleton and act as mechanosensors; they also share multiple signalling pathways that ultimately regulate the so called ‘adhesive crosstalk’ and cell fate (1, 2). Due to the mechanosensitivity of these molecules, cells sense the mechanical properties of their surroundings, responding not only to the elasticity of the substrate, but also to its viscosity. Indeed, while viscous interactions have been traditionally ignored, we previously demonstrated that cells actually sense viscosity using the same integrin-mediated mechanotransductive mechanism that they use to sense stiffness (3).

In this work, we address the role of surface viscosity in stem cell fate and, in particular, how it affects the adhesive crosstalk between integrins (RGD receptors) and cadherins (HAVDI-containing proteins) to elucidate stem cell mechanosensing of viscosity. To do this, we use supported lipid bilayers (SLBs) with varying ligand mobility, functionalised with RGD and HAVDI peptides (Figure 1A).

Experimental Methods

Supported lipid bilayers (SLBs) with varying viscosities (Figure 1a) were prepared by following the vesicle fusion method using either DOPC, which presents a more mobile fluid phase in cell culture conditions, or DPPC, which forms a more viscous gel phase bilayer. Functionalised glass was used as a non-mobile control surface. All the surfaces were functionalised with different ratios of RGD and HAVDI.

Human mesenchymal stem cells (hMSCs) were then seeded on these surfaces and parameters such as cell adhesion, protein translocation or expression of transcription factors were investigated via AFM, immunostaining and in-cell western.

Results and Discussion

When SLBs are functionalized with RGD, an increase in cell area and cell adhesion, in particular the strength of detachment of MSCs to the bilayer, are observed with higher viscosities and concentrations of RGD. Also, longer focal adhesions and decreased actin flow are observed when cells are seeded on the higher viscous surfaces with 2% of RGD. On the other hand, when HAVDI is included in the bilayers, cell spreading and strength of adhesion (Figure 1B) are reduced, compared with surfaces that only contain RGD, and actin flow increases (Figure 1C) in an HAVDI concentration dependent manner. Also, when the bilayers present HAVDI, there is a decrease in nuclear translocation of mechanosensitive proteins (i.e. YAP) are observed, showing an altered sensing of viscosity (Figure 1D).

This interplay between viscosity and ligand presentation provokes not only differences in adhesion and mechanosensing, but also in the expression of nuclear lamina and small GTPases activity, which inhibition has shown a differential implication of N-cadherin adhesion in Rac1 activity depending on the viscosity. Finally, differences in early differentiation markers (Figure 1E to G) confirming the effect of viscosity on cell fate. Osteogenesis increases with higher viscosities and concentration of RGD. On the other hand, adipogenesis increases as the mobility of the
substrate does, while chondrogenesis is enhanced on mobile surfaces and with higher (2\%) concentrations of the N-Cadherin adhesion peptide.

**Conclusion**

Our findings reveal that viscosity elicits a mechanotransductive response that ultimately controls stem cell differentiation. Moreover, when cell-cell interactions are activated, hMSCs have a different perception of the mechanical properties of their surroundings, presenting a low viscosity phenotype (i.e. rounder cells, less force of adhesion, higher actin flow or lower YAP nuclear translocation) compared to when only ECM-cell interactions are present. Also, inhibition of small GTPases showed their implication in the regulation of the adhesive crosstalk depending of viscosity. Further investigations on the mechanisms involved in this response will allow us to establish a paradigm to understand and exploit stem cell response to viscous interactions.

Introduction

Liver is the largest organ of the human body; it fulfills hundreds of viable functions, and could be considered as a major crossroad of human physiology. In vitro modelling the different features of this organ has always been considered crucial for investigating both physiological and pathological processes, as well as to support drug development. Structural and functional complexity of the liver, however, represented major boundaries to the realization of accurate models. Recent advantages in biomaterials science, together with the development of new processing techniques allowed to improve the outcomes in this challenge. The availability of tools enabling to grow even different cell types within the same 3D matrix, mimicking their natural microenvironment represents a step forward if compared to classical 2D cell cultures. Alginate is commonly exploited to encapsulate cells in a tailorable 3D environment [1]. Moreover, decellularized liver are commonly used as scaffold to be recellularized, or enzymatically degraded into a viscous solution to encapsulate cells [2]. Decellularized liver-ECM was previously introduced in alginate beads to specifically encapsulate HCCLM3 cells, showing enhanced viability and protein expression if compared to alginate alone [3]. In light of this, this work presents the development of a 3D in vitro model based on liver ECM and alginate to support hepatocytes growth and activity while tuning the rheological properties to meet the ones of human liver.

Experimental Methods

ECM was obtained from porcine (pECM) and bovine (bECM) livers, by a combination of different methods [4]. The decellularization buffer (TRIS-HCl buffer + 1% w/v SDS + 1% v/v Triton X100) was injected in multiple sites of 0.5 cm cubes of liver and then used to submerge the samples while under orbital shaking up to 7 days. Freeze-dried decellularized cubes were grinded into powder of controlled granulometry. Residual immunogenic content after decellularization was quantified through DNeasy Blood and Tissue Kit. Both pECM and bECM protein compounds were characterized through ELISA. Four different alginate hydrogels were produced exploiting internal gelation: alginate 2% w/v, alginate 2% w/v + gelatin 0.8% w/v, alginate 2% w/v + pECM 0.8% w/v, and alginate 2% w/v + bECM 0.8% w/v. Each solution or suspension was obtained in complete medium (EMEM + 10% v/v FBS + 1% v/v P+S + 1% v/v Na pyruvate + 1% v/v L-Gln). Hydrogels were dried in order to determine their water content. Stability was tested in culture conditions (37 °C; 95% humidity; 5% CO\(_2\)) up to 14 days. Each hydrogel was then subjected to rheological analyses. For cell-loaded hydrogels, HepG2 cell suspension was added to the gel-precursor solution, to obtain a final concentration of 2 x 10\(^6\) cells/ml; after cross-linking, gels were submerged with complete medium and incubated in culture condition. After 24, 48, and 96 hours, gels were dissolved using Na-citrate, cells were retrieved, seeded, and tested with MTT assay. Gels were stained with live/dead kit, and subsequently observed at the confocal microscope (CLSM) after 24, 48, and 96 hours of culture.

Results and Discussion

Agarose gel electrophoresis confirmed the presence of a negligible amount of residual DNA in both pECM and bECM, thus validating the decellularization procedure. Alginate allowed to tailor the cross-linking; it has been possible to Page 466 of 2028
easily tune the reagents amount, thus obtaining rheological characteristics reproducing the ones of physiological liver tissue. Additionally, another set of rheological tests has been applied to evaluate the processability of hydrogels via 3D-bioprinting. The possibility to retrieve the cells from the reversible 3D matrix, even after long culture periods, using a nontoxic Ca\(^{2+}\) ions chelator allowed to quantify cell metabolic activity by MTT assay. An improvement of the viability through time resulted in both gels containing pECM and bECM, if compared to other hydrogels. CLSM analyses with live/dead kit not only confirmed the results of MTT assay, but even allowed to observe 3D clusters, similar to those observed in vivo [5].

Conclusion
This study demonstrated the possibility to synergically combine the chemical features of liver-derived ECM with the structural characteristic of an alginate hydrogel, mimicking the in vivo liver microenvironment. The presence of ECM positively impacted cell viability. Ongoing studies will include the bioprinting of the model, aiming to accelerate and standardize its production.

Introduction
An increasing number of patients opt for dental implants to replace missing teeth. The success of dental implants depends on the quality and quantity of the patient’s bone. Due to long-term edentulism, periodontal disease or trauma, bone augmentation may be necessary before implant insertion. Therefore, autologous bone is considered as the “gold standard” but requires harvesting from a second surgical site (1). Alternatively, synthetic bone substitute materials such as calcium phosphate cement (CPC) are used. CPC is 3D-printable and allows manufacturing of patient-specific structures with varying pore size and geometry (2,3). The scaffold’s pores allow blood, bone and stem cells to migrate and thereby, to integrate the scaffold into the adjacent tissue. Furthermore, scaffolds in maxillofacial surgery have to withstand high forces during the chewing process (4, 5). Thus, their mechanical properties are of high clinical importance. In the present study, we investigated individual, 3D printed CPC scaffolds with different pore sizes and geometry regarding cell infiltration and mechanical properties in vitro. Based on the in vitro findings, we performed bone augmentation in 6 clinical cases (see figure 1). Our findings show the importance of the external and internal structure for individual scaffolds in maxillofacial surgery to fit all patient specific necessities and ensure stability and cell infiltration.

Experimental Methods
Shape and macro porosity of the printed scaffolds were studied by stereo microscopic investigation and scanning electron microscopy (SEM) analysis. Mechanical characterization was done via uniaxial compressive test. Compressive modulus and compressive strength were calculated. For studying the colonization, scaffolds were seeded with hMSC, covered with culture medium and incubated for up to 12 weeks. Live/Dead staining was performed. For the determination of the cell number DNA quantification and LDH activity were evaluated. Furthermore, fluorescence microscopic analyses of colonized scaffolds were performed. Hereinafter, bone augmentation surgery was performed. During the implant bed preparation, biopsies of the augmented tissue were collected to examine the scaffold’s state of degradation.

Results and Discussion
Energy absorption of the six different reference scaffold types is greatly reduced with increasing pore size. This intense decrease is also shown by compressive strength (see figure 2A). Nevertheless, all investigated scaffolds, independently from pore size, showed a higher energy absorption and strength in comparison to the control group (BioOss®). After seeding the scaffolds with hMSCs and incubation for up to 12 weeks, CPC strands were completely covered after 4 weeks. After 12 weeks, the cell number of scaffolds with lower pore size was significantly lower in comparison to the control and scaffolds with higher pore sizes (see figure 2B). According to these results individual scaffolds were printed with the approved pore size of 0.49 mm and a strand distance of 0.82 mm. Energy absorption of all investigated individual scaffolds, independently from shape, showed also a higher energy absorption and...
strength in comparison to the control group (BioOss®). Based on these data, individual CPC scaffolds (see figure 2C) were inserted in 6 different clinical cases (sinus floor elevation and onlay osteoplasty). After the healing period of 9 months, dental implants were inserted. After another 6 months, prosthetic treatment was supplied.

**Conclusion**

As the pore size strongly affects the migration of cells and the mechanical properties of the scaffolds, we demonstrated *in vitro* that scaffolds with a pore size of more than 490 µm could not meet the mechanical requirements of certain cases in the orofacial system (e.g. osteoplasty of the alveolar ridge). Due to its increased infiltration of cells and therefore an accelerated integration, such scaffolds seem to be indicated only for jaw regions with low mechanical stress such as the maxillary sinus.

Silicate mediated bone remodelling is modulated by Fe

Amy Li, Joel Turner, Azadeh Rezaei, Gavin Jell

University College London, Division of Surgery and Interventional Sciences, London, GB

Introduction
Despite over 50 years of silicate based Bioactive glass research, and successful clinical applications, it is still unclear how silicate affects the underlying cellular mechanisms involved in bone remodelling. Previous studies have shown that Si inhibits osteoclastogenesis and osteoclast resorption capacity [1]. Considering the known role of sodium silicate in Fe chelation in paper manufacture [2], and the important role of Fe and ROS in osteoclast function (e.g. in the function of the redox iron containing tartrate resistant acid phosphatase (TRAP) enzyme) [3], here we explore a possible mechanism for Silicate mediate bone remodelling, via Fe chelation and reduced ROS availability.

Experimental Methods
To determine if silicate reduced ROS availability a de-esterified 2’, 7’-dichlorofluorescein diacetate (H2DCF-DA) assay was performed based on the protocol described previously [4]. Si and BG solutions were prepared in PBS with the clinically relevant concentrations of Si 2mM, 1mM, 1mM Deferoxamine Mesylate (DFO) as a control iron chelator. The samples were incubated for 5 minutes in dry incubator before being transferred to a black-well plate measure at the fluorescence of excitation 495nm, emission 538nm. Osteoclast formation was determined with a subclone of RAW264.7 osteoclast precursor cell-line with 3ng/RANKL and 20ng/ml controls over 6 days of culture measured by TRAP-5b staining (Acid Phosphatase, Leukocyte (TRAP) Kit- 387A, sigma Aldrich). Osteoclast resorption was determined by primary MF-1 mice osteoclasts over 9 days of culture with addition of 200ng/ml M-CSF and 3ng/ml RANKL and dropping pH to 6.8 at day 7 to initiate resorption (Data not shown).

Results and Discussion
Si (2mM) resulted in complete inhibition osteoclastogenesis (Figure 1). This finding was confirmed in an acellular biochemical ROS study, where Si inhibited ROS production in sodium metasilicate form and Si-BG dissolution ions in a concentration dependant manner (>50% vs 1mM H2O2 alone in the presence of FeCl2 catalyst). This suggests that Si may be inhibiting the Fenton reaction and ROS availability. To investigate this theory in vitro, Fe(10-100µM) was added to Si containing culture which restored osteoclasts formation in Si (2mM) treated cells.

Conclusion
Silicate inhibition of osteoclastogenesis is mediated by Fe concentration. Understanding how Si based biomaterial interact in bone tissue engineering will allow the design of patient specific bone implants.

Introduction
The human bone undergoes a lifelong process, known as bone remodelling, where bone resorption by osteoclasts (OC) and new bone deposition by osteoblasts (OB) sequentially occur and are synergistically coupled. During this process, the resorption of bone portions by OC involves the excretion of enzymes that are able to digest the collagenous fraction causing the release of the growth factors (GFs) stored in the bone matrix [1]. In bone regenerative strategies the controlled release of GFs is one of the main targets to stimulate a successfully regeneration. Recent trends in the drug delivery field have led to an increasing interest in the development of biodegradable particles able to protect and vehicle active agents. In this frame, poly(lactic-co-glycolic) acid (PLGA) is one of the most used polymers for the realization of carriers due to its well-known biocompatibility and biodegradation [2]. The present research work reports the design and characterization of degradable PLGA nanocarriers suitable for the incorporation and subsequent release of Transforming Growth Factor-βeta1 (TGF-β1), a biomolecule that exerts a central role in the bone remodelling process, controlling both OB and OC migration, proliferation and maturation [3]. With the final purpose of designing a biomimetic 3D printed scaffold able to reproduce the natural bone composition and biology, the developed TGF-β1-containing PLGA nanocarriers (PLGA_TGF-β1) were incorporated into a type I collagen formulation. The obtained hybrid formulation was used for 3D printing a nanostructured scaffold mimicking the amount and distribution of TGF-β1 observed in the human bone extracellular matrix (ECM) able to provide a sustained GFs release for supporting bone regeneration.

Experimental Methods
Human bone samples have been processed by Università Politecnica delle Marche to localize and quantify TGF-β1 in human bone ECM performing immunohistochemical and ELISA analyses. TGF-β1 have been encapsulated into PLGA nanoparticles using a double evaporation technique and then, in order to obtain a sustained delivery, the PLGA_TGF-β1 nanoparticles have been dispersed in a type I collagen matrix. A special focus has been given to rheological studies to obtain a formulation suitable for 3D printing applications and 3D structures have been printed through 27G needles using a commercial bioprinter (BioX, CELLINK) equipped with a pneumatic temperature-controlled print-head. To improve the material stability after deposition, a chemical cross-linking using genipin has been used. The nanocarriers and the composite collagenous structures have been fully characterized and the release kinetics of TGF-β1 from both the nanoparticles alone and when embedded into the scaffold have been assessed under physiological conditions up to 28 days. Finally, the localization of TGF-β1 into the developed 3D collagen-based scaffold was evaluated using histochemical analyses.

Results and Discussion
Spherical and water-stable PLGA_TGF-β1 nanocarriers measuring 257±7.3 nm in diameter and with a high encapsulation efficiency (63.9±7.9%) have been successfully synthetized. Release test on the nanocarriers showed...
an initial burst release of about 38% of the incorporated GFs in the first 24 hours likely due to TGF-β1 adsorbed on the particle surface, followed by more gradual release kinetics reaching 97.6% of GFs released after 28 days. The nanocarriers were subsequently combined with type I collagen, obtaining a homogeneous hybrid suspension containing the same amount of TGF-β1 detected by the semi-quantitative evaluation of immunostaining on human bone tissue. After the optimization of the printing parameters and conditions, 10×10×1 mm³ mesh-like scaffolds have been printed. Morphological analyses confirmed the successful reconstruction of collagen fibrils after the incubation at 37°C as well as the uniform distribution and proper embedding of PLGA_TGF-β1 into the collagenous matrix. Furthermore, the resulting scaffolds showed the capability to slow down the TGF-β1 release compared to the PLGA nanocarriers alone, evidencing that their embedding within the collagenous matrix provides a modulatory effect on the biomolecule release. Finally, the histological staining and immunohistochemistry analyses proved that the developed collagenous 3D system incorporating the PLGA_TGF-β1 nanocarriers successfully reproduce the TGF-β1 quantity and its uniform distribution observed in human bone ECM.

**Conclusion**

PLGA nanocarriers able to encapsulate and gradually release TGF-β1 (PLGA_TGF-β1) have been successfully developed as promising tools for the design of devices for bone regeneration. A further goal achieved by this study was the design of a 3D composite scaffold based on type I collagen and PLGA nanoparticles (Coll/PLGA_TGF-β1) able to effectively mimic the bone ECM in terms of composition, TGF-β1 content and uniform localization in the bone tissue. Future studies will aim at investigating the effect of the released TGF-β1 on OB and OC crosstalk.

Bioinspired adhesive proteins as building blocks for liquified platforms with an impact on bone regenerative medicine

Ana R. Pinho, Maria C. Gomes, João F. Mano

Aveiro University, Department of Chemistry, CICECO - Aveiro Institute of Materials, Aveiro, PT

Introduction

Bone is one of the few tissues that regenerate spontaneously. However, pathological situations make healthy bone regeneration impossible, leading patients to painful clinical conditions and associated with expensive and time-consuming treatments. Bone tissue engineering has long sought biocompatible and biodegradable platforms that effectively promotes bone regeneration and easily translated into clinical practice. In this sense, we designed protein-based liquified microplatforms with unique adhesion and spontaneous mineralization inspired by aquatic organisms.

Experimental Methods

Inspired by the adhesive proteins found in mussels (such as Mfp-3), we chemically obtained synthetic adhesive proteins as building blocks to fashion liquified microcapsules by the combination of coaxial electrospray, and the coordination behavior of catechol-like moieties with metals. The adhesion and mineralization properties were evaluated by mechanical tests and exposure to simulated body fluids, respectively. Preliminary cell biocompatibility was also assessed to evaluate this microplatforms as biofactories.

Results and Discussion

By taking advantage of the adhesive properties, we were able to obtain biocompatible and biodegradable microplatforms with great adhesion and autonomous mineralization behavior. With great prospects for bone tissue regeneration, these microfactories provided the desired environment for cell growth and proliferation.

Conclusion

In the end, this study provides an interesting approach to construct liquified microcapsules with biomimetic adhesive and mineralization properties for bone tissue regeneration.

**Scaffold-based 3D cellular models mimicking the heterogeneity of osteosarcoma stem cell niche**

**Giada Bassi**, Silvia Panseri, Arianna Rossi, Elisabetta Campodoni, Monica Sandri, Massimiliano Dapporto, Simone Sprio, Anna Tampieri, Monica Montesi

*National Research Council of Italy, Institute of Science and Technology for Ceramics (ISTEC), Faenza (RA), 48018, IT*

**Introduction**

Worldwide cancer remains the second-most common cause of death, despite the advances in prevention, early detection, treatment; among the bone cancer osteosarcoma (OS) is the most common type diagnosed especially in children and young adults. The failure of the osteosarcoma conventional therapies leads to the growing need for novel therapeutic strategies. The lack of specificity for the Cancer Stem Cells (CSCs) population has been recently identified as the main limitation in the current therapies\(^1\). Moreover, the traditional two-dimensional (2D) *in vitro* models, employed in the drug testing and screening as well as in the study of cell and molecular biology, are affected by a poor *in vitro-in vivo* translation ability\(^2\).

To overcome these limitations, this work provides two 3D "tumour engineering" approaches as new tools to address osteosarcoma and improve therapy outcomes. In detail, two different hydroxyapatite-based bone-mimicking scaffolds\(^3,4\) were used to recapitulate aspects of the *in vivo* bone extracellular matrix, together with enriched-CSCs obtained by sarcosphere-forming culture starting from osteosarcoma cell lines (MG63 and SAOS-2)\(^5\).

**Experimental Methods**

**Scaffold synthesis.** Hybrid composite scaffolds obtained by a biomineralization process involving the direct nucleation of Mg-doped hydroxyapatite (MgHA) on self-assembling collagen fibres (MgHA/Coll)\(^3\) and porous hydroxyapatite scaffolds (HA) produced by direct foaming process\(^4\), were used.

**Sarcospheres-forming culture.** The enriched-CSCs were obtained from parental SAOS-2 and MG63 cell lines under specific culture conditions as reported in literature\(^5\), observing sarcospheres formation.

**3D *in vitro* osteosarcoma models.** The scaffolds were seeded with parental cells or sarcospheres on material upper surface for the development of 3D osteosarcoma models. Sarcospheres were supplied with fresh culture medium and factors cocktail every 3 days for a total of 10 days of culture.

A morphological analysis and immunofluorescence and gene expression profile of stemness and niche-related genes in osteosarcoma cell lines and enriched-CSCs cultured in standard 2D conditions *versus* the 3D culture systems has been performed.

**Results and Discussion**

The overall results showed how the CSCs maintained more their stemness phenotype and features when cultured in both MgHA/Coll and HA biomaterials compared to 2D model. The work confirmed that the use of the 3D scaffolds, together with sarcospheres implementation, improved the osteosarcoma stem cell niche microenvironment simulation, providing precise inputs supporting cell-cell and cell-ECM interactions and tumour signalling pathways *in vitro*. Molecular analysis showed slight variances attributable to the intrinsic biological differences of the two osteosarcoma cell lines and to the specific biomimetic scaffold features. However, also *in vivo* intratumoral variability can occur between tumour cells arising from the same mass, leading to the classification of different tumour cell subtypes that show a range of functional and morphological properties and a different molecular profile\(^1\). The extrinsic interactions between tumour cells and stromal microenvironments may be involved in the *in vivo* tumour heterogeneity as a crucial determinant of tumour malignancy\(^1\). Although recognizing the limitations of these simplified
3D osteosarcoma models, they provided a more accurate starting point to understand the cellular and molecular mechanisms involved in cancer cells/biomatrix interactions, particularly in CSCs population.

**Conclusion**

This work highlight the fundamental role of the tumour microenvironment providing the mimicry of osteosarcoma stem cell niche by the use of CSCs together with the biomimetic scaffolds, compared to conventional 2D culture systems. The proposed culture systems represent promising 3D *in vitro* tumour models that could improve the predictivity of preclinical studies and strongly enhance the clinical translation, closing the gap between the drug discovery and the clinical studies with the ultimate goal to be applied in personalized medicine.

Optimization of calcium phosphate production in a droplet-based microfluidics platform for bone regeneration

Yousra Alaoui Selsouli, Hoon S. Rho, Zeinab Tahmasebi Birgani, Pamela Habibovic

Maastricht university, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL

Introduction
Calcium phosphate (CaP) ceramics such as hydroxyapatite (HA) and tricalcium phosphate (TCP) are among the most widely used synthetic bone graft substitutes in the clinic [1]. Nevertheless, bone regenerative potential of most CaPs is not as high as that of natural bone grafts, and therefore, further improvement is required [2]. Microfluidic technology offers attractive tools for improving and accelerating development of new materials with higher throughput or in a more controlled manner than the conventional production methods [3]. Here, we explored the possibilities of a recently developed droplet-microfluidic platform for controlled synthesis of CaP ceramics.

Experimental Methods
CaP ceramics were synthesized inside microdroplets produced by a flow-focusing microfluidic device, which uses a mixture of calcium nitrate and phosphoric acid as water phase, and mineral oil with Span® 80 as oil phase (figure 1a). After the microdroplets were generated and collected, a base (ammonia or sodium hydroxide) was added to increase the pH, resulting in mineralization of CaPs inside of the droplets. The CaP particles were then purified to remove the oil phase by several washing/filtration steps (figure 1b) [4]. CaPs with different properties were produced by controlling the composition of the calcium and phosphate precursor solutions, pH and post-precipitation heat treatment. Upon production, the materials were characterized by x-ray diffraction (XRD), Fourier transformed infrared spectroscopy (FTIR) and scanning electron microscopy (SEM).

Results and Discussion
CaPs were successfully produced in single-emulsions using the microfluidic platform. By controlling processing parameters such as flow rate, microdroplets, and consequently spherical CaP particles with different sizes were synthesized (Figure 1). FTIR analysis of the materials showed that after the purification step, no traces of oil phase were present in the materials (figure 2a). XRD results showed that by varying Ca/P ratio of the precursors, pH conditions and by applying post-precipitation heat treatment, phase-pure CaP particles of monetite, brushite, hydroxyapatite (HA), β-tricalcium phosphate (β-TCP) and β-pyrophosphate (β-CPP) were successfully obtained. An example of the material produced using precursors with a calcium-to-phosphorus ratio of 1 before and after heat treatment is shown in figure 2b. SEM imaging showed that the precipitated particles exhibited a homogeneous morphology (figure 2c).

Conclusion
Here, we showed that the flow-focusing droplet microfluidic device is a suitable platform for synthesizing different CaP ceramics with control over their composition and size. To further explore the possibilities of the platform, we are currently performing a systematic study by varying the individual processing parameters and investigating their effects on the material properties such as their porosity and degradation behavior. Future steps aim at generating a combinatorial library of different CaP-based ceramics by introducing inorganic additives such as strontium, copper and magnesium, which are also present in bone mineral [5].

Calcium phosphate bioceramics with highly anisotropic pore structure produced from hollow filaments

Michael Gelinsky¹, Kathleen Schütz¹, Christine Hecker², Thomas Schulze³, Nadine Liebig⁴, Heike Illing-Günther⁴, Yvonne Joseph²

¹ TU Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE; ² TU Bergakademie Freiberg, Institute for Electronic and Sensor Materials, Freiberg, DE; ³ Thuringian Institute for Textile and Plastics Research, TITK, Rudolstadt, DE; ⁴ Saxon Textile Research Institute, STFI, Chemnitz, DE

Introduction

Most mammalian tissues have highly anisotropic structures, especially those of the musculoskeletal system. Nevertheless, the majority of biomaterials and scaffolds, utilised for example for bone reconstruction and tissue engineering have isotropic properties. Using a combination of textile and ceramic technologies, we have developed calcium phosphate bioceramics with a channel-like pore morphology, partly mimicking the osteon structure of cortical bone (Fig. 1). Such bioceramics can be produced from both hydroxyapatite (HA) and beta-tricalcium phosphate (TCP). We hypothesise that this morphology should be beneficial for the integration in living bone and for vascularisation.

Experimental Methods

As starting materials, composites consisting of cellulose and either HA or TCP powders have been prepared which then were used for wet spinning of continuous hollow filaments. The filaments were dried carefully in climate chambers and afterwards cut into convenient lengths of 0.3-1 m. The hollow fibres were bundled, and the bundles stabilised by sheathing with conventional polymer fibres, using the Kemafil process. Finally, these fibre bundles were impregnated with a calcium phosphate powder slurry and sintered at temperatures > 1000°C so that pure calcium phosphate ceramics remain and all organic components were burned out completely (Fig. 1). Phase composition was analysed using XRD and the morphology was studied by SEM. For cell culture experiments, disc-like samples of convenient lengths were made using a diamond cutting system. Cytocompatibility of the novel bioceramics was investigated both in indirect and direct cell seeding experiments, using the osteosarcoma cell line SAOS-2 and primary human mesenchymal stem cells (hMSC), isolated from bone marrow. Besides cell adhesion and proliferation, the ability for osteogenic differentiation and migration of the cells into the pore channels has been explored, using several methods.

Results and Discussion

After process optimisation and selection of the right cellulose-calcium phosphate ratio of 1:3 well defined and homogenous hollow filaments could be produced by wet spinning in continuous manner. The drying process is challenging as strong forces are generated by the shrinkage of the material but by continuous stretching of the fibres during drying deformation could be avoided. Typical dimensions of the dried hollow fibres are 400-450 µm outer diameter, 90-100 µm wall thickness and 220 µm lumen. Bundling and compaction of the parallel-aligned fibres led to fibre bundles with diameters of commonly ca. 0.8-1.5 cm. For further stabilisation and better handling these bundles were sheathed using polymer fibres applying the Kemafil process. For infiltration of the materials prior to sintering slurries of the same calcium phosphate powders that have been integrated in the respective hollow fibres were prepared and sucked in the voids between the fibres without closing their hollow lumen. Finally, the samples were sintered at different temperatures (1100, 1200 and 1250°C) to investigate the effects on stability, mechanical properties and cell growth. so that all organic residues (the cellulose content of the hollow fibres as well as the material used for sheathing) At this temperatures, all organic residues (the cellulose content of the hollow fibres as
well as the material used for sheathing) are removed completely, leaving behind pure calcium phosphate bioceramics. The sintering led to further reduction of the dimensions — so that the channel-like pores, originating in the hollow fibres, have typical diameters of around 150 µm depending on their initial dimensions and sintering conditions. XRD analyses confirmed the composition being either HA or beta-TCP, depending on the starting materials. Indirect cytotoxicity evaluation revealed good cytocompatibility of both HA and TCP based bioceramics. Applying a dynamic cell seeding method homogenous cell distribution of both sides of disc-shaped samples could be achieved, as well as high seeding efficiency (Fig. 2). SAOS-2 cells proliferated on the samples over cultivation periods of 14 days and a part of the cells migrated into the pore channels. Similar results could be achieved with hMSC, which also could be differentiated towards the osteogenic lineage after addition of the standard pro-osteogenic cell culture supplements.

**Conclusion**

In conclusion, we have demonstrated the applicability of a novel method for manufacturing of highly anisotropic calcium phosphate bioceramics with channel-like pores in large dimensions and quantities, starting of hollow cellulose-based filaments. In further experiments, we will study the biocompatibility of these materials, using suitable bone defect animal models and the suitability for vascular ingrowth into the pore channels.

Silk-based inks: from molecules to well-organized fibrous scaffolds

Martina Viola1,2, Susanna Piluso1, Marko Mihajlovic2, Jos Malda1, Miguel D. Castilho1, Vermorden Tina2

1 University Medical Center (UMC) Utrecht, Orthopaedics / Surgical Specialties, Utrecht, NL; 2 Utrecht University, Pharmaceutics, Utrecht, NL

Introduction
One open challenge in tissue engineering is to engineer biomaterials that can mimic the hierarchical fibrous structure of the extracellular matrix (ECM) found in living tissues.1, 2 Silk as a material – from its unique mechanical properties to its biological properties – has been continually inspiring materials scientists, biologists and tissue engineers. However, processing silk in well-organized structures that can potentially mimic native like ECM structures is still a challenge. In this study, we aim to investigate the electrohydrodynamic printing potential of a novel Silk Fibroin (SF) ink in order to create well organized and mechanical stable fibrous constructs.

Experimental Methods
Silk fibroin was extracted from Bombyx mori cocoons.3 These cocoons are cut and boiled for 5 minutes in a Na2CO3 solution (0.02M), in this step sericin is removed from the silk filaments, fibroin is isolated and left to dry overnight. Fibroin is then dissolved in a 60°C LiBr solution (9.3 M) for 4h, and subsequently purified by 5 days of dialysis (Fig 1A). The viscosity of the prepared SF solution was evaluated by rheological analysis with a plate-plate geometry (d = 20 mm). The same geometry of the rheometer was used to detect the strength of SF hydrogels (Fig.1B). Then electrohydrodynamic printing of SF solutions was investigated by studying the key instrument parameters (speed of the collector plate, voltage, pressure and distance between the plate and the extruder).4 Post-printing fibers were treated with a solution of sodium phosphate (1M) to induce physical crosslinking. Post-printing accuracy was evaluated analyzing the diameter and the stacking of the fibers with light microscopy.

Results and Discussion
In this work, we have demonstrated the electrohydrodynamic printing of SF in well-organized fibrous structures. To do so, we adjusted the rheological properties of the SF ink by varying the concentration of SF (15% w/v) and the concentration of polyethylene oxide (2% w/v) (Mw: 600-1000 kDa) (Fig. 1B), to obtain straight fibres with reduced fibre diameters, i.e. 10 to 20 μm. Moreover, we successfully produced fibrous scaffolds with a minimum inter- fibre distance of 200 μm (Fig. 2C) and a maximum thickness of approximately 100 μm (up to 15). After printing, the scaffolds were physically crosslinked with a solution of sodium phosphate (1M) ensure their stability in aqueous solutions and sufficient mechanical integrity (Fig. 2D).
We compared this crosslinking method with crosslinking with methanol, used several times in literature.5 We noticed how Na3PO4 crosslinking not only induced greater extensibility and elasticity of the fibres than those crosslinked with methanol, but also greater stability in an aqueous environment.

Conclusion
Overall, the electrohydrodynamic printing of novel SF inks allows the fabrication of uniquely organized fibrous scaffolds with micrometer resolutions. Our next steps will focus on studying the conformational changes of SF when treated with Na3PO4 by Raman spectroscopy. Furthermore, we will analyse the mechanical properties that SF scaffolds take on when treated with Na3PO4. Ultimately, we will apply the generated scaffolds to recreate the organized ECM structure found in native cartilage.

The effect of alkali activation on the porosity of 45S5 bioactive glass microspheres

Si Chen¹, Jozef Kraxner¹, Martin Michálek¹, Dušan Galusek¹,²

¹ A. Dubček University of Trenčín, FunGlass, Študentská 2, 911 50 Trenčín, SK; ² VILA – Join Glass Centre of the IIC SAS, TnUAD, FChPT STU, Študentská 2, 911 50 Trenčín, SK

Introduction
Hench et al. developed 45S5 bioactive glass (BG) in 1971. 45S5 BG can form a strong chemical bond to bone tissue [1]. It is widely used in the fabrication of scaffolds for bone tissue engineering, including ceramic/glass scaffolds, or as filler incorporated into composite scaffolds. 45S5 BG is also able to promote osteogenesis and angiogenesis [1]. The porous structure provides the necessary space for cell migration, angiogenesis and tissue growth which is one of the important criteria for bone tissue engineering [2]. Porous structures can be also used as drug carriers in 3D scaffold preparation. Porous/hollow microspheres can be fabricated by flame spheroidization process after alkali activation of 45S5 bioactive glass [3]. In this study, we investigated the effects of three parameters, namely concentration of NaOH solution, activation time, and temperature, on the porosity and pore size of the 45S5 bioactive glass microspheres prepared by flame spheroidization process.

Experimental Methods
45S5 bioactive glass was prepared by conventional melt quenching method. The BG was milled into a powder with a particle size ≤ 40 μm. The powder was dispersed in different concentrations of NaOH solutions (0.5M, 1M, 2M) at different temperatures (25°C, 50°C) with vigorous stirring for different times (0.5h, 1h, 3h). The three mentioned alkali activation process parameters were adjusted by single factor to assess their effect on the textural properties of produced porous/hollow microspheres. The suspensions were further aged at 75 ºC for 24 h. During aging, sodium silicate produced by the alkali activation caused the powder stick into lumps. Through further grinding and sieving, powders with a particle size of 40-80 μm were obtained and further processed by flame synthesis to obtain porous/hollow microspheres. The structural, morphological, chemical, and textural characteristics of the microspheres were analysed using XRD, SEM, Raman and Micro-CT. Microspheres were immersed in simulated body fluid (SBF) to evaluate their bioactive behaviour.

Results and Discussion
BG microspheres with various morphology and porosity were successfully fabricated by flame synthesis. Figure 1 illustrates a significant porosity difference of the microspheres prepared from alkali activated BG treated under different activation conditions.

The XRD patterns (Figure 2) of the glass after alkali activation confirmed the formation of crystalline sodium phosphate hydroxide hydrate (Na₆.33(PO₄)₂(OH)₀.33•24H₂O) and calcium silicate hydrate ((CaO)ₓ•SiO₂•ZH₂O). In addition to the aforementioned components, NaOH might be completely consumed, possibly yielding amorphous hydrated sodium silicate or remain in the sample after alkali activation. The residual of NaOH is going to be analysed by Raman spectroscopy. After flame synthesis, all samples were X-ray amorphous. Calcite (CaCO₃) crystals were formed after 1 day immersion of glass microspheres in SBF. Similar results were reported in the literature related to bioactive glasses and bioactivity measurement [4]. Compared to hydroxy carbonate apatite (HCA, Ca₁₀(PO₄)₃(CO₃)₃(OH)₂), calcite exhibits better osteogenesis and induces faster osteoblast remodelling [5]. After 3 and 7 days of immersion, the calcite diffraction lines almost disappeared and were replaced by the HCA diffraction lines. The 1M-3h-25°C sample showed significantly weaker HCA diffraction lines at 26° and 32° compared to 1M-1h-
50°C. This can be explained by the lower porosity and hence, a lower specific surface area of 1M-3h-25°C compared with 1M-1h-50°C.

**Conclusion**

Porous/hollow microspheres were successfully fabricated from the 45S5 bioactive glass by alkali activation followed by flame synthesis. The parameters of alkali activation significantly affect the porosity of the microspheres. The microspheres exhibited significant bioactivity.

LS | Lunch Symposium Rousselot: Biomedical Applications of Gelatins

Chairs

Jeff Daelman
Rousselot, Gent, BE
Jeroen Leijten
University of Twente, Enschede, NL

This symposium is held by:

Rousselot
Biomedical

We are proud to co-present a lunch symposium with Dr Jeroen Leijten, University of Twente, Enschede, Netherlands and our scientific expert Dr Jeff Daelman, in which the complexities and potential of gelatins for use in biomedical applications will be discussed.

Session discussion highlights include:

- **The unique properties of Gelatin for 3D bioprinting**: The use of gelatin to stably incorporate nanoparticles into printable bio-inks.
- **The biocompatibility of Gelatin for use in regenerative medicines**: The ability of gelatin to steer the behavior of immune cells such as macrophages towards a regenerative phenotype, or to endow bio-printed cartilage-like tissue constructs with spatially controlled mechanical properties.
- **The advantages of gelatin for use as a bio-adhesive**: The chemical modification of gelatin to act as hemostatic bio-adhesive or implantable energy storage devices

Our expert Dr Jeff Daelman will share insights from our latest research into how a ‘clean’ gelatin can reduce experimental bias and allow for efficient clinical translation.

Program:
Rousselot introduction – Jeff Daelman
Biomedical applications for Gelatins - Jeroen Leijten
Modified gelatins: from bench to patient – Jeff Daelman

Biomedical applications for Gelatins

Jeroen Leijten

University of Twente, Department of Developmental BioEngineering, Enschede, NL

Gelatin has become one of the most commonly used biomaterials for biomedical research. As a naturally-derived biomacromolecule, gelatins offer amongst others cytocompatibility, ease-of-handling, degradability, and cell attachment. Gelatin allows for facile chemical modifications that allow additional forms of crosslinking, which have been explored for numerous purposes including cell delivery, micropatterning, and additive manufacturing. Here, we will discuss some of the novel areas of application of gelatins. This will include chemical modification of gelatin to act as hemostatic bioadhesive or implantable energy storage devices, use of gelatin to stably incorporate nanoparticles into printable bioinks, ability of gelatin to steer the behavior of immune cells such as macrophages towards a regenerative phenotype, or to endow bioprinted cartilage-like tissue constructs with spatially controlled mechanical properties. For all these applications, a clean (e.g., endotoxin-low/free) and batch-to-batch consistent gelatin formulation is required. Indeed, a GMP-certified and FDA/EMA-compliant biomaterial formulation is required to reduce experimental bias and allow for clinical translation. We will therefore highlight the potential effects of these variables in relation to the presented studies.
Modified gelatins: from bench to patient

Jeff Daelman

Rousselot Biomedical, Rousselot BV, Ghent, Belgium

Modified gelatins (e.g. GelMA) have been around for over 2 decades, but despite a steadily growing body of scientific literature and an ever increasing list of patent applications, no clinical application has yet made it to the patient. We believe this is due to a lack of material suitable for use in clinical trials: materials that are consistent in their physical and chemical properties, are GMP certified and have the required level of purity.

Using 2 case studies, we will demonstrate the importance of considering upscaling and material consistency as early in the process as possible.

Mapping the immune and stromal response to biomaterials

Jennifer H. Elisseeff, Christopher Cherry

Johns Hopkins University, Baltimore, US

Biomaterials serve as the basis of implants, tissue engineering scaffolds, and multiple other biomedical therapeutics. New technologies, such as single cell RNA sequencing (scRNAseq), are enabling characterization of the biomaterial response to an unprecedented level of detail, facilitating new discoveries in the complex cellular environment surrounding materials. We performed scRNAseq and integrated data sets from multiple experiments to create a single cell atlas of the biomaterials response. We developed Domino (github.com/chris-cherry/domino), a computational tool which allows for identification of condition specific intercellular signaling patterns connected to transcription factor activation in the biomaterial response defining interactions between immune, fibroblast, and tissue-specific modules with biomaterials-specific communication patterns.
Development of a biomimetic implant with stiffness-dependent immunomodulatory functionality and neurotrophic characteristics for spinal cord injury

Ian U. Woods¹, Cian O'Connor¹, Lisa Frugoli¹, Séan Kerr¹, Martyna Stasiewicz¹, Alan Hibbits¹, Javier G. Gonzalez¹, Adrian Dervan¹, Fergal O’Brien¹,²,³

Introduction

The injured spinal cord (SC) generates a unique and complex pathophysiology which presents a multifaceted challenge for repair¹. Broadly, normally supportive astroglia become reactive following injury and form a glial scar. This scar in turn inhibits recovery by releasing an impenetrable inhibitive extracellular matrix (ECM)², which prevents axonal regrowth. Tissue engineering approaches aim to overcome these barriers by bridging the cyst with a physical neurotrophic substrate optimised for axonal growth. However, reactive astrocytes rapidly encapsulate these scaffolds, acting as a physical barrier to regeneration. Our previous experience in peripheral nerve repair demonstrates that composition and stiffness of scaffolds play an essential role in neural tissue regeneration, directing the behaviour of both axons and supporting cells³. Considering the physicochemical properties of SC tissue, it was hypothesized that comprehensive optimization of the structure, stiffness and composition of biomaterial scaffolds could provide both potent neurotrophic signalling and intrinsic immunomodulatory properties. Scaffolds with intrinsic signalling present an effective alternative to biochemical factors for solutions to the key clinical challenges of astrogliosis, the CNS foreign body response and cross-injury axonal regrowth.

Experimental Methods

Human SHSY-5Y projection neurons, murine NSC-34 motoneurons and human primary astrocytes were cultured for 7 days on poly-L-lysine-coated or ECM-coated (5 µg/ml) coverslips (n=12), or with increasing gradients of Brain Derived Neurotrophic Factor (BDNF). Fluorescence microscopy captured cell morphologies that were digitally analyzed using FIJI. To produce biomimetic scaffolds of varying mechanical stiffnesses, soft (3mg/ml), medium (5 mg/ml) and stiff (10 mg/ml) hyaluronic acid (Hya) hydrogels were prepared, after which the optimal ECM composition was mixed throughout the hydrogel. The physicochemical properties of the scaffolds were then characterized using compressive testing, scanning electron microscopy and histology.

Astrocytes, neurons and primary adult rat dorsal root ganglia (DRGs) were then seeded individually on the HyA scaffolds of low, medium or high stiffness and cultured for 1 - 3 weeks. ELISA analysis was performed on collected medium to examine the release of inflammatory markers IL-6 and IL-10 from the scaffold-resident astrocytes. Immunohistochemical analysis was performed to examine cell morphology, nuclear:cytoplasmic ratio and axonal extension.

Results and Discussion

Neurite outgrowth analysis indicated that the combination of collagen-IV (Coll-IV) and fibronectin (Fn) significantly (p<0.05) synergistically enhanced outgrowth with a similar potency to high concentrations (50 - 100 ng) of BDNF, a potent neurotrophic growth factor. Analysis of astrocyte behaviour on ECM substrates indicated significantly lower expression of GFAP as well as the adoption of more stellate morphologies, associated with a ‘resting’ or less reactive astrocyte phenotype⁴, on Coll-IV/Fn substrates compared to PLL controls.
Astrocytes seeded on HyA scaffolds (Fig. 1, A-F) exhibited significant changes in a manner dependent on both stiffness and composition. Astrocytes cultured in soft HyA scaffolds displayed stellate morphologies and exhibited significant changes in nuclear:cytoplasmic ratio, a marker of astrocyte reactivity, (p<0.001) (G) compared to astrocytes cultured on scaffolds of supraphysiological stiffnesses (10mg/ml). Furthermore, IL-10 production (H), a pro-regenerative, anti-inflammatory cytokine, was significantly upregulated on both softer and Coll-IV/Fn containing scaffolds. These results indicate capacity for scaffolds optimized for the SC environment to provide innate immunomodulation of astrocyte phenotype towards a neurotrophic subtype.

SH-SY5Y projection neurons exhibited significantly improved extension of βIII-tubulin labelled neurites on softer, ECM-functionalized scaffolds and scaffold stiffness exerted significant effects on both the distribution and morphology of their extensions. Finally, adult primary DRGs were used as an ex vivo model of axonal regeneration from mature neurons (Fig. 2 (A-F)) – an essential quality for clinical application. DRGs exhibited significantly enhanced axonal extension on Coll-IV/Fn-functionalized scaffolds while softer scaffolds (3mg/ml), enhanced both lateral and longitudinal axonal extension (p<0.001) (G – I).

**Conclusion**

Coll-IV/Fn functionalized HyA scaffolds trophically support and stimulate axon regeneration in both an in vitro model of neuronal growth and an ex vivo model of SC injury while also promoting adoption of a pro-regenerative phenotype in infiltrating astrocytes. This paper demonstrates that an optimally designed biomimetic scaffold containing endogenous cord proteins can direct essential inflammatory and regenerative processes towards SC repair in a stiffness-dependent manner.

**Figure 1.** Soft ECM-functionalized hyaluronic acid scaffolds mediate astrocyte polarization.

Astrocytes cultured in scaffolds of ranging stiffness with and without Coll-IV/FN functionalization were imaged to characterise individual cytoskeleton distribution (A-F). Nuclear:Cytoplasm ratio analysis also revealed a lower reactive index for astrocytes in soft scaffolds compared stiffer scaffolds (G). Significant differences in the secretion of IL-10 were observed in a stiffness and Coll-IV/FN dependent manner (H).
Figure 2. Soft, biomimetic scaffolds promote axonal regeneration in an ex vivo model of SCI.

DRGs seeded on softer scaffolds exhibited robust neurite outgrowth compared to stiffer substrates (A-C) while ECM-functionalization was shown to exert potent neurotrophic effects (D–F). Analysis of neurite outgrowth into 3mg/ml scaffolds (G) revealed profuse neurite influx (arrowheads) into the scaffold from the DRG body. Quantification of neurite outgrowth across the scaffold surface (H) and longitudinally (I) indicated that stiffness played a significant role in promoting neurite extension from seeded DRGs.

Introduction
Implanted biomaterials elicit an inflammatory response, where monocytes/macrophages are central players, conditioning inflammation and bone regeneration [1]. Thus, modulating macrophage response, promoting M1 to M2 phenotype switch, is an increasingly explored strategy in biomaterial development [2]. Our previous work showed that extracts of combinatory biomaterials (fibrinogen (Fg) sponges + metallic magnesium) reduced macrophage pro-inflammatory phenotype and stimulated their capacity to promote Mesenchymal Stem/Stromal Cells (MSC) osteogenic differentiation [3]. Magnesium ions (Mg\textsuperscript{2+}) are reported as immunomodulatory, reducing pro-inflammatory macrophage polarization [3,4]. The hypothesis underlying the current work was that the incorporation of Mg\textsuperscript{2+} ions into Fg-3D scaffolds should lead to an improved ability of the latter to modulate macrophage polarization.

Experimental Methods
A Fg solution (from human plasma, Grifols S.A.) and a magnesium sulphate (MgSO\textsubscript{4}) concentrated 200 mM solution were combined to obtain 3D scaffolds of Fg with 0, 10, 25 and 50 mM of MgSO\textsubscript{4} (FgMgSO\textsubscript{4}). The Fg\textsuperscript{+}MgSO\textsubscript{4} solution was cast, freeze-dried and EDC was used as chemically crosslinker [3]. The properties of the scaffolds were evaluated by: scanning electron microscopy (SEM), for structure and porosity; Fourier Transform Infra-Red (FTIR), for functional groups analysis; dynamic mechanical analysis (DMA) for mechanical properties; and electro kinetic analysis (EKA) for zeta potential. Human monocytes were isolated from buffy coats (kindly donated by Serviço de Immunohemoterapia, CHUSJ) and seeded directly on the scaffolds, in presence of M-CSF for macrophage differentiation. Cells were either left unstimulated (M0), or stimulated with LPS+IFN\gamma (M1). Lactate dehydrogenase (LDH) was measured using the CytoTox96® assay. Confocal microscopy was used to analyze M1 (CCR7) and M2 (CD163) polarization markers, and NF-\kappa B p65 nuclear translocation. Human bone marrow MSCs were cultured on FgMgSO\textsubscript{4} (0 and 10 mM) scaffolds, or in presence of macrophage secretome. Osteogenic differentiation was assessed through Alizarin Red staining.

Results and Discussion
Scaffolds of Fg alone or doped with MgSO\textsubscript{4} (10, 25 and 50 mM) presented a 3D network of interconnected pores. MgSO\textsubscript{4} increased the loss and storage modulus of Fg, as well as surface charge. The analysis of extracellular LDH showed a significant decrease in cell viability for macrophages cultured in 25 and 50 mM FgMgSO\textsubscript{4} scaffolds, either in M0 or M1 conditions. Importantly, FgMgSO\textsubscript{4} (10 mM) scaffolds increased the percentage of CD163 positive M2 cells and decreased the percentage of CCR7 positive M1 cells, in comparison with Fg alone and FgMgSO\textsubscript{4} (25 and 50 mM) scaffolds, both in unstimulated (M0) conditions and in response to LPS+IFN\gamma-driven macrophage M1 polarization. Mechanistically, NF-\kappa B p65 nuclear translocation, activated in response to M1 stimulation, was significantly decreased in macrophages cultured in FgMgSO\textsubscript{4} (10 mM) scaffolds, when compared with Fg scaffolds. The secretome of macrophages cultured in Fg and FgMgSO\textsubscript{4} (10 mM) scaffolds, either in M0 or M1 conditions, increased MSC osteogenic differentiation, when compared with secretome of plastic-cultured M0 and M1
macrophages. Also, MSC cultured directly on FgMgSO$_4$ (10 mM) scaffolds showed significantly increased calcium deposits, in comparison with those cultured on Fg scaffolds.

**Conclusion**

Our results show that doping Fg scaffolds with 10 mM of MgSO$_4$ modulates macrophage polarization towards an M2 phenotype and boosts MSC osteogenic differentiation. Thus, Fg scaffolds incorporating Mg$^{2+}$ ions modulate the host macrophage response. Currently, an animal model is being used to assess the *in vivo* behaviour of these scaffolds.

Hydrogels releasing sulfated hyaluronan improve impaired skin wound healing in condition of obesity induced diabetes by regulating inflammatory macrophage activities

Sophia Hauck¹, Marta Torregrossa¹, Ainur Kakpenova¹, Paula Zager¹, Norbert Haßler², Sandra Rother²,³, Stephanie Möller³, Matthias Schnabelrauch³, Jan C. Simon¹, Vera Hintze², Sandra Franz¹

Introduction
Non-healing wounds are stuck in a chronic inflammatory phase driven by uncontrolled infiltration and activation of macrophages leading to excessive tissue breakdown. Resolution of this unrestrained inflammatory loop represents an unmet challenge in the treatment of non-healing wounds. We have recently shown, that redirecting macrophage activities and resolving inflammation indeed rescues impaired wound healing in mice [1]. However, implementation of controlling macrophage functions in chronic skin wounds by an applicable immunomodulating wound dressing is still lacking [2]. Here, we developed immunomodulatory hydrogels containing sulfated hyaluronan (sHA) as immunoregulatory component for the modulation of inflammatory macrophage activities to control disturbed healing processes in chronic skin wounds. Hyaluronan (HA) is an essential component of the extracellular matrix and known to regulate inflammatory processes. Immunoregulatory properties of HA typically depend on its molecular size with high molecular weight HA (H-HA) being anti-inflammatory while the supposed pro-inflammatory activity of low molecular weight HA (L-HA) is controversially discussed.

Experimental Methods
Using in vitro assays with human and murine macrophages and skin ex vivo cultures, as well as mouse models of acute skin inflammation and of diabetic wound healing we show that immunoregulatory activities of HA can be uncoupled from its molecular size by chemical modification with sulfate groups and that artificially sulfated HA (sHA) possess potent anti-inflammatory activities towards inflammatory activated macrophages in vitro [1;2] and in skin inflammation in vivo which can be translated for the modulation of macrophage-driven impaired wound healing processes in skin.

Results and Discussion
First, we assessed immunoregulatory effects of sHA (48kDa) in comparison to H-HA (1174kDa), L-HA (48kDa) on human inflammatory macrophages (iMa) and analysed underlying molecular mechanisms using global quantitative proteomics, molecular modeling and targeted assays. We observed significant down-regulation of iMa activation by sHA that required rapid uptake of s-HA mediated by CD44, CD36 and Lox1. Induction of anti-oxidative proteins (SOD2, SOD3) and inhibition of transcription factor activation (pNFkB, pSTAT1, IRF5) resulted in reduced expression and release of pro-inflammatory cytokines (TNF, IL-12, MCP-1, IL-6) and upregulation of anti-inflammatory proteins (IL1RN, NMB). We further observed, that sHA interferes increased activation of inflammatory macrophage activities in conditions of an altered metabolic environment as it occurs in obesity, and in particular inhibits inflammasome activation in the macrophages. Skin ex vivo co-culture experiments showed that the reduced iMa activation by sHA had an impact on the induction of pro-inflammatory signals in the skin. We then, investigated the effect of sHA, H-HA and L-HA in the mouse model of imiquimod-induced acute skin inflammation. Administration of sHA reduced signs of skin inflammation (redness, scaling, epidermal thickness, immune cell infiltration) superior to H-HA. Monocytes/macrophages that we isolated from the inflamed tissue of sHA-treated skin showed reduced expression...
of inflammatory cytokines (IL-1b, TNF) while anti-inflammatory signals (IL-10, IL-1RA) were up-regulated. Finally, we designed hyaluronan/collagen (HA/coll)-based hydrogels that allow the continuous release of sHA over a period of at least 1 week. We tested the effect of sHA-releasing hydrogels in comparison to control hydrogels (no sHA release) in skin wounds of diabetic db/db mice, an established model for delayed diabetic wound healing. In a translational approach, we applied all hydrogels at day 3 post-wounding when inflammation in the wounds had already developed. The sHA-releasing hydrogels improved defective tissue repair in the diabetic mice with reduced inflammation and augmented alternative macrophage activation (down-regulation of IL-1b and up-regulation of IL-10, Relma), increased vascularization (up-regulation of VEGF, CD31) and accelearated new tissue formation (up-regulation of EGF, Ki67, granulation tissue).

**Conclusion**

In sum, our data show that sHA modulates pro-inflammatory macrophage activity in favour of pro-resolution functions and has the capability to improve outcome of disturbed skin wound healing.

Human protein-based sponges for fully xeno-free cell culture platforms

Sara C. Santos, Catarina A. Custódio, João F. Mano

University of Aveiro, CICECO-Aveiro Institute of Materials, Aveiro, PT

Introduction

Human platelet lysates (PL) are a source of growth factors and other bioactive proteins involved in cell growth, proliferation and differentiation processes. Therefore, they have been explored for multiple clinical and tissue engineering (TE) purposes [1,2]. We recently reported a bioactive human PL derivative precursor (PLMA) that can be cured upon light exposure to form a hydrogel with tuneable mechanical properties [2]. Moreover, the synthesized PLMA-derived hydrogels have proven to support distinct human derived cell cultures [2,3,4] that perform important biological processes such as growth, sprouting and migration. Indeed, we also demonstrated that PLMA cell culture platforms provide the controlled release of several growth factors that are essential for cell maintenance. Animal-derived serum is a ubiquitously used supplement in cell culture media. However, there are serious scientific and ethical concerns about the quality and safety as well as animal welfare [1]. Following a humanized and completely xeno-free strategy we propose PL sponges as a support for human 3D cell culture in animal serum free conditions.

Experimental Methods

PL methacryloyl (PLMA) were prepared by reaction of PL with methacrylic anhydride following a previously reported protocol [2]. PLMA hydrogels were formed by irradiating with UV light a solution of 15% (w/v) PLMA containing 0.5% (w/v) of Irgacure 2959. Afterwards, PLMA hydrogels were freeze-dried to produce PLMA sponges. PLMA-based sponges internal structural features were assessed by Scanning Electron Cryomicroscopy (CryoSEM). Pore size and swelling rate analysis of the scaffolds were performed. Human adipose-derived stem cells (hASCs) were seeded on top of PLMA sponges in order to assess the biological performance of such platforms. hASCs were cultured during 14 days with medium supplemented and no supplemented with FBS and tested for cell adhesion, viability, and proliferation at pre-determined time points (3, 7 and 14 days). As a control, a commercially available collagen type I sponge (SpongeCol®) was used.

Results and Discussion

PLMA hydrogels were already described as a platform for cell culture. Therefore, herein we proposed to produce PLMA sponges to be used as a scaffold for 3D human cell culture in a xeno-free environment. CryoSEM images (Fig. 1A) of PLMA sponges show an internal porous structure dependent on the concentration of PLMA. Swelling rate (Fig. 1B) results show complete re-swelling of the scaffolds after about 5 minutes in contact with PBS. Biological assays were performed by seeding of hASCs on top of PLMA sponges followed by culture in medium with and without animal-derived serum supplement. The cells were cultured for 14 days and as shown by fluorescence images of Live/Dead staining (Fig. 1C) hASCs exhibit high cell viability even when cultured in animal serum free conditions. Moreover, DAPI/Phalloidin staining images (Fig.1C) show the ability of cells to spread and form networks with neighboring cells when cultured on top of PLMA sponges. Cell proliferation and viability assays were performed by DNA quantification (Fig.1D) and MTS test (Fig.1E), respectively. Results show an increase in DNA content up to 14 days of cell culture even with no animal serum supplementation meaning that hASCs are able to proliferate when cultured in PLMA sponges. In addition, MTS test results also revealed the ability of hASCs to stay viable and proliferate. SpongeCol®, a commercially available collagen type I based sponge, was used as control in the biological performance tests. Results show that cells were not able to adhere and proliferate when SpongeCol® discs seeded with hASCs were cultured in medium without FBS. Therefore, such results support the idea that PLMA-based sponges have great potential to be used as platforms to support 3D xeno-free cell culture.
Conclusion
Our results showed that PLMA sponges are a promising platform for human 3D cell culture. Of note, they offer the possibility to culture cells avoiding the use of animal derived serum supplements. It is also a platform that could have an autologous origin, being adequate to produce personalized matrices for in vivo applications with no risk of cross-reactivity, immune reaction, or disease transmission.

Production and assessment of three-dimensional collagen scaffolds with controlled pore alignment and orientation for tissue engineering applications

Huijie L. Zhang, Ruth E. Cameron, Serena M. Best

University of Cambridge, Materials Science and Metallurgy, Cambridge, GB

Introduction

Ice-templating has been used widely in the production of porous collagen scaffolds for tissue engineering. Complex architectures can be achieved through careful design of the temperature profiles during the freezing process and using this technique, it is possible to fabricate biomimetic scaffolds for specific tissue repair applications. However, the random nature of ice nucleation can create issues with processing-structure-property reproducibility [1]. In this work, we describe a method to produce collagen scaffolds with controlled pore alignment and we offer a modelling design toolkit for rapid prediction of pore orientation. The structure of the scaffolds have been characterised using X-ray microtomography (μCT), generic cell studies have been carried out to assess cell migration, and the effects of pore architecture on the mechanical properties are reported.

Experimental Methods

1 wt% collagen in 0.05 M acetic acid was directionally cooled on custom-made device with a copper cold finger, and the structures were imaged and studied by μCT. The scaffolds were chemically crosslinked with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide and N-hydroxysuccinimide (EDC/NHS) at 10% concentration of that reported previously in the literature [2]. The elastic modulus was then measured by compression tests while scaffolds were fully immersed in water, using a 25 N load cell and crosshead speed of 5 mm/min. The scaffolds were tested in two directions in order to study the effects of pore orientation on stiffness, one along the aligned direction of pores and the other one perpendicular to the pore alignment (Fig. 1a). Additionally, a thin film resistance temperature detector was placed on polycarbonate mould as an external heating source to manipulate pore orientation. The heat transfer during the freezing process was predicted by finite element modelling (FEM) via COMSOL. Preliminary cell studies were undertaken using human dermal fibroblasts to assess cell migration within the three-dimensional scaffolds (1x1x1 cm³ cube) and results were recorded on Days 7, 10 and 14.

Results and Discussion

The technique successfully produced scaffolds with very high pore alignment. A small isotropic region was noticed at the base of the sample closest to the cold finger. The average pore size in the bulk of the sample increased with decreasing cold finger cooling rate. Pore sizes that could be produced ranged from 50-160 μm and were confirmed to be suitable for cell migration over a range of different time points. The mechanical test results for samples taken from the aligned regions showed that elastic modulus varied with direction from approximately 1 kPa in the x-y plane (Direction 2) to 8 kPa when samples were loaded in the z direction (Direction 1) (Fig. 1b).

The addition of a heat patch to the sample mould was designed to control the pore orientation in a precise manner, and this was modelled using FEM (Fig. 2a). The predicted growth of the ice freezing front was found to match well with pore orientation as demonstrated by the μCT images (Fig. 2b-c). A heatmap of the z-direction stiffnesses obtained for 10% EDC/NHS crosslinked samples taken from nine different regions is shown in Fig. 2d. The results combined, provide a design toolkit to rapidly achieve specific structures with desired elastic modulus.

Conclusion
The use of a custom-built freezing rig has allowed the production of scaffolds with highly aligned pores, and by additionally adding a heat patch, the pore orientation could be controlled. Using this method, it is possible to recapitulate architectural features of tissues, such as myocardium, nerve tissue and skeletal tissues. The flexibility of this technique for tissue engineering applications was demonstrated by (1) the range of pore sizes were available (50-160 μm) for cell invasion and vascularisation; (2) elastic modulus values in the kPa range, with the potential to match the properties of target tissues.

Combination of QK peptide and proteolytic sequences for the promotion and direction of angiogenesis in Elastin-Like Recombinamer (ELR) hydrogels

Fernando González-Pérez, Arturo Ibáñez-Fonseca, Matilde Alonso, José C. Rodríguez-Cabello

Universidad de Valladolid, Valladolid, ES

Introduction
The development of three-dimensional (3D) systems with the capacity to promote and spatio-temporally direct the cell infiltration and vascularization in biological tissues hold promise in the area of tissue engineering and regenerative medicine (TERM). To this purpose, fast (GTAR) and slow (DRIR) proteolytic sequences sensitive to uPA (urokinase plasminogen activator) enzyme and the QK vascular endothelial growth factor mimetic peptide have been exploited showing their potential activity for maintaining cell signalization for colonization [1] and promoting angiogenesis [2], respectively. Hydrogels based on Elastin-like recombinamers (ELRs) can be exploited in this regard, their bioactiveness can be tailored on-demand allowing to genetically encode proteolytic sequences into their polypeptide backbone as well as to covalently tether bioactive residues such as the QK peptide.

Experimental Methods
A pair of ELRs containing either the GTAR or DRIR sequence was designed and decorated with the QK pro-angiogenic peptide and click catalyst-free crosslinkable domains to produce the intended hydrogels. In vitro studies allowed to determine the effect of QK peptide over endothelial cell morphogenesis, whereas the elastic modulus of the prepared hydrogels was evaluated by rheology techniques. Coaxial binary ELR tubular constructs were designed to assess the ability of the designed ELRs to guide degradation and vascularization in vivo. In detail, scaffolds displaying the DRIR and the GTAR on the outer and inner part of the tube containing the QK peptide in the inner, both and none of them were fabricated. Cell colonization and vascularization was analyzed by histology and immunohistochemistry (IHC) upon subcutaneous implantation in Swiss CDR-1 mice with time.

Results and Discussion
In vitro studies revealed the pro-angiogenic effect of QK peptide on endothelial morphology. Coaxial binary ELR tubular constructs exhibited a marked increase in cellular colonization and degradation on the inner and fast degradable ELR tube, when compared to the outer part with slow cleavage kinetics. Histology and IHC results of in vivo studies further showed the QK peptide effect triggering high vascularization. Combination of both factors, namely proteolytic sequences and QK peptide, revealed a synergistic effect over angiogenesis process in vivo.

Conclusion
ELR hydrogels displaying proteolytic sequences and decorated with the QK peptide have reported to enhance colonization and vascularization in vivo in a pre-designed way. These results pave the way for developing ELR-based scaffolds for TERM applications with spatio-temporally controlled vascularization in the achievement of an optimal tissue repair.

Bioactive glasses represent a revolutionary technology in the healthcare sector. Numerous bioactive glass formulations have found applications to treat bone and dental injuries and, over the years, applications in soft tissue repair and drug delivery have emerged. This symposium is focused on bioactive glass advances based on the controlled release of biologically active ions for applications in soft tissue repair and wound healing, including skin, muscle and nerve tissue regeneration.

Prof. Aldo R. Boccaccini and Prof. Jonathan Massera are well known researchers in the field of bioactive glasses. They will be the keynote speakers in this symposium covering different aspects of the processing and characterisation of bioactive glasses in the field of tissue engineering. They will provide a broad overview of the field, highlighting challenges and opportunities of bioactive glasses in soft tissue regeneration.
Bioactive glasses-based biomaterials with potential in soft tissue engineering

Jonathan Massera

Tampere University, Faculty of Medicine and Health Technology, Tampere, FI

Introduction
Silicate-bioactive glasses have been extensively studied for bone tissue engineering. The “traditional” bioactive glasses (i.e. 45S5 and S53P4) have found space in clinics: from bone filler to ocular implants. The benefit of using bioactive glasses, lies in the ability to tailor the composition to control the dissolution/reaction rate or thermal properties (fiber drawing, scaffold sintering). More importantly, the ease to incorporate ions of therapeutic interest has led to remarkable discoveries. Indeed, control release of strontium, zinc, magnesium, silver, copper or boron, just to cite a few, has enabled to process materials with excellent osteogenesis, angiogenesis or antimicrobial properties [1]. However, while bioactive glasses, in bone related applications, was promising, the difficulties in shaping the grafts into the exact patient’s defect has, to some extent, limited their clinical use. Nevertheless, it appears clear that the unique properties of bioactive glasses are still of interest. Indeed, researchers are constantly studying their potential use in composites or hybrid biomaterials [2].

While many questions remain to be answered to better grasp the full potential of bioactive glasses in hard tissue regeneration, some researchers already devoted their energies to explore new avenues for such uniquely tailorable material. For instance, researchers have explored the potential of bioactive glasses in soft tissue regeneration. For example, tubular phosphate glass fibres have been found to give a promising alternative to end-to-end suturing in facial nerve reconstruction [3]. More recently, borate bioactive glass nanofibers (Mirragen™) has proved to be excellent in treating long-term venous stasis ulcer in diabetic patients who were irresponsible to conventional treatments [4].

These new results are opening new horizons for the use of bioactive glasses in clinics.

RESULTS AND DISCUSSION
In the recent years our work has focused on designing materials that, not only could be applicable to hard tissue engineering but also soft tissue. In order to develop innovative construct; able to not only support, but also trigger, soft tissue regeneration a survey study where bioactive glass (13-93) extract was performed to culture various cell types (adipose stem cells, lung fibroblasts, or uroepithelial cells). The hASCs and the WI fibroblasts remained viable in the extracts. Li and Sr appeared to have positive impact on the cell’s proliferation. However, the high Ca concentration inhibits the proliferation of UE cells.

Tubular structures (PLA/bioactive glasses) were efficiently produced with a controlled porosity (>50%) and pore size ranging from 100 to 400 µm (Fig 1). The glass (13-93) dispersion was found to be homogeneous within the structure. The glass loading (25-35 wt%) was consistent with the target loading. The presence of bioactive glass allowed to prevent acidification of the environment while contributing to the faster degradation of the polymer matrix. Hybrid biomaterials (wood based nanofibrils and bioactive glasses or gelatin/GPTMS/bioactive glasses) were also developed into inks for bioprinting. In this study we demonstrated the possibility to develop an ink that can be printed into the shape of a mandible (Fig.2) while maintaining cell viability. Composites and hybrids could have potential for nerve regeneration, urethra or trachea repair.

Finally, while ions can trigger signalling pathways leading to osteogenesis or angiogenesis, in recent years the use of light to direct tissue healing as gained increasing interest. As such, biophotonic bioactive glasses were develop. While their characterization is only starting, the ability to design material with persistent luminescence in wavelength...
ranging from UV to NIR has high potential in tissue engineering. Indeed, it was shown by Liu et al. that micro-patterned light emission can enable to orientate cells and create anisotropic cell sheets, thus mimicking the complex structure of soft tissue such as muscles, artery, and nervous system [5]

**Conclusion**

Bioactive glasses have been widely studied in hard tissue reconstruction. However, their potential in soft tissue is nowadays being investigating. Bioactive glass, when combined with natural or synthetic polymeric matrices, enables to design materials for a wide range of application (from restoring the nervous system to healing urethra defects). The benefit of ions released from the bioactive glass is undeniable. Combining controlled ion release, biophotonic and tissue engineering may open the door to significant breakthrough in soft tissue regeneration.

Applications of inorganic materials in soft tissue regeneration: progress and challenges

Aldo R. Boccaccini

University of Erlangen-Nuremberg, Institute of Biomaterials, Erlangen, DE

In 2021 the biomaterials community celebrates 50 years of bioactive glass (BG), the first man-made material capable to bond to tissues, discovered by the late Prof. Larry L. Hench [1]. It is well-known that the traditional applications of BGs have been in bone substitution, for example as bone defect filler, small bone and dental implants and as bioactive coatings for orthopedic and dental applications. Moreover BGs emerged as attractive inorganic materials for bone tissue engineering (TE) given their bone bonding ability and the effect of BG dissolution products on osteogenesis. More recently, BGs have started to be considered in soft TE and wound healing. Such TE applications exploit the biochemical interactions occurring at the interface between BG surfaces and the biological environment, which lead to the (controlled) release of biologically active ions to activate specific cellular pathways [2]. As an example, the effect of selected metallic ions on vascular endothelial growth factor release from stem cells has been demonstrated to indicate the angiogenic potential of BGs.

For applications in soft TE, BGs must be "softened" which is achieved by smart combination of BGs, usually in particulate or fibre form, with suitable biodegradable polymers. Processing techniques for biopolymer scaffolds such as freeze-drying, electrospinning and 3D printing, are commonly applied to develop BG containing scaffolds with suitable mechanical properties, porosity and degradation behaviour for soft tissue repair applications. Typical examples of such composites for a variety of soft TE applications, including wound healing, nerve and muscle regeneration will be discussed.

In the second part of the presentation, applications of BGs (e.g. as mesoporous nanoparticles) in the field of 3D bioprinting (biofabrication), which have been emerging in the last few years, will be introduced. Such applications expand the scope of applications of BGs in TE. In this context, the progress in the development and characterization of cell laden hydrogel-BG scaffolds by 3D bioprinting will be discussed. Examples of such applications will be presented highlighting the novel developments of hydrogel-bioactive glass composites as innovative multimaterial bioinks for cell encapsulation and for biofabrication of TE scaffolds of increasing complexity [3]. The author’s views on the challenges and opportunities for further research in the field will be presented.

Restoring bone regeneration in diabetic (hyperglycaemic) environments with HIF mimetics and bioactive glasses

Azadeh Rezaei, Joel Turner, Kaveh Shakib, Gavin Jell

University College London (UCL), Division of Surgery and Interventional Science, London, GB

Introduction
Diabetic patients have an increased risk of fracture and non-union fracture healing\(^1\). Diabetic patients and hyperglycaemic conditions have also been shown to cause an impaired hypoxia inducible factor-1α (HIF-1α) and reduced cellular response to low oxygen conditions (hypoxia)\(^2\). Whilst the HIF pathway is undoubtedly important in angiogenic signalling and restoring the vasculature in bone repair\(^3\), the direct role of HIF-1α on osteoblast behaviour and mineralisation in both normal and hyperglycaemic conditions is unclear. There may also be differing effects between hypoxia and HIF stabilisation. Using a multidisciplinary characterisation approach (biological, ultrastructural and microstructural quantitative techniques), this study investigates the role of hypoxia (1% O\(_2\)) and HIF-stabilisers (CoCl\(_2\) and dimethyloxalylglycine (DMOG), on bone formation, in normal and high glucose in vitro environments. Moreover, the effect of controlled cobalt ion release via cobalt bioactive glasses (CoBGs) on hyperglycaemic nodule formation will be studied with the aim to determine if targeting HIF pathway can promote bone regeneration in diabetic patients.

Experimental Methods
Primary osteoblasts were isolated from neonatal Sprague-Dawley rats and cultured in α-MEM supplemented with 2 mM β-glycerophosphate, 10nM dexamethasone, and 50μg/mL ascorbate. Once confluent, cells were exposed to normal (5.5mM), moderate (25mM) and high (50mM) glucose environments and kept in normoxia (20% O\(_2\)) and hypoxia (1% O\(_2\)) for 21 days. Cells were also treated with CoCl\(_2\) (12.5, 25 and 50μM), DMOG (250,500 and 1000μM) and CoBG conditioned medium (containing 0, 12.5 and 25μM cobalt) in the various glucose conditions. Metabolic activity, proliferation rate, alkaline phosphatase (ALP) activity and vascular endothelial growth factor (VEGF) expression. Bone nodules were characterised using Alizarin Red staining, scanning and transmission electron microscopy (SEM,TEM), Raman spectroscopy and interferometry for quantitative analysis of the nodule size.

Results and Discussion
Moderate and high glucose conditions inhibited nodule formation. Hypoxia (1% O\(_2\)), inhibited nodule formation in all glucose levels. HIF stabilisers (CoCl\(_2\), DMOG and CoBG) and CoBG conditioned media did not prevent nodule formation in normal glucose, and restored nodule formation in hyperglycaemic conditions (as determined by size)(Figure 1. a&b) All HIF stabilisers enhanced HIF-1α expression and VEGF production in moderate and high glucose environments. Glucose level did not have any effect on ALP activity.

Conclusion
A hyperglycaemic bone model was developed that demonstrated that hyperglycaemic environments inhibit bone nodule formation, whilst the use of HIF mimetics (CoCl\(_2\), DMOG and CoBG) restored bone nodule formation in these conditions. This develops our understanding of the role of the HIF pathway in bone mineralisation and the creation of biomaterials or tissue scaffolds designed for patients with impaired bone regeneration due to an impaired HIF-1α pathway.
Figure 1
The effect of best concentrations of HIF mimetics (Co 12.5µM and DMOG 500µM) on nodule formation in low, moderate and high glucose environments. Alizarin Red calcium staining showed that non-toxic range of CoCl_2 and DMOG restore bone formation in moderate and high glucose environments (scale bar is 200nm)

Sr-containing Mesoporous Bioactive Glasses Bio-Functionalized with ICOS-Fc: an advanced tool to target osteoporotic fractures

Sonia L. Fiorilli¹, Mattia Pagani¹, Elena Boggio²,³, Casimiro L. Gigliotti²,³, Chiara Dianzani⁴, Carlotta Pontremoli¹, Giorgia Montalbano¹, Umberto Dianzani³, Chiara Vitale-Brovarone¹

¹ Politecnico di Torino, Department of Applied Science and Technology, Turin, IT; ² NOVAICOS s.r.l.s, Novara, IT; ³ Università del Piemonte Orientale, Department of Health Sciences, Novara, IT; ⁴ Università di Torino, Department of Drug Science and Technology, Torino, IT

Introduction

Osteoporotic bone fractures represent a critical clinical issue and need personalized and specific treatments. The development of smart nano-biomaterials able to synergistically combine chemical and biological cues to impart specific therapeutic effects (i.e., pro-osteogenic, anti-clastogenic) can provide novel and effective medical solutions to target compromised bone remodeling. Recently, strontium-containing mesoporous bioactive glasses (Sr-MBGs) proved to exert a role in the activation of both osteoblast (Ob) and osteoclast (Oc) cell signaling pathways, which allows the promotion of osteoblast replication, differentiation, and survival while downregulating osteoclast activities [1]. In this contribution, with the aim to open new perspectives for advanced treatments of osteoporotic fractures, Sr-MBGs have been bio-functionalized with ICOS-Fc, a molecule able to reversibly inhibit Oc activity. The proposed strategy (Figure 1) aims to combine in single device the intrinsic properties of MBGs with the specific effect exerted by ICOS-Fc to deliver a multifunctional platform (i.e., bioactivity, stimulation of osteoblast cells, inhibition of osteoclast activity) for the treatment of osteoporotic fractures.

Experimental Methods

The extracellular portion of human ICOS was cloned as fusion protein to the human IgG1 Fc region, generating ICOS-Fc fusion protein, according to Di Niro et al. [2]. Sr-containing MBGs (10% mol.) were synthesized as reported in ref [3] and post-modified with ((3-aminopropyl)silanetriol to expose surface amino groups able to react with the carboxyl groups present on Fc residue of ICOS-Fc molecule. The Sr-MBGs after ICOS-Fc grafting were fully characterized by scanning electron microscopy, N₂ adsorption-desorption analysis, FT-IR spectroscopy, thermogravimetric analysis. Flow cytometry (Attune NxT, Life Technologies, Carlsbad, CA, USA) was performed to assess the presence of ICOS-Fc molecule on MBG surface and an in house-developed ELISA-Like Assay was performed to prove the retention of ICOS-Fc functionality upon grafting and the binding stability in aqueous medium. Cell Migration Assay were carried out in the Boyden chamber (BD Biosciences, Milan, Italy) migration assay by using ICOSL positive cell lines PC-3 (prostate cancer) and U2OS (osteosarcoma). The ability of grafted ICOS-Fc to inhibit osteoclast differentiation and function was assessed by monitoring the differentiation of monocyte-derived osteoclasts (MDOCs) up to 21 days.

Results and Discussion

N₂ adsorption analysis, FT-IR spectroscopy and flow-cytometry analysis proved the successful grafting of ICOS-Fc on the surface of Sr-containing MBGs, which were also proved to retain the peculiar ability to release osteogenic strontium ions and an excellent bioactivity after functionalization. An ELISA-like assay allowed to confirm that grafted ICOS-Fc molecules were able to bind ICOS-L (the ICOS binding ligand) and evidenced the stability of the surface binding to hydrolysis in aqueous environment up to 21 days. The migration assay demonstrated that, in analogy to the free form of the molecule, PC-3 and U2OS cell (ICOSL positive) migration was affected by ICOS-Fc grafted Sr-MBGs (in a dose dependent manner), at variance with HOS (ICOSL negative) cell migration, confirming the specificity of ICOS-Fc to bind ICOSL. Furthermore, grafted ICOS-Fc was able to strongly inhibit the differentiation of MDOCs.
which after the treatment showed a round shape and a morphology similar to a spindle. The strong inhibitory effect was also proved by the downregulation of DC-STAMP, OSCAR, and NFATc1 expression, as evidenced by real-time PCR after 21 days.

**Conclusion**

The functionality of ICOS-Fc molecule anchored to Sr-containing MBGs was confirmed by a custom-made ELISA-like and the binding stability was assessed up to 21 days of soaking in culture medium. The inhibitory effect of grafted ICOS-Fc on cell migratory activity was demonstrated by using ICOSL positive cell lines and the ability to inhibit osteoclast differentiation and function confirmed (in analogy to the free form of the molecule) by monitoring the differentiation of MDOCs, which revealed a strong inhibitory effect, also proved by the downregulation of Oc differentiation genes.

The obtained results are very promising and pave the way to personalized clinical solutions for bone regeneration of fractures in osteoporotic patients.

3D plotted composites consisting of calcium phosphate bone cement and mesoporous bioactive glass with drug delivery function

Richard F. Richter, Tilman Ahlfeld, Michael Gelinsky, Anja Lode

TU Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE

Introduction
Calcium phosphate bone cements (CPC) and mesoporous bioactive glasses (MBG) are two well studied biomaterial groups widely under investigation concerning their applicability to treat bone defects. Recently, a CPC-MBG composite was developed in our group which showed promising results with respect to cell response in vitro and new bone formation in vivo [1,2]. Unlike conventional powder/liquid cements, the used CPC is a hydrophobic carrier-liquid (cl) based paste; it maintains a good injectability until contact with aqueous environment that allows its application for extrusion-based additive manufacturing techniques like 3D plotting [3]. By variation of the amount of cl, it is possible to prepare CPC-MBG composites that are suitable for 3D plotting as well and the advantage of 3D plotted scaffolds of such composites compared to bulk scaffolds regarding ion release were shown recently [4]. The aim of the present study was to analyse the degradation behavior of different CPC-MBG composites and the influence of the single components in detail. Furthermore, due to their high specific surface area, MBG are promising candidates to be used as carrier system for proteins, growth factors or anti-inflammatory agents. This study therefore aimed to develop a method that allows to load MBG with proteins and incorporate them into CPC pastes without affecting the plottability.

Experimental Methods
CPC and strontium-modified CPC pastes were provided by INNOTERE GmbH, Germany and MBG particles (< 45 µm) were prepared as previously described [5]. Additionally, strontium-modified MBG particles were synthesized by complete substitution of the calcium part with strontium. To study the degradation behavior, mass loss, change of porosity and ion release of 3D plotted scaffolds (Figure 1) made from different CPC-MBG combinations were evaluated and compared to those of 3D plotted scaffolds or samples made of the single components. Afterwards, a protocol for loading MBG particles with proteins was developed. The protein uptake kinetics for different types of MBG and various initial protein concentrations were studied using lysozyme as a model protein. The release of lysozyme from pure MBG and from 3D plotted CPC-MBG scaffolds was investigated and it was verified whether the released lysozyme retained its biological activity. Finally, this developed protocol was transferred to the proangiogenic growth factor VEGF (Vascular Endothelial Growth Factor) and again the release and biological activity were analysed and verified.

Results and Discussion
Based on our previous work it was possible, by varying the amount of cl, to increase the addition of MBG to 16 wt% and maintain the extrudability of the composites. Composites with at least 8 wt% MBG showed a significantly higher initial porosity and significantly greater mass loss after degradation. Regarding the ion release, again composites with a minimum addition of 8 wt% MBG showed a significantly improved release of ions, e.g. Sr²⁺ compared to pure strontium-modified CPC scaffolds.

Additionally, a protocol for loading MBG particles with proteins was successfully developed, that allowed the incorporation of such functionalised MBG particles into CPC pastes without impairing the plottability. The protein
release from plotted scaffolds could be varied by addition of different amounts of protein-laden MBG into the composite (Figure 2) and the released lysozyme from pure MBG and from plotted composite scaffolds maintained its biological activity. Finally, the established protocol for protein loading of MBG was successfully applied to VEGF and the release from MBG and CPC-MBG composites, while retaining the biological activity, was demonstrated.

**Conclusion**

In this study, we showed the development of a functionalised CPC-MBG composite applicable for 3D plotting that allows fabrication of patient-specific implants. Furthermore, the results of ion and protein release showed the high flexibility of this material system and suggest it as a promising material toolbox to treat bone defects.

Federico Soria
European Network of Multidisciplinary Research to improve the Urinary Stents, ENIUS Chairman. CA16217 COST Actions, Brussels, BE

Antimicrobial biomaterials Infection is a serious healthcare issue, and the current pandemic times are a huge proof of that. Antimicrobial biomaterials have always been a strong focus of both the Portuguese and Spanish scientific biomaterials community. This symposium highlights different fields of research in this topic, including both coatings and new designs of polymeric and metallic antimicrobial biomaterials, and ranging several biomedical applications, such as the urinary stents presented by our keynote speaker Federico Soria, as well as bone implants, ventilators, and protection masks.
Urinary stents. Side effects in patients. Why do we need to improve them? Biofilm, Coatings and new stent designs.

Federico Soria¹², Julia E. de la Cruz¹

¹ Jesus Uson Minimally Invasive Surgery Centre, Endoscopy, Caceres, ES; ² European Network of Multidisciplinary Research to Improve Urinary Stents. Chairman. CA16217, Brussels, BE

Urinary stents are an essential tool in the urological armamentarium. They have proven their efficacy in maintaining urine drainage, preventing or relieving ureteral or urethral obstruction caused by both intrinsic and extrinsic circumstances of the urinary tract. Indications include urinary calculi, urinary obstructions, benign or malignance strictures, urinary fistulas, retroperitoneal fibrosis and neoplasms. Urinary stents play a fundamental role in pre- and postoperative endourological management of ureteral lithiasis, as well as in reconstructive surgery of the urinary tract. Stents acts as an internal scaffold favouring tissue healing and ensuring urinary drainage (1).

However, its use is not free of side effects and complications that may affect the quality of life of up to 80% of patients with ureteral stents (2). In addition to the impairment of the patients’ quality of life, complications such as incontinence, nocturia, vesicoureteral reflux, haematuria, as well as inflammatory reactions causing obstruction of the urinary tract can also occur. Since urine represents a hostile environment for any biomaterial, the stent surface provides the ideal substrate for bacterial colonization, biofilm development and encrustation (2). Biofilm and encrustation, in addition to causing irritation and inflammation of the urothelium, worsen the symptoms described above, may also cause obstruction, stent malfunction and the appearance of infections with clinical symptoms, resulting in emergency replacement or removal of the stents, the need for antibiotic therapy and even hospitalization (3).

So, where can we focus research to improve stents, reduce their side effects and improve patients’ quality of life? Mainly, the cornerstones for the improvement of urinary stents focus on: 1. Preventing the formation of biofilm and encrustation on the surface of the stents (3); 2. Developing new coatings with antifouling and antibacterial properties like Antimicrobial peptides (AMPs), and coatings which are able to release drugs into the urinary tract (4); 3. Designing new stents that are better adapted to the anatomy and physiology of the urinary tract (5); 4. Providing stents with new properties such as the biodegradability of their biomaterials to avoid the necessary re-operation that is currently mandatory with these medical devices (5).

It is therefore necessary to develop multidisciplinary research groups to advance in the improvement of current urinary stents, as only from an interdisciplinary approach will it be possible to overcome the present limitations in this area of knowledge, which brings together researchers, urologists, bioengineers, patients and industrial partners (4).

Manufacture of open-cell titanium structures with antibacterial properties

Elia Vidal, Elisa Ruperez, Daniel Rodriguez-Rius

Technical University of Catalonia, Dept. Materials Science and Engineering, Sant Adrià del Besòs, ES

Introduction
The biomechanics of the skeletal system require implants and prostheses to support high mechanical loads. For this reason, these implants are usually manufactured with metallic biomaterials (stainless steel, cobalt-chromium alloys or titanium alloys) with high mechanical resistance. These biomaterials, however, can present problems such as stress shielding, due to their high stiffness, which can result in bone resorption and possibly implant failure [1]. Porous titanium structures have attracted considerable attention since they reduce the stress shielding of the implant towards the bone by presenting an apparent elastic modulus lower than that of the bulk material, and which can be modulated depending on the structure generated. The manufacture of such structures, however, is not easy, due to the high reactivity of titanium and its high melting point. Despite this, porous structures have been manufactured using techniques such as space holder, laser sintering or direct ink writing of metallic inks [2]. Another prominent problem in metal implants and prostheses is the possible appearance of infections in the tissues surrounding the implant, either due to a nosocomial infection in surgery or due to the formation of a biofilm on the surface of the biomaterial by opportunistic planktonic bacteria. In orthopedic applications that require a bone-implant junction, the formation of the bacterial biofilm prevents proper osseointegration and can lead to prosthesis failure. One strategy to avoid this is to cover the prosthesis with a layer with antibacterial properties. There are various possibilities to generate antibacterial properties, such as using metal ions such as silver, doping the surface with polymers or peptides such as AMPs, depositing a layer with antifouling effect, or using a layer as a carrier for an antimicrobial agent [3]. Calcium phosphate can be used as a carrier that releases antibacterial drugs.

Experimental Methods
Porous titanium samples were prepared by 3D printing using Pluronic 127 hydrogel as a binder. The samples were sintered at 1250°C under ultra high vacuum in a modified Hobersal tube furnace. Mechanical compression tests were carried out with an MTS Bionix 858 traction-compression testing machine specially designed to work on biomaterials, with the added ability to perform fatigue and torsion tests. This machine was equipped with a 25KN MTS load cell. The equipment was controlled by connection to a PC equipped with a TestStar II® software package. 6 different samples were tested, taking as the maximum value of compressive strength either the moment when a fracture was detected or the moment when the deformation exceeded 33%.

Pulsed electrodeposition was studied as a coating process, in order to manufacture a calcium phosphate (CaP) coating on porous titanium samples in a single step, doped with an antibacterial agent. The electrolytic process was carried out using the titanium sample as cathode and a solution of Ca(NO₃)₂·4H₂O and NH₄H₂PO₄ as electrolyte. Different conditions of temperature (40-60°C), pulse polarity (unipolar-bipolar) and current density (2-5 mA/cm²) were studied. In order to avoid possible infections around the implant, the CaP coating has been used as a platform for the controlled release of drugs. The coating was doped with Chlorhexidine Digluconate (CHX) by codeposition and adsorption.

The physicochemical properties of the coating were determined by SEM/EDS, FIB, XRD and microCT. In vitro studies made it possible to evaluate the antibacterial response to the S. aureus strain.

Results and Discussion
The morphological analysis of the samples showed that different microstructures can be obtained by varying the process parameters (Figure 1).

Page 518 of 2028
During the compression tests, no fracture occurred, so the value of compressive strength was measured when reaching the established deformation limit of 33%. The average value registered has been 235 MPa. This shows that this material is very ductile. An average modulus of elasticity of 7.5GPa was calculated, with a standard deviation of 0.4GPa. In contrast, the incorporation of CHX did not affect the morphology of the coating. Finally, in the in vitro tests, good results of antibacterial activity of the coating were obtained.

**Conclusion**

A promising solution have been shown for the antibacterial biofunctionalization of titanium orthopedic implants manufactured with a porous structure that limits the problem of stress shielding.

A wide-spectrum antimicrobial coating to fight multi-species biofilms in ventilator-associated pneumonia infections

Diana Alves, Maria O. Pereira, Susana P. Lopes

University of Minho, Centre of Biological Engineering, Braga, PT

Introduction
Ventilator-associated pneumonia (VAP) is currently one of the top five most common nosocomial infections and it has been associated with prolonged hospitalization and high morbidity and mortality rates [1]. The use of an endotracheal tube (EET) constitutes the major risk factor for the development of this condition, since it is the airway access point for microorganisms. Indeed, microorganisms’ migration along and within the inside of the EET results in a so-called biofilm which, combined with a network of secretions, will be ultimately leaked down to lungs [2]. Biofilm formation is a crucial step in the pathogenesis of VAP, as microbial cells within a biofilm enlace themselves in a self-produced matrix of extracellular polymeric substances, conferring them protection against both antimicrobial treatments and the host immune system. Furthermore, the polymicrobial nature of biofilms formed on the surfaces of ETT has been increasingly addressed [3].

Experimental Methods
This study aimed to design a wide-spectrum antimicrobial coating to impart endotracheal tubes with the ability to prevent the adhesion and subsequent biofilm formation of several microorganisms commonly associated to VAP, without compromising the viability of lung cells. For that, ciprofloxacin (CIP) and chlorhexidine (CHX), two compounds with different action spectra, were co-immobilized on polyvinyl chloride (PVC) surfaces to obtain a dual-drug release antimicrobial coating. Immobilization was performed using a one-step polydopamine (pDA)-based approach, in which PVC substrata were simply immersed on a solution of dopamine dissolved together with CHX and/or CIP, allowing their incorporation throughout the full thickness of the pDA film.

Results and Discussion
The antimicrobial performance of modified surfaces was evaluated against 5 bacterial species (Pseudomonas aeruginosa, Acinetobacter baumannii, Klebsiella pneumoniae, Staphylococcus aureus and Staphylococcus epidermidis) and 1 yeast species (Candida albicans) as individual, dual and triple consortia. Regarding the single-species colonisation of PVC surfaces, results showed that after 24 h of exposure, co-immobilization of CHX and CIP caused a significant reduction (more than 4 Log) in the number of bacterial cells adhered to the surfaces, while being less efficient against the adhesion of C. albicans (0.5 Log). It is worth mentioning that the combination of CIP and CHX in the proposed coating resulted both in a synergetic effect against P. aeruginosa, A. baumannii and C. albicans and in a facilitative effect against all tested species. Coatings were also tested against the dual adhesion of P. aeruginosa in consortium with all tested species. In general, results showed that the antimicrobial effect observed for each species was not compromised by the presence of any other species. Inhibition of C. albicans was actually more effective (approximately 2 Log reduction) when combined with P. aeruginosa. When the antimicrobial coating was exposed to a triple consortium comprised by P. aeruginosa, S. aureus and C. albicans, its antimicrobial effect against bacterial species was not compromised and it was able to inhibit the adhesion of yeast by about 1 Log. In terms of biocompatibility, the amount of CHX and CIP released from the surfaces did not compromise the growth of lung epithelial cells. Surfaces functionalization with CIP and/or CHX was confirmed by SEM, AFM and contact angle measurements.

Conclusion
In conclusion, the combination of CIP and CHX, using dopamine chemistry, results in a coating with antimicrobial activity towards a wide spectrum of microorganisms commonly associated to VAP. Therefore, this approach holds great potential to be applied in EET, proving to be important in the fight against VAP.

Multifunctional coatings to improve soft tissue integration of metallic implants

Adriana Vilaça¹,², Rui M. Domingues¹,², Hanna Tiainen³, Barbara B. Mendes¹,², Alejandro Barrantes⁴, Rui R. Reis¹,², Manuela E. Gomes¹,², Manuel Gomez-Florit¹,²

¹ University of Minho, 3B's Research Group, Barco, PT; ² ICVS/3B’s-PT Associated Laboratory, Braga/Guimarães, PT; ³ University of Oslo, Department of Biomaterials, Oslo, NO; ⁴ University of Oslo, Oral Research Laboratory, Oslo, NO

Introduction
Metallic implants are widely used in diverse clinical applications to aid in recovery from lesions or to replace native hard tissues.[1] However, the lack of integration of metallic surfaces with soft tissue interfaces causes the occurrence of biomaterial-associated infections, which can trigger a complicated inflammatory response and, ultimately, implant failure. Therefore, these devices would benefit from engineered surfaces with favorable soft tissue integration properties that promote the development of a sufficient biological seal between the metal implants and the surrounding soft tissue, to create effective barriers between internal and external environments preventing bacterial invasion, tissue inflammation, loosening and failure of the implants.[2,3] We hypothesized the development of multifunctional surfaces that mimic the anisotropic organization of soft tissues and, at the same time, favor cell adhesion, modulate the inflammatory response and inhibit bacterial adhesion and/or growth on the implant surfaces would increase implants long-term success (Figure 1).

Experimental Methods
Anisotropic radial nanopatterns were produced on polished titanium (Ti) surfaces by spin coating cellulose nanocrystals (CNC) at high speed. Then, in order to introduce bioactivity, we used the surface chemistry of CNC to sequester bioactive molecules from platelet lysate (PL) on the surfaces. The formation of the protein coating was analyzed by quartz crystal microbalance with dissipation monitoring (QCM-D). The coatings were thoroughly characterized by atomic force microscopy, profilometry, and contact angle measurement. The specific PL proteins sequestered on the CNC surfaces were studied by proteomic analysis. Adhesion, spreading and growth of human gingival fibroblasts was evaluated. Similarly, the anti-inflammatory properties of the nanocoated surfaces were tested using a macrophages polarization assay. Finally, the effect of the nanocoating on adherence and viability of Staphylococcus aureus was examined.

Results and Discussion
We were able to obtain a layer-by-layer-like coating on Ti surfaces showing nanotopographical cues provided by highly-oriented CNC combined with the multiple bioactive molecules from PL [4]. Fibroblasts demonstrated to sense the nanotopography of these surfaces effectively and tended to orient themselves in the same direction of CNC radial orientation up to 14 days, which, at the end, could lead to an organization that mimics the soft tissue around teeth in healthy gingiva inducing integration and regeneration of the implant. As well, we showed that the PL-derived biomolecules effectively inhibited CCR7 expression while increasing CD206 expression on human macrophages, suggesting an enhanced anti-inflammatory response, which could contribute to a controlled performance of inflammatory processes after implant placement. Moreover, the PL nanocoating decreased initial bacterial viability using S. aureus, which could prevent early bacterial colonization on the implant, thus, potentially preventing peri-implantitis.

Conclusion
We identified two complementary strategies that would potentially contribute to development of a multifunctional surface coating offering an improvement on soft tissue integration, a controlled inflammation process and antimicrobial properties to increase dental implant success. Ultimately, this work demonstrates a multifunctional surface design with a potential to improve success rate of dental implants.

Bactericidal action of eugenol-containing essential oils within chitosan-based blended films towards *Staphylococcus aureus* or *Pseudomonas aeruginosa*

Joana C. Antunes, Tânia D. Tavares, Marta A. Teixeira, Marta O. Teixeira, M. Teresa P. Amorim, Natália C. Homem, Helena P. Felgueiras

*University of Minho, Centre for Textile Science and Technology, Guimarães, PT*

**Introduction**

Diabetic foot ulcers (DFUs) are a common complication of patients suffering from diabetes mellitus (DM), a disabling and incurable chronic disorder, highly prevalent worldwide. DFUs often become infected, with *Staphylococcus aureus* and *Pseudomonas aeruginosa* as the most commonly isolated pathogens within DFUs in Portugal [1]. Surgical debridement, wound cleansing, and antibiotic administration, typically precede the application of a wound dressing over the lesion site to protect the wound, fight infection and promote healing. But current therapeutics are ineffective against most DFU-associated infections, particularly due to bacterial resistance to therapeutics, hence the urgency for efficient alternatives. Hence, we proposed to engineer films via solvent casting and phase inversion method from chitosan (CS) and poly (vinyl alcohol) (PVA) blends, polymers widely combined as templates for antimicrobial (AM) action due to their inherent AM activity (CS), flexibility and hydrophilicity (PVA). CS and PVA readily form hydrogen bonds due to a large number of -OH groups from the monomeric units of both polymers. Loading them with the antibacterial cinnamon leaf (CLO; ≈79% eugenol) or clove essential oils (CO; ≈81% eugenol) should reinforce their AM action. Ergo, the main goal of the present study was to explore the potential of CS and essential oil (EO)’s over *S. aureus* and *P. aeruginosa* survival within a CS/PVA matrix for prospective DFU treatments [2]. Very few have explored CS/PVA blended films as EO delivery platforms and none, to the author’s knowledge, has used the proposed approach.

**Experimental Methods**

Detailed methodology can be consulted at Antunes *et al.* [2]. Briefly, EOs, purchased from Folha d’Água (Santo Tirso, Portugal), were selected based on AM testing results obtained elsewhere by the team, against *S. aureus* (ATCC 6538, grown in TS/TSA) and *P. aeruginosa* (ATCC 25853, grown in NB/NA) [3,4], apart from the minimum inhibitory concentration value of CO while incubated with *P. aeruginosa* that was here determined, using a broth microdilution procedure. CS and poly (vinyl alcohol) (PVA) films were prepared (ratio 30/70 w/w; 9 wt%) by the solvent casting and phase inversion method. Films were supplemented with 1 and 10 wt% of EO in relation to total polymeric mass. Representative images of the films’ macroscopic structures were taken, followed by thickness measurements, and degree of swelling (DS, in %) determined similarly as in Felgueiras *et al.* [5]. Chemical structure (through Fourier-transform Infrared spectroscopy with attenuated total reflection, FTIR-ATR), thermal properties [via thermal gravimetric analysis (TGA) and differential scanning calorimeter (DSC)], EO-loading amount (using UV-visible spectroscopy), and, finally AM assays (namely agar diffusion assay and time-kill kinetics) were conducted on unloaded and EO-loaded films.

**Results and Discussion**

Smooth and homogeneous films were obtained. Film thickness and DS tended to increase with EO content, particularly with 10 wt% CLO (* p<0.05). CS/PVA’s spectrum shows peaks from both CS and PVA, and new peaks are absent, thereby suggesting the occurrence of polymer blending. Spectra of EO-loaded films showed a commitment of free -OH groups with increasing EO amount, suggesting that hydrogen bonds are formed between
EO and the polymer chains. With 10% CLO, the peak decreased 55%. CO inclusion within CS/PVA films promoted a 15% reduction in the intensity of this region of the spectra. The film’s thermal stability data reinforced polymer blending and EO entrapment. UV-visible absorbance scans in the 250–320 cm\(^{-1}\) region confirmed the successful uptake of CLO and CO into CS/PVA films, particularly with films loaded with 10 wt% EO that contained 5.30/5.32 times more CLO/CO than films supplemented with 1 wt% EO. AM testing revealed that CS films alone were effective against both bacteria and capable of eradicating all *P. aeruginosa* within the hour (**p<0.001). Still, loaded CS/PVA films showed significantly improved AM traits in relation to unloaded films within 2 h of contact, especially CS/PVA/CLO 10% (*p<0.0001) following incubation with *S. aureus* and CS/PVA/CO 10% (**p<0.001) with *P. aeruginosa* (Figures 1 and 2).

**Conclusion**
This study is a first proof of concept that CLO and CO can be dispersed into CS/PVA films. CLO incorporated 31% more EO than CO, an amount that appeared to be also bound to the polymer chains in a more effective way. Still, both film types showed significant bactericidal effects, particularly CS/PVA/CLO 10% against *S. aureus*, this way paving the way for efficient DFU therapeutics. Future work will be directed towards a balance between AM action of CS and its mechanical hindrance after processing, together with the combination with CLO or CO for an intensified antimicrobial profile against both bacteria.

Introduction

Peri-implantitis is an inflammation of the gingival tissue caused by oral pathogens and it is one of the main causes of dental implant failure [1]. The great potential of some metallic nanoparticles as bactericidal agent could be an additional solution to the existing therapies. In particular, the antibacterial activity of copper and silver nanoparticles is known as potentially effective against different bacterial pathogens [2]. Although the size reduction to the nanoscale is behind these bactericidal properties, other features such as morphology or crystallinity of the particles, have a key role in the bactericidal effect. These features mostly depend on the fabrication method. The laser ablation technique allows to control these features by tuning the processing parameters [3]. In addition, opposite to other chemical based methods of nanoparticle production, laser ablation allows obtaining nanoparticles without any additional reagent that can be harmful to the healthy tissues.

The objective of the present work is to produce silver and copper nanoparticles by laser ablation on titanium substrates and check their effect as bactericidal agent against two common bacteria linked to peri-implantitis: \textit{Lactobacillus Salivarius} and \textit{Staphylococcus aureus}.

Experimental Methods

Silver and copper foils with 99.99% of purity, were used separately as laser ablation targets. Each target was ablated in open air by two different laser sources. In the case of the silver target, a nanosecond laser emitting at a wavelength of 532nm in the nanosecond regime (Green - ns) and an infrared laser (wavelength of 1064nm) emitting pulses in the millisecond range (Infrared - ms) were used. While in the case of copper the same Green - ns laser was used together with a picosecond laser emitting at 1064nm of wavelength (Infrared - ps). In all experiments, commercially pure (cp) titanium discs Grade 2 were used as substrates for collecting the ablated material as shown in Figure 1. Experiments are summarized in Table 1.

Size, morphology, crystalline phases and optical properties of the deposited nanoparticles were studied by means of transmission electron microscopy (TEM), high resolution transmission electron microscopy (HRTEM) and UV/VIS absorption spectroscopy. Additionally, scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDS) on the sectioning layer of the nanocoatings, were used to analyse respectively the morphology and composition of the nanoparticles on the titanium surface.
The antibacterial properties of the nanoparticles were evaluated in dynamic conditions with *Lactobacillus Salivarius*, a common bacteria strain localized in the mouth with an important role in the biofilm formation and with *Staphylococcus aureus*, a Gram positive bacterial strain which is one of the main pathogens responsible for inducing periimplantitis.

**Results and Discussion**

Silver and copper oxide nanoparticles have been synthetized and deposited on cp Ti substrates in one-step process by means of laser ablation in open air. The process, resulted in coatings of nanoparticles with spongy appearance (see Figure 2). The deposited nanoparticles are crystalline and round with diameters from few nanometers to 60 nm. Average diameters are around 15 nm for silver and 5 nm in case of copper nanoparticles. However, the nanoparticles are smaller and more homogeneous in size when the Green - ns laser is used with both metals. Microbiology tests confirm the strong activity of silver and copper nanoparticle coatings. On one hand, the deposited Ag NPs reduce the adhesion of *L. salivarius* around 61% in relation to the cp Ti without NPs. On the other hand, the adhesion of *S. aureus* decreases about 80% in contact with the Cu NPs coating.

**Conclusion**

Feasibility of laser ablation to produce Ag and Cu NPs coatings on Ti by one-step process without any additional chemical compound is demonstrated. The laser source determines the features of the deposited nanoparticles. Bactericidal activity of these coatings against *L. salivarius* and *S. aureus* encourages their use as anti-periimplantitis agent in oral implants.

*Escherichia* virus MS2, mimic of SARS-CoV-2, inhibition via essential oils-loaded nanofibers: a potential formulation for antiviral individual protection masks

Joana Domingues¹,², Samira Silva¹, Joana C. Antunes¹, Helena P. Felgueiras¹

¹ University of Minho, Centre for Textile Science and Technology (2C2T), University of Minho, Campus de Azurém 4800-058 Guimarães, Portugal., Guimarães, PT; ² University of Minho, Centre of Biological Engineering (CEB), University of Minho, Campus de Gualtar, 4710-057 Braga, Portugal, Braga, PT

**Introduction**

In December 2019, a novel strain of coronavirus, SARS-CoV-2, was identified. Infected patients revealed symptoms of fever, cough (dry), sore throat, and fatigue, which began manifesting after 5 days of incubation. Hoping to prevent transmission, many countries adopted a mandatory mask use in closed and open public spaces [1]. Still, most mask options display a passive-like action against COVID-19, only preventing its infiltration but not eliminating it. Essential oils (EOs) are highly abundant concentrated plant extracts, endowed with antiviral, antibacterial, antifungal, anti-inflammatory, anxiolytic, analgesic, and antioxidant properties [2]. EOs have already proved efficiency against SARS-CoV-2, with garlic oil (GLO) being capable of inhibiting the angiotensin-converting enzyme 2 protein, leading SARS-CoV-2 to lose its host receptor and attack the PDB6LU7 protein (its main protease), thus preventing virus maturation and spreading [3]. The purpose of this work is to investigate other EOs for their antiviral potential against the *Escherichia* virus MS2 (a mimic of SARS-CoV-2) and to incorporate the most effective on electrospun nanofibrous mats adaptable for individual three-layer protection masks (as inner layer).

**Experimental Methods**

Twenty EOs selected based on their antimicrobial nature [4] were examined for the first time against the *Escherichia coli* virus MS2 (ATCC 15597-B1). Minimum inhibitory concentrations (MIC) were established using the broth microdilution method. The virus was grown at 2x10⁵ PFUs/mL and combined at 50/50 v/v with the EOs at concentration varying from 732.5 to 85.6 mg/mL in Mueller Hinton Broth (MHB), for 24 h at 37°C and 120 rpm. Polycaprolactone (PCL) and cellulose acetate (CA) were prepared individually at 14 wt% in chloroform/dimethylformamide (DMF) and 10 wt% in acetone/DMF, respectively, and combined at 3:1 ratio. Polymeric solutions were processed via electrospinning with processing parameters being optimized to 24.7 kV (potential difference), 3.2 mL/h (flow rate) and 21 cm (distance to collector). Mats were characterized by thermogravimetry (TGA), differential scanning calorimetry (DSC), dynamometer, goniometer, Fourier-transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM). Loading of the nanofibrous mats was accomplished via physisorption using the terminal -OH groups of the CA as linkers. Mats were loaded with the three most effective EOs against the MS2 virus at 2xMIC concentration, in an alcoholic solution, for 72 h (saturation). Loading amount was determined by UV-visible spectroscopy. In parallel, EOs at MIC were also incorporated within the polymeric solution prior to electrospinning and extruded in the form of EO-loaded nanofibers. Processing parameters were optimized for each of the three selected oils. Surface characterization resorted to TGA, DSC, FTIR and SEM, for both fiber uniformity and EOs presence. Antimicrobial testing via Kirby-Bauer method was conducted for 24 h, to establish the oils diffusion abilities from the mats. Time-kill kinetics (JIS L 1902) studies were conducted for 1, 2, 4, 6, 24, 48 h to verify the activity of the oils while loaded and the overall antiviral features of the engineered mat.

**Results and Discussion**
From the twenty tested oils (listed in [4]), the most effective were the lemongrass (LO), Niaouli (NO) and eucalyptus (ELO) with a MIC of 356.0 mg/mL, 365.2 mg/mL and 586.0 mg/mL, respectively. PCL/CA nanofibrous mats were successfully produced both in the presence and absence of the oils within the polymeric solutions. Uniform, beadless nanofibers were obtained. Mats were characterized as mechanically resilient, to endure movements arising from mask positioning, and hydrophobic in nature, to repel aqueous droplets coming from the exterior. TGA, DSC and FTIR techniques confirmed the homogeneity of the polymeric blends and the oils presence. In the oil-free mats, loading was accomplished after 72h of immersion. In the three tested cases, a loading amount close to MIC was detected. Antimicrobial testing via halo determination, verified the loaded oils diffusion abilities, determining oil liberation from physisorbed surfaces more important. Time-kill kinetics studies of the loaded mats attested to the EOs capability to fight the virus MS2 even when bonded to the nanofibers. Here, EOs-physisorbed surfaces were quicker in their action, while those entrapping the EOs in their polymer matrix retained the antiviral activity of the mat for longer.

**Conclusion**

Data demonstrated the potential of the EOs, LO, NO and ELO, loaded onto PCL/CA nanofibrous mats to work as COVID-19 active barriers in individual protection masks.

3D printed dynamic scaffolds for nanovibration-driven tissue regeneration

Sandra Camarero-Espinosa\textsuperscript{1,2}, Lorenzo Moroni\textsuperscript{3}

\textsuperscript{1} University of The Basque Country, POLYMAT, Donostia / San Sebastian, ES; \textsuperscript{2} IKERBASQUE, Basque Foundation for Science, Bilbao, ES; \textsuperscript{3} Maastricht University, MERLN, Maastricht, NL

Introduction
Stimulation of cell cultures with physical and electrical cues has potential to modulate multiple cellular functions including migration, differentiation and survival. Despite the great potential shown by in-vitro models, these are generally based on sophisticated systems with compromised potential to be exploited in-vivo, being the main shortcoming the incapability to apply the stimuli “remotely” and on a controlled manner. Here, we report on the fabrication and exploitation of dynamic additive-manufactured scaffolds that are activated on-command via external application of ultrasounds\cite{1}, resulting in a mechanical nanovibration and an electrical signal that is transmitted to the surrounding cells.

Experimental Methods
Scaffolds were produced via 3D printing from pre-formed polymer blends that spontaneously phase-segregated into well-defined structures, including Janus and particles, following the traditional nucleation and spinoidal decomposition model. 3D printed structures of biodegradable polycaprolactone (PCL) and polylactide (PLA) blends behave as ultrasound transducers (acoustic to mechanical) where the PLA and PCL phases represent the active and backing materials, respectively. To introduce piezoelectricity, biorewable and biocompatible cellulose nanocrystals were added to the PLA phase, at different loading ratios. Human bone marrow derived stromal cells (hBMSCs) were cultured in basal or osteogenic media and used at passage 5 for all experiments.

Results and Discussion
Remote stimulation of scaffolds led to a nanovibration and/or electrical signal generated by piezoelectric cellulose nanocrystals. Control over the material composition (polymer blend ratio and loading of nanoparticles) and structure formation allowed us to control the amplitude of the deflection, the pulse of this one and the intensity of the electrical signal.

Culture of hBMSCs on dynamic scaffolds resulted in enhanced cell proliferation, matrix deposition and osteogenic differentiation as measured by PCR and release and deposition of characteristic markers and matrix proteins. Further, we evidenced that the hBMSC response is a consequence of the formation and activation of voltage-gated calcium ion channels.

Conclusion
Here, we showed a novel method to render 3D printed scaffolds dynamic by the use of ultrasound stimulation. Spatial control over the chemistry of the scaffolds and the inclusion of cellulose nanocrystals allowed us to control the amplitude and pulse of the deflection and the electrical signal generated, respectively. Culture of hBMSCs into these dynamic scaffolds results in an enhanced proliferation, matrix deposition and differentiation when the appropriate parameters are selected. Thus, we believe this to be a novel approach to the regeneration of damaged tissues in which scaffolds can be remotely controlled to guide cell function.

Introduction

Gelatin is a very popular material in the fields of tissue engineering and biofabrication as reflected by the high number of publications covering a plethora of chemical modifications (1-3). Especially the widely investigated gelatin-methacryl hydrogels hold an impressive track record (3). While these different chemical modifications allow to tailor the properties of the hydrogel, one very interesting approach is the use of thiol-ene chemistry, as this generates additional control over the hydrogel properties via adjusting the thiol-ene ratio, but also by varying the applied crosslinker itself (4). Additionally, these thiol-ene systems exhibit a higher reactivity along with superior biocompatibility and processability (4-5).

Experimental Methods

In order to exploit this photo-click chemistry, often an ene-functionality is introduced onto gelatin followed by crosslinking in the presence of a multifunctional thiol. In the present work gelatin was modified with norbornene functionalities as previously described [4].

Results and Discussion

To date, very limited research has been performed on the influence of the applied thiolated crosslinker on the final hydrogel properties. Therefore, the present work assesses the influence of different thiolated crosslinkers on the crosslinking kinetics, mechanical properties and biological performance of the hydrogels upon encapsulation of adipose tissue-derived stem cells. Furthermore, the different formulations were processed using two-photon polymerisation which indicated, in addition to differences in processing window and swelling ratio, a previously unreported phenomenon. At high intensities, the laser results in cleavage of the gelatin backbone even in the absence of distinct photo-cleavable functionalities. This can have potential to introduce channels or softer regions in gels to result in zones characterized by different degradation speeds or the formation of blood vessels (Figure 1).

Conclusion

Consequently, the present study can be used to provide guidance towards tailoring the thiol-ene system towards the desired applications.

4D printing of thermoresponsive shape-transforming hydrogel actuators

Daria Podstawczyk

Wrocław University of Science and Technology, Department of Process Engineering and Technology of Polymer and Carbon Materials, Wrocław, PL

Introduction

4D printing has emerged as an important technique for fabricating three-dimensional objects from programmable materials capable of time-dependent reshaping. The 4D approach combines 3D printing with functional shape-memory materials (SMMs) to produce objects that can undergo temporal shape transformation under external stimuli, e.g. temperature, electric/magnetic field, moisture, light, or chemical signal [1,2]. The material returns to its initial configuration as the stimulus ceases. Poly-N-isopropyl acrylamide (PNIPAAm) is the most popular thermosensitive polymer that exhibits temperature-induced shape transforming behavior. Motions of PNIPAAm-based materials originate from their anisotropic nature and the presence of regions of different swelling behaviors within their network. It has been demonstrated that shear generated during printing induces the alignment of the anisotropic fillers along the printing direction [2,3]. The present investigation demonstrates new 4D inks that contain laponite nanoclay, poly(N-isopropylacrylamide) (PNIPAAm), and alginate. The inks were further used for extrusion-based direct printing of shape-morphing structures, whose shape change was activated by a temperature change. This abstract is based on the paper prepared by my group that has a detailed presentation of the results [2].

Experimental Methods

The inks were prepared by mixing aqueous solutions of precursors (NIPAAm, N,N’-methylenebis(acrylamide) (MBA), 2-hydroxy-4-(2-hydroxyethoxy)-2-methylpropioophenone (I2959), poly(ethylene glycol) diacrylate (PEGDA), and sodium alginate) with laponite XLG under stirring at ambient temperature. Before printing, inks were overnight stored at 4°C and then centrifuged to remove air bubbles that could impede extrusion. 3D printing was carried out using a temperature-controlled pneumatic-based extrusion printer (BioX, Cellink). The 3D constructs were designed in CAD software (AutoDesk Inventor) and exported to a file format acceptable by the 3D bioprinter (*.stl). Completed 3D objects (actuators) were cured under UV light for 5 minutes and then soaked in 0.5M CaCl₂ for 24h for PNIPAAm and alginate cross-linking, respectively. The rheological properties of the inks were determined using a parallel-plate rotational rheometer. The printed and cross-linked objects were further characterized in terms of surface/cross-section morphology, swelling behavior, and mechanical stability. The temperature-induced shape transformation was measured by measuring the curvature of the self-folding sample cyclically immersed in cold and hot waters.

Results and Discussion

The 4D inks exhibited elastic behavior as shear storage modulus (G’) was higher than shear loss modulus (G”) within the measured range of frequency from 0.01 Hz to 100 Hz and behaved in a shear-thinning manner. SEM images demonstrated the anisotropic nature of the printed actuators. Under shear stress generated within the nozzle, the nanoclay that is contained in the inks’ network aligns along the deposition direction causing heterogeneous arrangement of the chains. The compositionally tunable hydrogel discs were programmed to exhibit different actuation behaviors at different temperatures. In cold water, the disc actuator self-folded forming a tube in 15 min. When immersed in hot water, the tubular construct exhibited rapid unrolling behavior, followed by the slight curving in the opposite direction. Dually photo-crosslinked PNIPAAm-based structures showed inversed action and rolled up in hot and unfolded in cold waters. The samples were further examined for their cytotoxicity. It was found out that the hydrogels maintain >80% viability of fibroblasts.
Conclusion
The printed actuators exhibited very good actuating performance in response to temperature because of the temperature-dependent asymmetric swelling/shrinkage behavior governed by the anisotropic nature of the composites. The direct printing technique was found to be an excellent tool to introduce both structural and geometrical anisotropy into printed hydrogels.

Bioprinting as a strategy to fabricate cell-hydrogel-microfibre composite tissue constructs for a potential skin tissue engineering application

Marcin Kotlarz\textsuperscript{1}, Ana Ferreira-Duarte\textsuperscript{1}, Piergiorgio Gentile\textsuperscript{1}, Stephen J. Russell\textsuperscript{2}, Kenneth Dalgarno\textsuperscript{1}

Introduction
Composites offer an opportunity to couple particular benefits of their constituents to achieve unique material properties that can be of extra value in many tissue engineering applications\textsuperscript{1}. Strategies combing hydrogels with fibre-based scaffolds create a chance to develop more biologically and structurally functional tissue constructs. This research investigated the feasibility of a droplet-based bioprinting system called the Reactive Jet Impingement (ReJI) to integrate a cell-laden hydrogel within a fibre-based substrate.

Experimental Methods
Calcium alginate (CaAlg) fibre-based substrate was manufactured in a three-step process of fibre formation, dry-laid web formation and needlepunching. Two nominal print cell densities ($5 \times 10^6$ and $30 \times 10^6$ cell/ml) of neonatal human dermal fibroblasts were embedded in a tricomponent collagen-alginate-fibrin hydrogel and bioprinted using the ReJI system onto the CaAlg mesh. Cell-hydrogel-microfibre composites were assessed \textit{in vitro} using immunofluorescence, SEM, histological analysis, and metabolic activity and DNA content quantification assays.

Results and Discussion
The ReJI system allowed for mid-air processing of low viscosity bio-inks that upon the meet, react to form a hydrogel\textsuperscript{2}. Fibroblasts in the constructs maintained high viability post-printing. Specifically, the lower fibroblast density triggered proliferation within the composite construct whereas the higher fibroblast density accelerated extracellular matrix deposition. Additionally, the fibrous component of the composite was characterised by its high swelling properties and quick calcium ions release. Our results demonstrate that the ReJI process can produce cell-gel-fibre constructs with high cell densities. Future work will consider application of the constructs for wound healing and skin tissue engineering.

Conclusion
The ReJI system is an effective strategy to fabricate cell-hydrogel-microfibre composite tissue constructs.

In vitro effect of ZnO piezoelectric nanogenerators on skin cells

Andreu Blanquer¹, Laura Lefai², Elena Filova¹, Jaume Esteve², Gonzalo Murillo², Lucie Bacakova¹

¹ Institute of Physiology of the Czech Academy of Sciences, Biomaterials and Tissue Engineering, Prague, CZ; ² Institut de Microelectronic de Barcelona, Cerdanyola del Valles, ES

Introduction
Skin wound healing is a complex physiological process involving several cell types, such as keratinocytes, fibroblasts, endothelial cells and immune cells. In some cases, skin regeneration is reduced due to several factors including diabetes and people aging causing chronic wounds [1]. It is estimated that 1-2% of the population would experience a chronic wound during their lifetime and would become a serious problem for health services in developed countries [2]. In recent years, some studies analysed the effect of exogenous electric field to enhance wound healing [3]. Piezoelectric nanogenerators (NGs) are materials which create an inherent electric field when strained. The use of piezoelectric NGs could enhance skin regeneration due to the electrical stimulation of cells involved in wound healing. Here, we demonstrate the in vitro effect of ZnO piezoelectric NGs on the viability, adhesion, proliferation and differentiation of selected cell types involved in skin wound healing.

Experimental Methods
ZnO NGs were synthesized by hydrothermal growth on an AlN thin-film layer. Human keratinocytes and human fibroblasts were used for in vitro analyses on ZnO NGs. Cell viability was analysed after 24 h in culture using Live/Dead Kit (Invitrogen). Initial cell adhesion and cytoskeleton morphology was analysed after 24 h in culture by phalloidin staining of actin stress fibres. Cell proliferation was quantified up to 14 days in culture using resazurin assay (Sigma-Alrich). Differentiation markers of keratinocytes (basal cytokeratin 14 and differentiated cytokeratin 10) and type I collagen synthesis by fibroblasts were analysed by immunofluorescence and visualized with confocal laser scanning microscope (Leica SP8).

Results and Discussion
Results indicated that all cell types tested were able to adhere and grow on ZnO NGs. Cell viability assay showed that ZnO NGs were not cytotoxic. In addition, after 24 h in culture, an increased number of keratinocytes were adhered on ZnO NGs. Both fibroblasts and endothelial cells showed similar morphology on both ZnO NGs and glass coverslips (control). All three cell types were able to proliferate on ZnO NGs reaching a confluent monolayer after 7 days in case of fibroblasts, and 14 days in case of keratinocytes. The quantification of collagen synthesis by fibroblasts indicated 50% increased amount of collagen on ZnO NGs compared to control samples (Figure 1A). Collagen is a main component of the extracellular matrix of skin and plays an important role in skin regeneration. Images of cytokeratin 10 and 14 immunostaining showed differentiated cells positive for cytokeratin 10 on both ZnO NGs (Figure 1B) and control. Keratinocytes positive for cytokeratin 10 were detected in the upper layers of cells in accordance with other researchers that evaluated the presence of cytokeratin in stratified skin [4]. In addition, the quantification of differentiated cells positive for cytokeratin 10 indicated an increased cell differentiation on ZnO NGs. These results indicate a positive effect of piezoelectric ZnO NGs on cell differentiation. We hypothesize that the electric fields generated by the inherent forces produced by adhering cells are responsible for the increased differentiation of skin cell types.

Conclusion
Piezoelectric ZnO NGs were able to support the skin cell adhesion and proliferation and proved to be cytocompatible. Moreover, the enhanced type I collagen synthesis by fibroblasts and the keratinocyte differentiation on ZnO NGs
allow considering them as promising nanomaterials for skin tissue engineering. Future experiments with immune cells and co-culture systems will be performed to elucidate the potential of ZnO NGs on skin wound healing.

Plasma-based hydrogels supplemented with commercial fibrinogen for the generation of human skin equivalents

Ignacio Risueño¹, Cristina Quílez¹, Gonzalo de Aranda¹, Sara Martín¹, Nataliya Debera², Leticia Valencia¹, José Luis Jorcano¹, Diego Velasco¹,³

¹ Universidad Carlos III de Madrid, Department of Bioengineering and Aerospace Engineering, Leganés, Madrid, ES; ² Faculty of Engineering University of Porto, Institute of Biomedical Sciences Abel Salazar, Porto, PT; ³ Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, ES

Introduction

Over the last years, advances have been made towards the development and production of in vitro human skin for clinical use and for in vitro toxicology testing [1,2]. Our group has developed engineered human bi-layered skin equivalents using plasma-derived fibrin hydrogels containing primary human fibroblasts (hFBs) and keratinocytes (hKCs) from skin biopsies for different skin tissue engineering applications, although several issues related to the hydrogel stability were found due to the limited concentration of fibrinogen in human plasma (2-4 mg/mL) [3]. Supplementing plasma gels adding commercially available fibrinogen could help to improve the stability and lifespan of the constructs. The objective of this work is to study the changes in the behaviour of commercial fibrinogen-supplemented gels and their suitability for generating organotypic skin cultures.

Experimental Methods

Commercial fibrinogen from human origin was used to supplement human plasma gels with a basal concentration of 1.2 mg/mL of fibrin, increasing their final concentration to 2, 2.5, 3.5 and 4.5 mg/mL. Plasma gels with 1.2 mg/mL of fibrin were used as controls. Gelation kinetics was studied by turbidimetry measuring gel absorbance to light. Hydrogels were completely dried and weighed at time points 1, 7 and 14 for gel degradation study. Fibroblast-mediated matrix contraction was studied by measuring the surface reduction of hydrogels containing 20,000 hFBs/mL. AlamarBlue and MTS assays were performed to measure hFBs viability inside the gels and hKCs proliferation on top of the hydrogels respectively. Organotypic skin cultures were prepared for each condition with hFBs and hKCs using transwell culture plates in the air-liquid interface for epidermal differentiation. After 15 days of culture, hematoxylin/eosin staining and immunofluorescence were performed for structural and biochemical characterization.

Results and Discussion

Increasing fibrin concentration of the hydrogels with commercial fibrinogen did not show changes in gelation kinetics. Hydrogels showed an important weight loss on the first day although it was reduced progressively as fibrin concentration was increased. Fibroblasts-mediated matrix contraction was reduced by more than 70% between the 1.2 mg/mL control gels and the more concentrated fibrin gels (4.5 mg/mL). Fibroblasts embedded in the hydrogels showed a controlled and slower proliferation compared to that of the control plasma hydrogel. Hematoxylin/eosin staining showed both a more stabilized dermal compartment for the plasma/commercial fibrinogen conditions and normal development of a fully differentiated and mature epidermis (Figure1). This was confirmed by the presence of specific epidermal markers such as keratins 5 and 10 and filaggrin; normal hFBs growth was shown by vimentin expression.

Conclusion

The stability of the human plasma-based hydrogels was increased with the addition of commercial fibrinogen, reducing both their degradation and contraction while not disturbing the gelation process. When applied to organotypic skin cultures, these supplemented gels formed a more stable dermal compartment compared to those...
generated only with plasma, but still allowing embedded hFBs to proliferate and the development of a mature and differentiated epidermis on top. This approach could be a very promising alternative to overcome the persisting issues associated with plasma hydrogels and to increase their properties while maintaining the capacity of generating organotypic skin cultures.

Bioactive nanofibrillated cellulose modulates the chronic wound environment in vitro

Introduction
The number of patients suffering from chronic wounds is reaching epidemic proportions. This translates into high economic costs, estimated to be 2-4% of the health budgets [1], [2] and a significant impact on the patient’s quality of life. Chronic wounds are characterized by an imbalance of the wound equilibrium, with an excess of tissue degradation over the regeneration and healing of the damaged tissue. An abnormal high level of reactive oxygen species (ROS) and matrix metalloproteases (MMPs) are two of the main characteristic factors of a chronic wound environment. Current treatments usually consist of the application of wound dressings that provide a humid environment, absorption of exudate and physical protection of dirt and trauma. It is believed that bioactive dressings that actively target the ROS and MMPs excessive activity could aid in the healing of chronic wounds by restoring the biochemical imbalance typically found in these hard-to-heal wounds [3].

Nanocellulose from wood has emerged as an interesting material for biomedical applications due to its high chemical and physical tuneability and its renewable source. Nanocellulosic materials can be tailored as nanofibers in suspension, hydrogels, aerogels and films. Wood-derived cellulose nanofibrils (CNF) have been described as a promising material for the treatment of wounds [4], [5].

In this work, cysteine was chosen as active molecule to provide CNF with radical scavenging properties and capacity to inhibit the activity of MMP by metal ion capture. Cysteine was covalently incorporated into the nanocellulose fibres and the ability of the functionalized material to modulate the chronic wound environment was investigated in vitro.

Experimental Methods
The cysteine amino acid was covalently incorporated to carboxylated CNF (c-CNF) via EDC/NHS coupling. The chemical structure of the cysteine-functionalized CNF (cys-CNF) was characterized by solid state nuclear magnetic resonance (NMR) spectroscopy and the cysteine content was quantified by elemental analysis. The number of thiol groups was evaluated with the Ellman assay. The radical scavenging capacity of cys-CNF was assayed with the free radical DPPH (1,1-Diphenyl-2-picrylhydrazyl radical). The interaction of cys-CNF with collagenase, chosen as MMP model, was evaluated by quantifying the enzyme activity after incubation with the material using the EnzCheck assay. Moreover, the potential entrapment of the protein within the nanofibers network was investigated. Finally, the safety profile of the cys-CNF was evaluated with human dermal fibroblasts.

Results and Discussion
The solid-state NMR indicated the presence of covalently bound cysteine in cys-CNF and the formation of its oxidized dimer cystine. The elemental analysis of cys-CNF showed that 60 % of the initial carboxyl groups in CNF were substituted by cysteine. Since the potential ability of cys-CNF to modulate the chronic wound environment is expected to depend on the presence of free thiol groups, the material was further characterized in terms of free thiol content by the Ellman assay, which showed that the number of free thiols corresponded to 26% of the total sulfur content in the cys-CNF. The decrease in thiol groups with respect to the total sulfur content may be explained by the formation of the oxidized dimer cystine, seen in the NMR spectrum.
The DPPH study indicated that cysteine endowed CNF with free radical scavenging properties, with cys-CNF showing a concentration-dependent DPPH inhibition (Figure 1a). Thus, demonstrating that the covalent functionalization of the cellulose nanofibers with cysteine is a promising approach to obtain a nanocellulose-based dressing capable of directly reacting with free radicals.

The cys-CNF material was able to inhibit the collagenase activity in a dose-dependent manner (Figure 1b), while the entrapment of the protein within the nanofiber network was not significant. This indicated that the observed decrease in collagenase activity after incubation with cys-CNF was most probably due to the inactivation of the protease, rather than just the entrapment of the protein within the fibril network. The ability of the cys-CNF to chelate zinc ions in solution could explain the inhibition of the collagenase activity since the sequestration of the zinc ions from the MMP active site is expected to be detrimental for the protease activity.

The evaluation of the cys-CNF safety profile indicated that the material did not induce toxic effects on human dermal fibroblasts when tested in concentrations up to 0.5 mg/mL.

**Conclusion**

Cysteine was successfully covalently incorporated into CNF, which endowed the material with radical scavenging properties and the capacity to inhibit the activity of MMP. This bioactivity against two characteristic factors of the chronic wound environment, together with the safety profile evaluated in vitro, are expected to contribute to the recovery of physiological conditions in the chronic wound bed and promote the healing of the tissue.

**Introduction**

Chronic wounds are one of the most frequent complications associated to diabetes mellitus, contributing to a high morbidity. Its long healing process is mostly associated with the overproduction of reactive oxygen species (ROS) and may result in ulceration and serious infections [1]. In this context, the choice of the adequate dressing is of great importance and it needs to reflect the requirements of a particular wound according to its stage. Recently, natural-based hydrogel formulations are gaining increasing attention since they can provide control over shape, physical properties and encapsulated cargo, offering the possibility that more advanced products will soon reach the clinic [2]. In this work, a novel *in situ* crosslinked sericin-based hydrogel for wound healing was prepared by a simple methodology using horseradish peroxidase (HRP). The hydrogel was characterized in terms of its thermal stability, fluid interaction and antimicrobial properties. The antioxidant effect was assessed *in vitro* and *in vivo*, after *in situ* application on a diabetic mouse model.

**Experimental Methods**

Silk sericin extracted from *Bombyx mori* cocoons was used to prepare a fast gelling hydrogel by HRP-mediated crosslinking [3]. The hydrogel was characterized by differential scanning calorimetry (DSC) analysis and its transparency evaluated by colorimetry. The hydration degree and the degradation behavior were also assessed. The antimicrobial activity of sericin solution was determined using an inoculum of 0.5 McFarland (1.5 x 10⁸ CFU/mL). Antioxidant potential was quantified *in vitro* by ORAC assay under physiological protease degradation and investigated *in vivo*. An excisional wound-healing model in genetically induced diabetic db/db mice was performed to evaluate the effect of sericin-based hydrogel in chronic wounds. Animals were randomly divided into three experimental groups (n=6 per group) as follows: Control (wounds were left untreated); Tegaderm group (wounds covered with Tegaderm); and sericin hydrogel group (sericin hydrogel covered with Tegaderm). Superoxide dismutase (SOD) and catalase activity were quantified to clarify if sericin hydrogel could affect the endogenous protective mechanisms against oxidative stress. Transmission electron microscopy (TEM) was performed to analyse collagen fibres at the wound bed treated with sericin hydrogel.

**Results and Discussion**

HRP-mediated silk sericin hydrogel was developed with a gelation kinetics of ~2-3 minutes, in agreement to previous rheological study [3]. The hydrogel presented a high degree of transparency. This study evaluates, for the first time, the antioxidant potential by ORAC methodology under physiological protease degradation (3.5 U/mg), up to 24 h at 37 °C. The results showed an increase of antioxidant activity of the sericin hydrogels. This can be related to the availability of the phenolic groups that were previously bound by the crosslinking and became free to react after degradation.

The sericin solution and sericin-based hydrogel formulations did not present antimicrobial activity against important pathogens of wound infection, such as *S. aureus*, *P. aeruginosa* and *E. coli*, since there was no bacterial growth up to 24 h for all strains as well as there was no inhibition halo for hydrogels.
Sericin hydrogel was applied into diabetic wounds to evaluate their in vivo antioxidant behavior. Wounds treated with sericin hydrogel closed at a similar rate when compared to Tegaderm group, although with reduced granulation tissue and decreased wound edge distance and wound thickness, demonstrating that this treatment is more effective in relation to Tegaderm alone. Application of wound dressings of sericin hydrogel could promote a more controlled inflammatory response and deposition of collagen fibers with smaller diameter that could be an advantage to stimulate re-epithelialization, when compared to Tegaderm alone. Oxidative stress and ROS production have been implicated as major contributors in non-healing wounds [4],[5]. The results showed that sericin hydrogel treatment slightly induced two important endogenous antioxidant defenses, SOD and catalase, although without statistical significance. This result was interesting, since the effect of this wound dressing was explored on oxidative damage. It was possible to denote a significant decrease in the content of advanced oxidation proteins products at wound bed, being the sericin hydrogel able to protect wound from oxidative protein damage.

**Conclusion**

Sericin hydrogel is biocompatible and a promising candidate to be applied in diabetic wound healing to protect against oxidative stress. This is of paramount interest to diabetic patients, due to improvements in some of the comorbidities associated with non-healing wounds.

Introduction
Chronic wounds (CW) are characterized by a poor healing capacity. External stimuli arising from wound dressings can be effective in stimulating healing[1]. To that effect, nanofibrous dressings with a porous structure resembling the extracellular matrix have been engineered via electrospinning, and functionalized with natural extracts, curcumin and piperine, endowed with antimicrobial, anti-inflammatory and antioxidant properties[2]. Various synthetic and natural polymers have been used in the production of polymeric nanofibrous mats via electrospinning. Poly(vinyl alcohol) (PVA) and cellulose derivatives such as, cellulose acetate (CA) and cellulose nanocrystalline (CNC) are polymers well established in this field for their biocompatibility and biodegradability. In combinations, PVA provides excellent electrospinability and mechanical stability, while derivatives confer cellular viability, being that CNC also increase mats’ mechanical resilience[3]. The present work reports the antimicrobial capacity and hemocompatibility of natural extracts when immobilized onto PVA/CA and PVA/CNC crosslinked mats. To this day very little research has been presented on the use of piperine in healing processes.

Experimental Methods
PVA/CA and PVA/CNC mats were produced by electrospinning at 10 wt% at different ratios, 100/0, 90/10 and 80/20 v/v% in 75/25 v/v% acetic acid/distilled water (dH2O) for PVA/CA and dH2O for PVA/CNC. Optimal processing conditions for both polymeric combinations were established at 25 kV, feeding rate of 0.8 mL/h and distance between needle and collector of 18 cm. Crosslinking process was carried out by applying vapor of glutaraldehyde (GA) for 7h at 60°C. Polymers homogeneity and crosslinking effectiveness, along with the mats morphology and porosity, permeability, thermal and mechanical properties, were assessed using scanning electron microscopy, Fourier-transformed infrared spectroscopy (FTIR), air and water vapor permeability testing equipment, thermogravimetry and a dynamometer. Before mats functionalization, minimum inhibitory concentrations for curcumin and piperine were determined using the broth microdilution procedure described by Wiegand et al[4], against Staphylococcus aureus (S. aureus). Mats were functionalized with the natural extracts at 2xMIC by physisorption and the amount bonded was determined by differences in absorbance before and after binding, mapped via UV-Visible spectroscopy. Release characteristics of curcumin and piperine from loaded mats were also investigated by UV–visible spectroscopy at 420 and 342 nm, respectively[5]. Antimicrobial testing via Kirby-Bauer method was conducted for 24 h against S. aureus, to establish the extracts diffusion abilities from the mats. Time-kill kinetics (JIS L 1902) studies were conducted for 1, 2, 4, 6 and 24 h to verify the bactericidal performance of the extracts while loaded. Clotting time was established visually by the loss of movement of re-calculated plasma, following the Lee-White method. Platelet’s adhesion and activation was analysed using brightfield microscopy.

Results and Discussion
PVA/CA and PVA/CNC porous nanofibrous mats were successfully produced via electrospinning. Crosslinking with GA vapor was effective by promoting intermolecular acetal bridges between the -OH in PVA and CA/CNC and the difunctional aldehyde molecule of GA, as confirmed by the presence of a FTIR peak at 1143 cm\(^{-1}\), attributed to the -O-C-O vibration of the acetal group. After crosslinking, the average diameters increased slightly, maintaining appropriated porosity. Permeability index, even on crosslinked mats, registered values above 80%. The cellulose derivatives increased the ultimate tensile strength and the thermal stability of electrospun mats, being most significative after crosslinking. Extracts were found effective against *S. aureus*. Curcumin was the most effective biomolecule, requiring only 7.8-31.2 µg/mL to inhibit its growth, while piperine needed 31.2-125 µg/mL to induce the same effect. Mats were successfully functionalized with natural extracts and a sustained release rate was attained, which was consistent with the time-kill kinetics evaluations against *S. aureus* (elimination of most bacteria after 24 h contact). Diffusion in agar was not as effective, meaning the action of these extracts against bacteria, while loaded, is more important in a dynamic, aqueous environment. These natural extracts were seen to enhance the clotting time and platelets activation compared to the control groups and, therefore, contributing to a potentially quicker wound closure.

**Conclusion**

Data revealed curcumin and piperine as potential biological cues, capable of fighting infection and promoting wound closure, to be used in CW applications.

Bioactive glass fibrous scaffold for chronic wound healing

Xingchen Zhao¹, Joel Turner², Dong Zhai³, Chengtie Wu³, Gavin Jell², Julian Jones¹

¹ Imperial College London, Department of Materials, London, GB; ² University College London, Division of Surgery & Interventional Science, Department of Surgical Biotechnology, London, GB; ³ Shanghai Institute of Ceramics, Chinese Academy of Sciences, State Key Laboratory of High Performance Ceramics and Superfine Microstructure, Shanghai, CN

Introduction

Inorganic materials are now being applied in wound healing due to their release of therapeutic ions and specific surface affinities to host tissue [1]. Recently, Mirragen (ETS Woundcare, USA), a borosilicate glass fiber mat, received FDA approval for use in diabetic foot ulcers. The mechanism of its success remains unknown. While Mirragen releases therapeutic ions (e.g. borate, silica, calcium, copper, and zinc), its degradation also releases large amounts of Na and K, which interrupt the integration of regenerated tissue [2]. Its fibers are also not uniform, with up to 4 μm in thickness, and only 25% of the glass becomes fiber, while the remaining 75% are beads. Here, we propose a novel 3D borosilicate bioactive glass (BG) scaffold with uniform fiber diameters that mimic the fibers of the extracellular matrix. The fibers have tailorable degradation and ion-release kinetics. In vitro studies on fibroblasts and endothelial cells and in vivo studies on diabetic C57BL/6J mice further verified angiogenic properties and wound healing effects of the scaffolds.

Experimental Methods

Novel 3D ECM-mimic borosilicate BG fibrous scaffolds were prepared through the sol-gel electrospinning approach. Polyvinyl butyral solution was used as a sol-gel binder to maintain the ideal viscosity during electrospinning [3]. Parameters, including voltage, flow rate, air gap distance, and ambient humidity were studied and adjusted corresponding to the change of composition [4]. Characterizations including XRD, FTIR, and SEM were applied. The dissolution of the BG scaffolds was assessed through ICP-AES and in vitro studies investigated the proliferation (CCK-8), migration (Transwell), and gene expression (Elisa) of fibroblasts (human dermal fibroblasts) and endothelial (human umbilical vein endothelial cell) cells. Scaffolds were further applied to diabetic wound models on C57BL/6J mice to investigate their wound healing efficacy in vivo.

Results and Discussion

The BG scaffolds performed a 3D structure (thickness of 0.5-2 mm) and consisted of long and homogeneous fibers with diameters of 180-270 nm Fig.1). This was induced by the branching effect resulting from calcium ion repulsion. XRD and FTIR characterization proved that the scaffold had no sign of crystallization and unreacted compounds. The dissolution profiles revealed a sustained release of therapeutic ions within the ideal concentration range [5]. The wound healing mechanism of the resultant scaffolds was studied in vitro and in vivo. Fig.2 (a-e) shows that dissolution products of borosilicate BG scaffolds induced much higher normalized protein expressions from fibroblasts compared to the control and borate-free scaffolds. Borosilicate BG scaffolds also induced higher migration of endothelial cells compared with the control media solution and borate-free scaffolds (Fig.2(f)). In diabetic C57BL/6J mice, borosilicate BG scaffolds stimulated faster wound closure, higher collagen deposition, and more blood vessel regeneration compared with the control and borate-free scaffolds.

Conclusion

3D ECM-mimic borosilicate BG scaffolds mimic the fibrils in ECM and induce a controllable therapeutic ion release. In vitro and in vivo studies further confirmed the capability of the resultant scaffolds in sprouting cell proliferation, cell
migration, gene expression, collagen deposition, and angiogenesis. All results suggested the promising potential of the resultant scaffolds in chronic wound regeneration.

Hyaluronan/collagen-based hydrogels with anti-inflammatory nanoparticles for promoting chronic wound healing

Norbert Halfter, Eva Espinosa-Cano, Albrecht Berg, Stephanie Moeller, Matthias Schnabelrauch, Maria R. Aguilar, Vera Hintze

Technische Universität Dresden, Max Bergmann Center of Biomaterials, Institute of Materials Science, Dresden, DE; Institute of Polymer Science and Technology, Biomaterials Group, Madrid, ES; Networking Biomedical Research Centre in Bioengineering, Biomaterials and Nanomedicine, Madrid, ES; INNOVENT e. V., Biomaterials Department, Jena, DE

Introduction

Novel innovative material concepts are needed to tackle the growing number of chronic wounds arising due to the demographic changes in western civilizations with an increase in multimorbid patients. Using biomaterials based on extracellular matrix (ECM) components is a promising approach, since the ECM conveys fundamental biological functions regarding tissue homeostasis, cellular differentiation and angiogenesis [1]. The most abundant ECM molecules are collagen type I (coll) and proteoglycans. The latter have a protein core with glycosaminoglycans (GAG) bound to it. GAG itself can bind and protect growth factors and affect proliferation, cell adhesion and differentiation [1]. The GAG hyaluronan (HA) is abundantly available and can be chemical derivatized in a controlled and reproducible manner (e. g. (meth)acrylation) [1]. Hence, HA is suitable for use as functional biomaterial with tunable properties. Previously, HA/coll-based hydrogels (HG) successfully enhanced endothelial cell proliferation showing their capability to support the regeneration of vascularized tissue [2]. To further tune the HG for wound healing purpose, e. g. as skin grafts or dressing in particular for non-healing, chronic wounds, positively charged nanoparticles (NP) containing a non-steroidal anti-inflammatory drug reported to show promising anti-inflammatory properties in vitro, were applied on these HG containing negatively charged HA [3].

Experimental Methods

Fabrication of HA/coll-based HG was done as previously by photo-crosslinking reported by Rother et al. [2]. Additionally, cryogels (CG) were made by freezing of the premixed components before photo-crosslinking. NP were synthesized as reported before by Espinosa-Cano et al. via a nanoprecipitation method and for concentration determination or visualization loaded with coumarin-6 [3]. Incorporation of NP into HG was done either via soaking freeze-dried HG or by the addition before photo-crosslinking with different target concentrations. The elastic modulus of the gels was analyzed with a MicroTester (CellScale) and the morphology was studied via scanning electron microscopy (SEM). To determine the NP distribution inside the HG, laser scanning microscopy (LSM) was applied. The release of the NP was determined via fluorescent measurements by incubation of the gels in PBS for up to 7 days at 37 °C. Murine macrophages (RAW264.7) were used to examine cellular interactions with the HG/NP-systems. Next to the cell proliferation with AlamarBlue® assay, the cell viability and the anti-inflammatory activity after LPS stimulation were determined by live/dead staining and by quantifying the nitric oxide (NO) release with Griess reagent kit, respectively. Furthermore, macrophage spreading and the formation of multinucleated cells was evaluated with fluorescence microscopy after staining of actin filaments and nuclei.

Results and Discussion

HG were loaded with different amounts of NP, with only a marginal NP release over 7 d. Depending on the HG fabrication method NP were differentially distributed within the HG as revealed by LSM. While including NP before HG crosslinking and in CG via soaking led to a distribution over the whole cross-section, all other variants were only decorated with NP on the surface. This was confirmed via SEM. CG had a lower elastic modulus than HG but there
was no significant difference when loaded with NP. Cells proliferated well on all HG variants and in particular on CG. Live/dead staining revealed high cell viability over 90% for all variants. All NP containing HG reduced the NO release significantly except for the variant with NP incorporated before crosslinking. This indicates that direct access to NP for cells is an important factor for the anti-inflammatory effects of the NP. In line with the NO release studies, all NP containing gels display small cell areas indicating reduced macrophage differentiation.

**Conclusion**
HA/coll-based HG and NP were successfully combined and were non-toxic to cells. Depending on the NP incorporation method, anti-inflammatory behavior of the NP was observed. Further, this material platform could be modified with additional immunomodulatory molecules, e.g., sulfated HA, to further increase its anti-inflammatory effect. Future experiments need to reveal if this translates into an *in vivo* anti-inflammatory effect in chronic inflammatory wound models.

3D printed patches based on exosomes and methacrylated hyaluronic enhance the regeneration of diabetic wound

Alfredo Ronca¹, Ugo D’Amora¹, Barbara Zavan², Luigi Ambrosio¹

¹ National Research Council, Institute of Polymers, Composites and Biomaterials, Napoli, IT; ² University of Ferrara, Dept. of Translational Medicine, Ferrara, IT

Introduction
Chronic diabetic wound causes serious threat to human health due to its long inflammatory phase and the reduced vascularization [1]. Recently, chronic wounds severely deteriorate the life quality of patients due to the lack of effective treatments, which not only increased family burden but even lead to amputations. Numerous novel hydrogel dressings have been developed to relieve the inflammation response, thus accelerating wound healing [2]. Hyaluronic acid (HA)-based biomaterials have been explored for a number of applications in biomedical engineering, particularly as tissue regeneration scaffold. However, its high solubility, high degradation rate and low mechanical properties limit its use for tissue engineering. Chemical modification of HA with subsequent crosslinking is one of the most used methods to improve the mechanical properties also reducing the degradation time in vivo [3]. Crosslinked forms of HA are more robust and provide tunable mechanical properties and degradation rates that are critical in regenerative medicine [4]. Exosomes, nanovesicles enriched on miRNA secreted by cells to exert paracrine communication, if products from mesenchymal stem cells show antinflammatory and immunomodulative action during regenerative processes. In this work a methacrylated HA in combination with stem cell derived exosomes has been developed and characterized as bioink for the realization of 3D printed patches to promote the healing process of diabetic wounds.

Experimental Methods
HA (Mw~340 kDa) was modified to graft photoactive groups by reacting with methacrylic anhydride (ME) in order to obtain methacrylated hyaluronic acid (MEHA). The bioprinting was performed using a slurry containing 2 wt% MEHA and 0.1wt% Irgacure 2959 (Sigma Aldrich) as biocompatible photoinitiator by an In vivo Rokit 3D bioprinter (Rokit Healthcare Inc.). The printability of MEHA based bioinks was optimized by a homogenous UV pre-crosslinking to produce a rectangular porous structure. After printing, the structures were postcured for 15 minutes in order to complete the photocrosslinking process. The morphology of the structures was investigated by scanning electron microscopy (SEM) and dynamic mechanical analysis (DMA) was carried out to study the mechanical properties. EVs isolation was performed from the growth medium MSCGM™ of MSCs. Cell culture supernatants were collected and centrifuged at 4°C for 10 min at 200 g and then for 10 min at 500 g, thawed and spun down vertically at 4°C for 20 min at 2000g and then centrifuged horizontally at 100.000g for 75 min. Finally, the supernatant was discarded and the exosomes pellet was re-suspended in 1 mL of PBS. The isolated EVs were marked with PKH26 (Red Fluorescent Cell Linker Kits MINI26; Sigma-Aldrich Co., St Louis, MO, USA) for 5 min at room temperature in dark room and blocked with fetal bovine serum, according to manufacturer’s instructions. Exosomes were printed within MEHA at a density of 5 × 10¹⁰ cm⁻². Wound healing process has been evaluated following the Peirce model [5].

Results and Discussion
The methacrylation method provides degree of functionalization around 86% as showed by ¹H-NMR analysis. The bioink was investigated in terms of physico-chemical properties to assess the success of the functionalization. DMA was employed to compare mechanical properties of neat MEHA and MEHA/Exosomes 3D structures as a function of material composition. The presence of exosomes did not alter the mechanical properties of MEHA 3D structures that showed Young modulus of about 4kPa. SEM analyses highlighted a well-organized structure with a fiber
diameter of ~200 µm and a porosity of ~700 µm, confirming the capability of retaining the designed 3D structure without collapse. Exosomes were present inside the patches maintaining their biological activity as confirmed from the tests.

**Conclusion**

Modified-HA based hydrogels have gained research attention as UV photocrosslinkable materials to be used as matrix to produce substrates (i.e. patches) and/or scaffolds with interesting physico-chemical and biological properties. In this work, 3D printed MEHA and MEHA/Exosomes structures were realized and characterized from morphological, mechanical and biological point of view. Wound healing ability analysed by means of histological and molecular biology evaluation confirmed that the presence of exosomes reduces the inflammatory event during the first days, improves the granulation tissue quality and the healing of the wound. The collective mechanical and biological performance profile of the MEHA/Exosomes hydrogels strongly suggests that this class of material has great potential as application for diabetic wound.

Introduction
The treatment of large volume bone defects, which frequently result in delayed or non-union of tissue, remains one of the biggest challenges of modern bone tissue engineering. The use of growth factors such as bone morphogenetic protein-2 (BMP-2) has yielded some success but is expensive and associated with numerous side effects. The delivery of microRNAs (miRs) potentially offers a more attractive alternative inducing the host cells to produce multiple therapeutic proteins with a physiologically relevant release profile and limited side-effects [1-3]. However, identifying a safe and effective microRNA delivery platform remains a key challenge due to their poor stability and challenges with achieving intracellular cytosolic delivery [4]. Here, we investigate the potential of a scaffold-based approach, for sustained delivery of miRs to enhance bone repair. Collagen-hydroxyapatite scaffolds [1,2,4] were coupled with a cell-penetrating peptide [5] to establish a miR-activated scaffold system which uniquely co-delivers both mimics and inhibitors of microRNA activity, i.e miR-26a-mimic [3] and miR-133a-inhibitor [1,2], for bone repair.

Experimental Methods
Collagen-hydroxyapatite scaffolds were fabricated using established freeze-drying techniques [1,2,4], sterilized dehydrothermally and cross-linked with the EDAC/NHS solution. miRs were complexed with a RALA peptide as a non-viral vector [5] and incorporated into scaffolds. The morphology of the scaffolds with miR nanoparticles (NPs) were assessed by scanning electron microscopy (SEM). The distribution of the miR NPs within the scaffold was determined by confocal laser scanning microscope while the release of miR NPs was determined through spectroscopic methods. Human mesenchymal stem cells (hMSC) were seeded on the scaffolds and evaluated in terms of miR-26a-mimic and miR-133a-inhibitor expression, metabolic activity, DNA content, ALP activity and calcium content. Calcium and H&E staining were evaluated at day 28.

Results and Discussion
This study describes the development of a 3D microRNA-activated scaffold system with a novel cell penetrating peptide for controlled and sustained delivery of therapeutic microRNAs for orthopedic applications. The scaffolds developed here effectively co-delivers both microRNA mimics and microRNA inhibitors at the same time. The miRs were homogeneously incorporated into scaffold without affecting its optimal porosity for bone repair (Fig 1A). The scaffolds retained approx. 60% of miR-cargo up to 28 days (Fig 1B) and transfected the hMSCs. Importantly, the dual-delivery miR-26a-mimic/miR-133a-inhibitor scaffold effectively delivered both cargoes to hMSCs. The miR-activated scaffolds enhanced cellular proliferation of approx. 40% (Fig 1C). The miR-26a-mimic and miR-133a-inhibitor scaffolds stimulated ALP activity (Fig 1C) and the mineralization of hMSCs (Fig 1D). The dual-delivery system enhanced osteogenesis to greater extent compared to miR-26a-mimic and miR-133a-inhibitor alone.

Conclusion
This study describes the development of a 3D microRNA-activated scaffold system with a novel cell penetrating peptide for controlled and sustained delivery of therapeutic microRNAs for orthopedic applications. The scaffolds developed here effectively co-delivers both microRNA mimics and microRNA inhibitors at the same time. The miRs were homogeneously incorporated into scaffold without affecting its optimal porosity for bone repair (Fig 1A). The scaffolds retained approx. 60% of miR-cargo up to 28 days (Fig 1B) and transfected the hMSCs. Importantly, the dual-delivery miR-26a-mimic/miR-133a-inhibitor scaffold effectively delivered both cargoes to hMSCs. The miR-activated scaffolds enhanced cellular proliferation of approx. 40% (Fig 1C). The miR-26a-mimic and miR-133a-inhibitor scaffolds stimulated ALP activity (Fig 1C) and the mineralization of hMSCs (Fig 1D). The dual-delivery system enhanced osteogenesis to greater extent compared to miR-26a-mimic and miR-133a-inhibitor alone.
In this study, collagen-hydroxyapatite scaffolds were successfully used as a system for unique co-delivery of therapeutic microRNA mimics and microRNA inhibitors complexed with novel, cell-penetrating peptide. This demonstrates the potential of the scaffolds to be used as next generation of therapeutics for bone regeneration. A novel dual-microRNA scaffold system could be used as a feasible and universal template for delivery of any therapeutic miRs tailoring for a myriad of applications beyond bone repair.

Simultaneous sterilization and production of medicated scaffolds by supercritical CO$_2$ technology

**Víctor Santos-Rosales**, Beatriz Magariños, Carmen Alvarez-Lorenzo, Carlos A. García-González

Universidade Santiago de Compostela, Departamento de Farmacología, Farmacia y Tecnología Farmacéutica, I+D Farma Group, Facultad de Farmacia, Agrupación Estratégica de Materiales (AeMAT) and Health Research Institute of Santiago de Compostela (IDIS), Santiago de Compostela, ES; Universidade Santiago de Compostela, Departamento de Microbiología y Parasitología, Facultad de Biología, CIBUS, Santiago de Compostela, ES

**Introduction**

The sterilization treatment of medical devices must ensure a sterility assurance level (SAL-6) against bacterial endospores prior to their usage, according to the current legal framework. This scenario represents a major hurdle in the development and commercialization of new generation biomedical product, including scaffolds [1]. Conventional sterilization techniques frequently lead to significant morphological and physicochemical modifications in the treated products. Carbon dioxide under supercritical (sc-) conditions incorporating low contents of hydrogen peroxide is able to inactivate bacterial endospores while preserving the physiochemical properties of the treated biomaterial, emerging as a promising method for scaffold sterilization [2].

On the other hand, the sc-foaming technology allows the manufacturing of drug-loaded scaffolds in absence of organic solvents [3]. The scaffold porous morphology can be modulated in order to match the natural bone tissue characteristics by means of the fine control of the working parameters [4].

In this work, vancomycin-loaded poly(caprolactone) scaffolds were obtained through a simultaneous sterilization and foaming procedure based on scCO$_2$ technology. Mild pressure and temperature conditions along with the addition of H$_2$O$_2$ (1200 ppm) ensured a SAL-6 level against dry bacterial endospores of biological indicators (*Bacillus stearothermophilus*, *Bacillus pumilus* and *Bacillus atrophaeus*).

**Experimental Methods**

Hydrogen peroxide was added in liquid form (1200 ppm) in a high-pressure autoclave (100 mL) containing scaffolds components (PCL, PCL-vancomycin 5 wt.%). The system was heated to 39 ºC and pressurized at 140 bar, maintaining a continuous CO$_2$ flow for 2.5 h. Finally, the system was depressurized at a constant venting rate of 3 bar/min until atmospheric pressure.

The characterization of the scaffolds was performed in physicochemical and morphological terms. Biocompatibility tests were performed and the vancomycin release kinetics were evaluated for 14 days.

**Results and Discussion**

The developed method successfully achieved SAL-6 levels against dry spores of *B. stearothermophilus*, *B. pumilus* and *B. atrophaeus* (Figure 1). These three microorganisms are the biological indicators used in steam and hydrogen peroxide vapor sterilization, radiation sterilization and ethylene oxide or dry heat sterilization, respectively.

Sterile PCL scaffolds loaded with vancomycin with a porous architecture in the 100-600 µm range were obtained, which is coherent for their application in bone tissue regeneration (Figure 2). In addition, scaffolds showed good cytocompatibility and a two-stage vancomycin release pattern suitable for the prophylaxis and treatment of infections at the grafted area.

**Conclusion**

A simultaneous sterilization and manufacture procedure for scaffold manufacturing based on the use of scCO$_2$ technology is presented for the first time. Sterile PCL scaffolds loaded with vancomycin were obtained, meeting the
morphological requirements to be used as bone grafts substitutes while ensuring a sustained release of the drug for over two weeks.

Manufacturing and characterisation of PLA bioresorbable warp-knitted spacer fabric scaffolds for bone critical sized defects

Flavia Caronna¹, Nikola Glimpel², Georg-Philipp Paar², Khoa Do³, Thomas Gries², Eimear B. Dolan¹, William Ronan¹

¹ National University of Ireland Galway, Biomechanics Research Centre (BMEC), Biomedical Engineering, School of Engineering, Galway, IE; ² RWTH Aachen University, Institut für Textiltechnik (ITA), Aachen, DE; ³ ITA GmbH, Aachen, DE

Introduction

Critical sized bone defects are one of the most challenging orthopaedic conditions to treat. Such problems, in which bone is unable to heal spontaneously within a patient lifetime, could be successfully tackled by tissue engineering. Biodegradable polymers are very attractive for medical implants applications since they reduce the need for revision surgeries and avoid biocompatibility issues associated with conventional permanent implants (1). In this context, textile technology stands out as versatile and innovative tool for scaffold design, allowing a fine control over the final product architecture and microstructure while scaling easily to large volumes. In parallel, acceptance of in silico trials by regulatory agencies is increasing since they provide a reduction of costs and clinical and pre-clinical trials are both reduced and only required later in the product development.

In this work, 3D polylactide (PLA) scaffolds are fabricated by warp-knitting and their performance is assessed. The degradation behaviour of the PLA yarns during accelerated in vitro degradation tests is reported and is used to calibrate a computational model.

Experimental Methods

Warp-knitted spacer fabrics are manufactured with a double needle-bar Raschel knitting machine (Karl Mayer, Germany). Designed to be suitable for bone tissue engineering applications, the textile features a tricot cover area made of multifilament yarns and a monofilament spacer yarn. To confer dimensional stability to the fabricated textile, heat setting is carried out in a convection oven in constrained conditions at 90, 120, and 150°C for 5 minutes. Following this, fabric thickness, porosity, and pore size are measured from µCT data, and mechanical compression tests are performed. Separately, accelerated degradation of PLA yarns is carried out in vitro in phosphate buffered saline (PBS) at 58.5 °C and pH 7.4 (2). Additional degradation tests including pre-treatment of yarns with different heat setting conditions are also conducted.

A simplified reaction-diffusion model for semicrystalline polymer degradation (3, 4) is implemented in COMSOL Multiphysics® software. The present molecular weight model considers ester bond hydrolysis, acidic autocatalysis, monomer diffusion, and the effects of the crystalline volume phase and porosity on polymer degradation. The model is calibrated based on the in vitro yarn degradation data.

Results and Discussion

The manufactured spacer fabric is shown in Figure 1a. The average textile thickness decreases up to 36% after heat setting (Figure 1b, black) with little change in textile porosity, with a minimum value of 81.5% at 120°C (Figure 1b, brown). A general reduction of pore size is observed after heat setting (Figure 1c), with an improvement in mechanical properties with increasing setting temperature (Figure 1d). Textiles heat set at 150°C exhibit the most suitable physical and mechanical properties for bone tissue regeneration.

Crystallinity evolution during yarn degradation (Figure 2a) suggests that chain scission induced crystallization is taking place. Yarns lose mechanical integrity after 15 days of accelerated degradation, during which the ultimate strength drops up to 87% (Figure 2b), with Young’s modulus remaining approximately constant (Figure 2c). The heat

Page 568 of 2028
setting process affects yarn’s initial properties without substantially affecting its degradation behaviour. Preliminary simulation results are shown in Figure 2d with heterogeneous degradation evident, i.e., the interior degrades faster due to trapped autocatalytic reaction products.

**Conclusion**

The present study shows that bioresorbable warp-knitted scaffolds represent a promising technology in the field of bone tissue regeneration, offering large, interconnected pore spaces (>100-400µm) for cells migration, nutrient supply, metabolic waste removal, and high surface to volume ratio (which favours cell attachment and growth). Stacking of spacer fabric layers has the potential to bridge bone defects of critical size (>2cm).

Scaffold degradation *in vitro* will be studied to explore the impact of autocatalysis on structure resorption and acid release. A computational model will predict the degradation of complex structures from material data inputs, thus simplifying and accelerating the development of polymeric bioresorbable implants.

Ongoing work is focused on the assessment of scaffold biocompatibility (including the effect of manufacturing processes). The performance of knitted PLA scaffolds (cell attachment, proliferation, and differentiation) will be investigated *in vitro*, reproducing mechanobiological cues to mimic the bone *in vivo* microenvironment.

Bioinspired bone marrow units: a strategic cell-biomaterial combination in liquified capsules as a new therapeutic approach for bone regeneration

Claudia S. Oliveira, Maria C. Gomes, Sara Nadine, Clara Correia, João F. Mano

University of Aveiro, CICECO-Aveiro Institute of Materials, Aveiro, PT

Introduction
The reconstruction of bone defects has been correlated with several disadvantages, namely patient immobility, prolonged pain, support dependence, and expensive treatment costs. Aiming to circumvent the limitations of the current treatment for these conditions, bone tissue engineering (BTE) has developed implantable biomimetic devices to accelerate the bone regeneration process after implantation (1). However, the majority of BTE approaches are deprived of an integrated strategy of the three co-existing systems of the native bone marrow (BM), namely skeletal, vascular and hematopoietic, essential for bone regeneration and healing. Herein, the novelty was to combine these three systems in liquified compartments as a promising approach to recapitulate and exploit the regenerative properties of the BM microenvironment under in vitro conditions.

Experimental Methods
Mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs), and human umbilical vein endothelial cells (HUVECs) were isolated from the umbilical cord. Before the encapsulation setup, aggregates of MSCs with surface-modified polycaprolactone microparticles (µPCL) were performed under osteogenic stimulation for 21 days. At 21 days, multilayered and liquified alginate capsules were produced as described (2,3). In order to recapitulated as close as possible the BM microenvironment, co-culture capsules (aggregates of MSCs, HSCs, and HUVECs) and co-culture (aggregates of MSCs and HUVECs) were maintained in static and dynamic culture systems (spinning flasks) for 7 days. After seven days in culture, the microenvironment of the capsules was analysed.

Results and Discussion
The dynamic system promoted an increase in cell viability, proliferation and allowed more complex cellular interactions and connections when compared to the static condition (Figure 1). The expression of bone formation markers such as osteopontin, osteocalcin, bone morphogenetic protein-2, type IV collagen, fibronectin were observed in both types of capsules, but much higher in the dynamic system compared to static, and more significant in the presence of HSCs (Figure 2). The presence of angiogenic factors, namely vascular endothelial growth factor (VEGF) was also observed with significant amounts.

Conclusion
Considering the repair of bone fracture a complex biological mechanism that requires the recruitment of stem cells from the bone marrow (BM), this microenvironment and its components become a powerful candidate to improve bone regeneration. In fact, our results evidence the superior biological outcome resulting from the direct crosstalk between the BM cell components in the tri-coculture capsules. This privileged three dimensional (3D) microenvironment strategically combined with cells in liquified capsules provides ideal support for cell viability, secretion of osteo key components, and vasculogenic factors, essential steps involved with new bone tissue formation and regeneration. The recapitulation of the BM microenvironment under in vitro conditions may provide an advanced platform of fundamental importance for bone regeneration applications.

Introduction
Mechanical stimulation plays a key role in enhancing osteogenic differentiation of stem cells in the physiological bone environment [1]. To better replicate this behaviour in vitro, several studies have shown that stimulation by flow perfusion and cyclic mechanical compression enhances the bone cell mechano-transduction [2], [3]. In this context, a computational study can help optimize the stimulation transmitted to cells by evaluating the mechanical load and flow shear stresses. Here, we present an optimization procedure of a 3D printed bone scaffold design based on finite element (FE) simulation approach. A preliminary FE analysis on three different scaffold designs was implemented to investigate the optimal scaffold geometry, orientation, and loading condition for cyclic mechanical stimulation. From this analysis, the best performing geometry and loading direction was selected to be further analysed in a more complex FE model considering the fluid-structure interaction (FSI). These combined simulations can represent a tool to achieve information not only about the optimal scaffold design, but also about the overall mechanical stress and wall shear stresses (WSS) due to fluid flow acting on the cells for bone tissue regeneration in vitro.

Experimental Methods
Three different scaffold geometries were investigated (Fig. 1): (a) a cylindrical scaffold of 5 mm diameter, 1 mm height, and with a line internal infill (geometry 1); (b) a cylindrical scaffold of 5 mm diameter, 1 mm height, and with four vertical pores (geometry 2); (c) a rectangular scaffold with sides of 5 mm and 1 mm height, with infill lines at 45° (geometry 3). This last geometry represents a unit slice of the final scaffold, whose height was further optimized through simulation. For all geometries the internal porosity was 50%. A linear, elastic, homogeneous, and isotropic mechanical behavior was defined for the scaffold material (Young modulus: 2.52 GPa, Poisson ratio: 0.3, density: 1,200 kg/m³). All three geometries were meshed with tetrahedral element, with an element size of 0.4 mm. Regarding the boundary conditions, to model the mechanical loading phase during in vitro stimulation, a boundary condition with a prescribed displacement of 200 µm was chosen for the loaded boundary, while the opposite boundary was set to fixed constraint. These boundary settings allowed to simulate the loading condition as applied in bioreactors such as the CellScale MTX. The load was applied to the top surface of the scaffold for geometry 1 and 2, while for geometry 3 to the scaffold side (Fig. 1). The other boundaries were set to free displacement. Furthermore, a parametric optimization was completed to optimize the scaffold thickness in terms of maximum compressive strength and stiffness. Finally, a computational fluid dynamic and FSI model was developed to investigate the WSS under fluid perfusion. Regarding the material properties, a dynamic viscosity of 1.4 mPa*s was considered for the fluid. Ten noded tetrahedral elements were considered for the discretisation of the scaffold, with an edge length of 0.5-2 mm. In the CFD model, a constant velocity of 100 µm/s was applied at the inlet while a zero-pressure condition was applied at the outlet. The scaffold surface was assumed as a non-slip wall boundary.

Results and Discussion
Data from the preliminary simulations were expressed in terms of the total displacement inside the scaffold, which represents a measure of the portion of stimulation that the cells ‘feel’ \textit{in vitro}. Geometry 1 did not show any relevant displacement in the central struts of the scaffold, since all the loading was sustained by the external walls (Fig. 1). For geometry 2 and geometry 3, the displacement field was more uniform, so seeded cells can virtually feel the mechanical load due to stimulation.

Furthermore, since geometry 3 can be more easily seeded during the experiments, it was chosen to be further evaluated through simulations. In particular, the parametric optimization of geometry 3 resulted in a 5 mm thickness, which demonstrates stresses well within the range of maximum yield strength of 42.6 MPa.

This geometry was further evaluated through a FSI simulation. Preliminary results of the FSI analysis indicated that 70% of total scaffold surface area were evident to levels of WSS, which were deemed adequate to stimulate bone differentiation [2]. However, the combined loading of fluid perfusion and mechanical compression might amplify the WSS at the scaffold surface.

**Conclusion**

The present study showed that the displacement field is more uniform inside the pores in case of geometry 2 and geometry 3 as compared to geometry 1. However, geometry 3 (rectangular scaffold with infill lines at 45°) demonstrated better agreement in terms of cell seeding. The study also concluded that understanding the behavior of mechanical stimulation under different loading conditions can be useful to the researchers in terms of design and optimisation of 3D scaffolds.

Malleolus Fractures Treated with Bioresorbable Magnesium-based Compression Screws ZX00: First in man study

Patrick Holweg, Martin Ornig, Paul Puchwein, Andreas Leithner, Franz Seibert

Medical University Graz, Austria, Department of orthopaedics and trauma, Graz, AT

Introduction
Over the last decade, the development of new and alternative materials in trauma care using bioresorbable metals has increased, concentrating mainly on magnesium (Mg) alloys. No prospective clinical trial has investigated the clinical long-term results of lean bioresorbable screws made of Mg, calcium (Ca) and zinc (Zn), without any rare earth elements (REE), denoted as ZX00. This prospective cohort study investigated this bioresorbable Mg-alloy in compression screws for medial malleolar fracture and the patient-related outcome regarding function and complication. Questions/Purposes: (1) Do Mg-alloy (ZX00) compression screws stabilize medial malleolar fracture fragments in patients? (2) Do patients recover their ankle mobility? (3) Does the degradation rate of Mg-alloy screw correlate with the bone healing? (4) Are the Mg alloy screws completely resorbed after one year?

Experimental Methods
Twenty patients with isolated, bimalleolar, or trimalleolar ankle fractures were recruited and treated with bioresorbable Mg alloy (ZX00) compression screws. Patient-reported outcome measures (PROMs) including visual analog scale (VAS) for pain, American Orthopaedic Foot & Ankle Society (AOFAS) scales and the presence of complications (adverse events) during one year of follow-up were used. The functional outcomes were analyzed through the range of motion (ROM) of the ankle joint. Fracture reduction and the bioresorbability of the screws were evaluated using several plane radiographs. Quantitative data were analyzed using general linear models (GLM) for repeated measures.

Results and Discussion
All fractures were stabilized with 2 screws without any screw failures. The difference in the range of motion of the talocrural joint between the treated and the non-treated site decreased from 39°±12° after 2 weeks to 7°±13° and 2°±11° after 24 weeks and 52 weeks, respectively. The within-subject effect of this difference in the one-year follow-up is statistically significant (p<0.001). A complete consolidation of all fractures was achieved after 12 weeks with all patients, even with one patient suffering from osteoporosis, demonstrating that the radiolucent areas attributed to gas formation did not affect clinical or functional outcomes. After one-year follow-up, in 17 patients (85%), the head of screws was completely resorbed without adverse reactions.

Conclusion
Bioresorbable Mg alloy (ZX00) compression screws prove to be an excellent and safe alternative compared to titanium (Ti) screws while avoiding a second, costly and unnecessary implant removal operation.
Fracture fixation with ZX00 screws
Anteroposterior ankle radiographs of a 29-year-old male patient with a medial malleolar fracture (A) reduced by two Mg-based screws. After 6 weeks (B), a small fracture line is still visible; small radiolucent zones within the bone surrounding the screws. These radiolucent zones resulting from the degradation of the screws decreased after 24 (C) and 52 weeks (D).
Introduction
A major challenge in the development of scaffolds for oral and maxillofacial surgery includes the engineering of materials that simultaneously promote hard (bone) and soft (mucosa) tissue regeneration. The scaffold should support the growth and differentiation of the relevant cell populations, directing cellular interactions, as well as promoting the formation and maintenance of extracellular matrix heterogeneity. This bimodal material must also exhibit a gradation in mechanical properties that mimics the native insertion site and must be biodegradable at a relevant time scale, in order to be gradually replaced by the host tissue.

Recently, our group has developed a Sr-hybrid system, composed of Sr-doped HAp microspheres, delivered in an alginate vehicle crosslinked with Sr (1). This material has already shown to be capable of promoting bone regeneration and possess an immunomodulatory effect (2, 3). Based on these findings, we herein propose an innovative bimodal injectable biomaterial, composed of a bottom layer (bone-like layer - BL) to induce bone regeneration, and a top layer (mucosa-like layer - ML) for periodontal tissue integration.

The bimodal material is further enriched with either human decellularized fetal membranes (dFMs) particles and/or platelet-rich plasma (PRP), due to their potential for regenerative medicine since it is known they contain a vast number of interesting growth, angiogenic and immunomodulatory factors.

Experimental Methods
Both biomaterial layers include as a vehicle a 3.5% (w/v) ultrapure sodium alginate solution being its in situ gelation promoted by the addition of Sr carbonate and Glucone-δ-lactone, biochemical enriched with decellularized human amniotic and chorionic membrane lyophylyzed particles (1:1 ratio) in a concentration of 20 mg/mL. BL was mechanically reinforced with hydroxyapatite Sr-rich microspheres (35% w) with a diameter between 500-560 μm. Fetal membranes were isolated from placental tissue, and followed a previously optimized decellularization protocol. PRP was isolated from whole human blood. The dFMs were characterized by histology, scanning electron microscopy (SEM), transmission electron microscopy (TEM) and atomic force microscopy (AFM). Furthermore, the bimodal biomaterial was mechanically and structurally characterized by dynamic mechanical analysis (DMA), and micro-computed tomography (m-CT), respectively. Cell viability, metabolic activity, proliferation and differentiation of gingival fibroblasts (hGFs) and human mesenchymal stem cells (hMSCs) were investigated. Moreover, a proteomic profile of the cellular response was performed using a transwell experimental design, where the biomaterial was placed on the top compartment and cells seeded on the bottom.

Results and Discussion
A fully functional bimodal biomaterial was obtained, with a uniform and stable interface, even when agitation or compressive forces were applied. dFMs were found to be sucessfully decellularized, while mainting their tissue architecture and were homogenously distributed within the system. PRP was easily dissolved into the hydrogel. Both cell types exhibited an increase in cell number and viability, when in the presence of dFMs. dFMs seem to lead to the formation of cell agglomerates, suggesting them as potential anchoring sites. An increase in mineralization sites...
was observed in the hMSCs for formulations containing dFMs. Proteomic analysis revealed that ML incorporating FMs increase the hGF ECM remodeling potential, particularly when combined with PRP. FMs seem to have an immunomodulatory effect through the regulation of both IL-7 and IFN-\(\gamma\). Concerning the hMSCs response, an enrichment in the ECM-related proteins was observed in the Sr-hybrid containing FMs, particularly when PRP was also present. Moreover, hMSCs differentiation seems to be particularly increased in the formulation containing both FMs and PRP, what is in accordance with the cell culture assays.

**Conclusion**

The bimodal material promoted hGFs (ML-layer) and hMSCs cell growth and hMSCs osteogenic differentiation (BL-layer). This effect is more evident when combining dFMs and PRP, suggesting they act in a synergistic way. The results obtained indicate that the developed bimodal material provides a promising multifunctional approach for maxillofacial regeneration.

Introduction

On the design of new biomaterials, research often finds inspiration in the multifunctional materials present in nature. Two examples suitable for the design of freestanding films are the robust nacre’s structure and the water-resistant adhesive proteins secreted by marine mussels (MAPs).

Nacre in a natural laminate composite, which composes the inner layer of mollusc shells, with remarkable high fracture toughness and energy absorption properties owing to unique lamellar and staggered organic-inorganic structure with multiple-length sizes, composed of 95 wt% aragonite and 5 wt% organic material.

MAPs overexpress the amino acid 3,4-dihydroxy-L-phenylalanine (DOPA), which has a critical role in the wet adhesion due to the presence of catechol groups since they are able to form strong covalent and noncovalent bonds with distinct inorganic/organic/metallic surfaces and even biomacromolecules. We stress the novelty of this work, as nacre-inspired freestanding films were successfully developed through spin-assembly LbL (SA-LbL) combining catechol-modified natural polymers, CHIcat, and HAcat, and BGs. The main goal of this work was to study the potential of these nanostructured FS membranes for guided bone regeneration.

Experimental Methods

Bioinspired freestanding films were produced through the SA-LbL technique, composed of natural polymers (chitosan and hyaluronic acid) and bioactive glass nanoparticles (BGs), which were crosslinked with genipin to improve their stability in a wet environment. Both polymers were modified with catechol groups to increase the adhesiveness of the films. Six different films were produced: controls (CTR) with 50 and 100 tetralayers (T), BGs (BG) containing films with 50 and 100T, catechol-containing (Cat) films with 50T, and catechol and BGs (CatBG) films with 50T. Their physicochemical (SEM, TGA, WCA, swelling, and degradation tests) and mechanical properties (DMA and AFM tests) were characterized in detail, as well as their bioactive and possible cytotoxicity effects under physiological-simulated conditions.

Results and Discussion

Catechol-containing films led to the construction of thinner films, moreover, the combination of catechol-modified polymers with BGs showed some porosity and revealed a more compact structure. Although both films with 100 T were slightly thicker than their 50 T counterparts, increasing the layer number did not have a significant impact on the film thickness.

Similar WCA values were obtained for all BGNPs-containing films, meaning that the differences in BGs’ content did not have an impact on the films' wettability, and the genipin crosslinking of the films decreased the WCA of both surfaces, becoming more hydrophilic.
BG100 presented a higher weight loss, due to the higher amount of BGNPs that could be released and dissolved from the films. A lower weight loss was observed for the catechol-containing films, being CatBG50 the lowest, suggesting that the catechol incorporation increased the film stability. The inclusion of catechol groups resulted in increased film stiffness and, when BGNPs were also combined, the highest E’ values were achieved. Unsurprisingly, higher adhesion values were shown for both films containing catechol-modified polymers, Cat50 and CatBG50. Preliminary biological assays indicated that the use of either catechol-modified polymers or BGNPs by itself did not affect negatively cell viability. On the other hand, the combination of BG with catechol groups in CatBG50 led to a higher metabolic activity compared to the other tested film formulation, adhesion, and proliferation similar to CTR50. Summarily, CatBG50 presented the advantage of a lower weight loss rate, while maintaining its bioactive character. Moreover, the stiffness and roughness increase and water uptake decrease also contributed to an enhanced cellular behavior, since cells tend to prefer stiffer and lower hydration surfaces.

**Conclusion**

These bioactive LbL freestanding films that combine good adhesion with improved mechanical properties, and also presented hydrophilic surfaces, reduced biodegradability, decreased swelling, and promoted higher cellular metabolic activity, could be an alternative strategy for guided hard tissue regeneration.

Introduction

Biodegradable biomaterials have been extensively investigated in bone fracture fixation and scaffolding as they eliminate the need for a second surgical intervention for implant removal. In addition, biodegradable materials will allow complete tissue regeneration without the risk of chronic inflammation and stress shielding. In addition, biodegradation can be capitalized on to locally release drugs. Drug loading into the implant bulk requires low processing temperatures, which often restricts the biomaterial choice to biodegradable polymers or ceramics. However, polymers are weak and ceramics are brittle for load-bearing applications. To unlock the potential of biodegradable metals (e.g., Mg, Fe, Zn) for local drug delivery and bone scaffolding, an advanced cold sintering process (CS) for fabricating metals at ambient temperatures can be employed.

In recent studies, we showed the feasibility of drug loading and release from bulk Fe-Ag nanocomposites [1]. In the present work, we focused on improving the mechanical properties of drug-loaded bulk biodegradable metals and describe the processing, degradation, mechanical, antibacterial, and cell compatibility properties of vancomycin hydrochloride (VH)-loaded Fe-based biomaterials.

Experimental Methods

Fe and Fe-Fe₂O₃ (5, 10 vol.% of Fe₂O₃) powder blends were prepared from carbonyl Fe powders (5-9 μm) and Fe₂O₃ nanopowders (50 nm) by manual mixing in mortar. Here, Fe₂O₃ nanoparticles were utilized as phase increasing mechanical and corrosion properties of Fe [2]. VH was utilized as a model drug in this study. VH powder was manually mixed with Fe and Fe-Fe₂O₃ blends in a mortar to prepare Fe-VH and Fe-Fe₂O₃-VH blends. Then, powders with and without the drug were cold sintered/high pressure consolidated in high-speed tool steel die at pressure 2.5 GPa (Fig. 1), room temperature to obtain dense drug-carrying samples [1].

Materials were characterized by high resolution scanning electron microscopy (HR-SEM) with energy dispersive spectroscopy (EDS), by using the focused ion beam (FIB) slicing technique and Avizo software for 3D-reconstruction of samples microstructure. The mechanical properties were tested in compression. Degradation behavior in vitro was studied employing immersion test in modified Hank’s solution [3] for periods up to 8 weeks. Drug release in vitro was analyzed by a zone of inhibition (ZOI) technique on VH-sensitive Staphylococcus aureus (S. aureus) [4]. The drug release profile was studied in modified Hank’s solution by UV-spectrophotometry. Finally, the compatibility of drug-eluting metals was studied in vitro on human smooth muscle cells (hSMC).

Results and Discussion

The proposed processing approach allows loading of antibiotics and antitumor drugs during fabrication of bulk metallic samples. Near dense, 90 to 95% of theoretical density, Fe and Fe-Fe₂O₃ samples with 1-5 wt.% VH loaded into system of interconnected pores were prepared by cold sintering (Fig. 2a). Plastic deformation of metallic particles induced by hydrostatic pressure exceeding shear strength of particles (by Hertz model) [4], enables particles sintering. Thus, drug phase was encapsulated between sintered metallic particles, which was verified at 3D-reconstructions of samples microstructure.
VH-loaded Fe-Fe₂O₃ samples also showed high compressive ultimate strength (600 MPa) with almost no change after the loading of 1 wt.% drug. The VH release and analysis of surface microstructure showed that the initial release (first 1-2 weeks) was due to drug dissolution from the material surface and the system of open pores adjacent to outer layers. Then, the release slowed down and was associated to biodegradation. This observation correlated well with results of ZOI analysis (Fig. 2b) showing a decrease in antibacterial activity of bulk samples after ~2 weeks. Finally, preliminary in vitro culture test on hSMC line showed that Fe and Fe-Fe₂O₃ samples loaded with VH are not cytotoxic.

**Conclusion**

In this work on the example of Fe and Fe-Fe₂O₃, we present the capabilities of advanced cold sintering/high-pressure consolidation technique to encapsulate drug into bulk metal-based materials. Cold sintering is a simple and versatile method that can be implemented with different small-molecule drugs and active macromolecules (e.g., proteins). Our findings demonstrate the promise of this strategy in local delivery of bioactive substances at bone healing sites via degradation of temporary metallic implants.

Engineering Mucosal Barriers in Health and Disease: From Organoids to Organs – on – Chips

Linda Griffith

Massachusetts Institute of Technology, School of Engineering Teaching Innovation Chair of Biological and Mechanical Engineering, Cambridge, US

Mucosal barriers are the gateways to all internal organs, serving to transport oxygen, nutrients, and waste and at the same time performing enormous feats of protection against infection and other hazardous insults. The explosion of interest in the human microbiome – especially but not only that in the gut – has driven new interest in building human mucosal barrier models. This talk will highlight the development of synthetic “one size fits all” biomaterial hydrogels to engineer complex 3D epithelial-stromal-immune mucosal barriers, with a focus on the endometrium and the gut in health and disease. A central feature of the approach is defining a parameter space capturing physical, biochemical, and cell-specific features. Semi-empirical exploration of the parameter space provides efficient definition of hydrogel formulations that foster both initial cell survival and proliferation and subsequent differentiated function. While some phenotypic functions are adequately captured in 3D static culture, complex functions involving microbiome-mucosa interactions or vascular-mucosa interactions require incorporation into micro- or meso-fluidic devices. Examples will emphasize how these approaches can be used to model chronic inflammatory diseases, especially endometriosis and Crohn’s disease.

Ligia Marques

Sogrape Distribuição, S.A., Porto, Portugal

Ligia Marques from Sogrape will give a seminar about portuguese wine.

About Sogrape
"Founded in 1942 by Fernando Van Zeller Guedes, Sogrape was born to demonstrate the quality of Portuguese wines to the world. From a single winery in the Douro Valley focused on the production of Mateus Rose, this family company has become global, with presence in more than 120 markets, owning c. 1,600 hectares of vineyards in Portugal, Spain, Chile, Argentina and New Zealand. Moved by the purpose of bringing Friendship and Happiness to everyone it touches through its wonderful wines, the family spirit and the peak performing team culture lived at Sogrape are key in the successful path that it has been building for almost 80 years. Under the leadership of Fernando da Cunha Guedes, current President and 3rd generation of the founding family, the leading company in Portugal aims to spread Sograpiness through the world and be affirmed as a catalyst for positive societal change, respecting the limits of the planet in the construction of a more sustainable and inclusive future."

ESB-AERoGELS COST Action Joint Symposium

Title: Symposium on aerogels for biomedical applications

Aerogels are unique nanostructured porous materials with special properties adapted to fit certain advanced applications. Namely, aerogel-based materials can be used in biomedical applications as drug carriers, synthetic bone grafts for regenerative medicine and advanced wound dressings. Advances on aerogels and other nanostructured materials in these fields need to assemble expertise from interdisciplinary and intersectorial domains. Technological developments in terms of novel designs, processes, modelling tools, characterization techniques and uses for aerogels should be aligned to boost the progresses on the topic. This symposium aims at assembling and integrating the most recent scientific-technological knowledge in aerogels and other nanostructured materials on a wide range of fundamental topics and particularly applied in biomedical applications.

About AERoGELS COST Action:
AERoGELS COST Action brings together the knowledge on research and technology of aerogels at the international level from more than 200 institutions from academia, industry and regulatory experts. In AERoGELS Action, the use of aerogels is mainly focused on life sciences (pharma, biomedical, food) and environmental (treatment and removal of pollutants, energy management, life cycle analysis) applications.

Functional Bacterial Nanocellulose Materials

Anna Roig, Cristina Mira, Soledad Roig-Sanchez, Anna Laromaine

Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Campus UAB, Bellaterra, ES

Introduction
Nanocelluloses and their nanocomposites are gathering increased interest due to the enhanced properties arising from the combination of the nanocellulose with the functionalities characteristic of inorganic nanoparticles. Bacterial nanoellulose (BC) is an animal and donor-free natural polymer presenting some inherent characteristics that are highly regarded in the healthcare sector - purity, biocompatibility, mechanical resistance, thermal stability and a fibrilar microstructure similar to that of the collagen extra-cellular matter.

Experimental Methods
BC hydrogels were synthesized by Komagataeibacter xylinus grown on Hestrin-Schramm medium. K. xylinus cultures were culture for 3 d under static conditions at 30 °C to obtain BC fleeces that were sterilized by autoclaving.

Results and Discussion
I will describe some strategies to control BC topography [1] and microstructuration during the microbial cellulose biosynthetic process (Figure 1A) and then show routes to attain multi-nanoparticle millefeuilles [2] or patterning a BC film with nanoparticles (Figure 1B)

Conclusion
Several approaches to expand the scope, versatility and biomedical uses of bacterial cellulose by simple and scalable processes will be presented.

Alginate aerogel capsules obtained by prilling in tandem with supercritical drying for wound healing applications

Pasquale Del Gaudio1, Carlos A. García-González2, Renata Adami3, Chiara Amante1, Chiara De Soricellis1, Paola Russo1, Rita P. Aquino1

1 University of Salerno, Department of Pharmacy, Fisciano, IT; 2 University of Santiago de Compostela, Department of Farmacología, Farmacia y Tecnología Farmacéutica, Santiago de Compostela, ES; 3 University of Salerno, Department of Industrial Engineering, Fisciano, IT

Introduction
The incidence of chronic wounds is continuously growing due to the incessant population ageing and its related problems: cardiovascular diseases, diabetes and bedsores. One of the main drawbacks related to the healing of chronic wounds is the lack of an “ideal dressing” able to promote healing process [1]. Ideal wound dressings, in fact, should have a proper adhesion to the wound site, able to fit completely the wound bed, and easy to apply and remove. Moreover, they should provide a good absorbance of exudates without drying excessively the wound; as well as to control the delivery of active pharmaceutical ingredients (APIs). Aerogels in form of in-situ gelling formulations could represent an alternative to conventional dressing thanks to their ability to gel only on the lesion, when in contact with wound fluids, and not on the perilesional skin, thus avoiding a traumatic removal [2]. In this work the possibility to produce polysaccharide-based aerogels in form of beads, with an inner hollow, able to load hydrophobic APIs and to enhance the exudate uptake has been explored using inverse gelation prilling in tandem with supercritical CO2 drying.

Experimental Methods
Manufacturing of core-shell loaded-particles was conducted using alginate solutions at different concentrations (1.50% - 2.25%, (w/v)) to form the shell of the gel beads and an (O/W/O) emulsion was used to form the core. Drug-loaded microparticles were obtained adding ketoprofen lysinate (1% - 25% (w/w)) to the polymer solution. The obtained gel-beads were collected in a 0.3M CaCl2 aqueous or ethanolic solution and maintained under gentle stirring during 5 minutes before being rinsed and collected in water or absolute ethanol, respectively. Previously at the supercritical CO2 drying process, a solvent exchange was carried twice in order to eliminate the possible traces of water. The sc-CO2 drying was carried out at 40ºC and at a CO2 flow rate of 7 g/min during the first hour and at 5 g/min during the rest of the process. Different assays were carried out at 120 bar during 210 minutes and 140 bar during 270 minutes for the production of aerogels capsules.

Results and Discussion
Preparation of O/W/O emulsion was conducted using different concentrations of aqueous CaCl2 solutions to determine the appropriate concentration able to produce the inverse gelation at the nozzle. AI tools [3] were used to optimize CaCl2 concentration (set at 13.4 g/L) and prilling operating variables to produce spherical droplets without nozzle blocking. Homogeneous single droplet core-shell particles with an alginate thin shell were obtained with alginate concentrations between 1.75% and 2.25% (w/v), whereas non-optimized conditions lead to the formation of non-spherical particles inhomogeneous distribution of the oily phase into the shell (figure 1). The supercritical drying of the optimized particles led to aerogels with high porosity (89.9% - 95.3%) specific surface area BET specific surface area (Sb), between 2.50 and 27.5 m2/g and pore volumes ranging between 0.02 and 0.30 cm3/g. SEM images of aerogels showed that sphericity of the beads was retained during the drying process, and they presented an alginate porous layer about 30 µm thick (figure 2). Fluid uptake ability of the aerogel capsules was evaluated using simulated wound fluid. Aerogels capsules were able
to uptake up to 10 folds their weight in SWF. Gelling rate was very fast for all formulations with a total gelling time reduced to 6 seconds for aerogels with thinner alginate layer.

**Conclusion**

In the present work it was developed a robust manufacturing method for the production of core-shell beads by prilling technique in tandem with supercritical drying for the production of aerogels. The obtained optimized gel beads produced by prilling showed a single spherical core encapsulated into an alginate thin shell and had a size > 1 mm. These optimized aerogels capsules showed high surface areas and porosities. Furthermore, aerogels were able to absorb high amount of exudate and easily handled improving in this manner the patient compliance during its direct spreading on a wound. Moreover, the properties of the alginate layer strongly promoted the fast uptake of high amounts of exudate, moving from aerogel to a soft hydrogel, in less than 10 seconds to total gelation. Although those are preliminary studies such results suggest that alginate aerogel capsules could be administered as a self-consistent dosage forms in the treatment of both acute and chronic wounds.

Alginate and Hyaluronic Acid Aerogels as Novel Materials for Wound Dressing applications

Tamara Athamneh¹, Drew Lawrence², Pavel Gurikov³, Irina Smirnova²

¹ The Hashemite University, Department of Pharmaceutics and Pharmaceutical Technology, Zarqa, JO; ² Hamburg University of Technology, Institute of Thermal Separation Processes, Hamburg, DE; ³ Hamburg University of Technology, Laboratory for Development and Modelling of Novel Nanoporous Materials, Hamburg, DE

Introduction

The optimal wound dressing material should be able to absorb wound exudates while keeping the wound moist, insulate the wound to keep it at an appropriate biological temperature, allow gases to permeate through the dressing to allow for oxygen exchange and exhibit desirable mechanical characteristics so they are easy to handle but remain stable for extended periods of time [1]. In the case of medicated wound dressings, the dressing material preferred to have a high inner surface area to allow for loading and sustained release of the drug [1]. Thus, aerogels present a suitable option for wound dressing, specifically, bio-based aerogels, because of their high stability, low toxicity, non-allergenic characteristics and good biological performance [2]. In the present study alginate (Alg) and hyaluronic acid (HA) and alginate/hyaluronic acid (Alg/HA) aerogels were produced via drying the chemically or physically cross-linked gels with supercritical carbon dioxide and evaluated as potential wound dressing materials.

Experimental Methods

The physically cross-linked gels were prepared from 2 % solution (HA or Alg) in distilled water. The gelation was triggered by the addition of 6 % D-glucono-d-lactone (GDL), which reduced the polymeric solution pH to 2.5 in 24 hours. The solutions were left overnight to allow gelation and solvent exchange with ethanol was conducted in the next day with sequence of ethanol concentrations: 75 %, 90 %, 100 %. To prepare the chemically cross-linked gel, 2 % Alg or Alg/HA solution were prepared. Calcium carbonate was added to the polymeric solutions to achieve a ratio of 0.1825g CaCO₃ per 1 g Alg. The required mass of GDL was measured and added to achieve 6 % GDL in the final solution. The solution was stirred for 10 seconds before being drawn into a syringe and dispensed into the final containers for gelation. The solvent exchange was conducted as the physically cross-linked gel. Finally, all hydrogel samples were dried using supercritical carbon dioxide at 50°C and 120 bar. The samples were dried for three hours before beginning depressurization, which was performed at a maximum rate of 2 bar/min. Samples were then stored in airtight containers in a desiccator to avoid any effect of moisture in the air.

The prepared aerogel formulations were evaluated for suitability as novel wound dressing materials with high capacity for absorption of wound exudates, by testing density, BET surface area, absorption capacity, and compressive young’s modulus.

Results and Discussion

All the prepared aerogel showed promising results, with superior results for the hybrid aerogel consisting of calcium cross-linked alginate and hyaluronic acid which showed an absorptivity of over 1500 % (Figure 1) and a compressive Young’s modulus of 1.49 MPa. This aerogel also achieved a BET surface area over 400 m²/g and a low density less than 0.1 g/cm³.

Based on the absorptivity test, the calcium-crosslinked aerogels were found to have potential to be used as wound dressing material. The physically cross-linked Alg and HA showed superior absorptivity at the first 30 min, but after that and due to the absence of strong cross-linking mechanism, the aerogel started to dissolve. The ratio of Alg to HA can be manipulated to control the mechanical characteristics depending on the desired application of the aerogel.
Conclusion

Besides the well-known advantages of HA on wound healing, the hybridization of Alg with HA hybrid showed a synergistic effect with a very high absorptivity, high BET surface area, very low density and superior porosity. Making this aerogel an effective candidate for the absorption of wound exudates, isolation of the wound area, and possibly the delivery of antimicrobial or growth agents.

Mid-term stability of starch-based aerogels upon storage

Victor Santos-Rosales¹, Gerardo Alvarez-Rivera², Ameya Rege³, Carlos A. García-González¹

¹ Universidade Santiago de Compostela, Pharmacology, Pharmacy and Pharmaceutical Technology, Santiago de Compostela, ES; ² Laboratory of Foodmics, Institute of Food Science, Madrid, ES; ³ Department of Aerogels and Aerogel Composites, Institute of Material Research, German Aerospace Center (DLR), Cologne, DE

Introduction
Starch aerogels are attractive materials for biomedical applications because of their low density and high open porosity coupled with high surface areas. However, the lack of macropores in conventionally manufactured polysaccharide aerogels is a limitation to their use as scaffolds for regenerative medicine [1]. Moreover, the evaluation of the stability under storage of polysaccharide aerogels is critical for biomedical purposes and scarcely studied so far.

In this work, a new macropore population (1-2 μm) well integrated into the starch aerogel backbone was successfully conferred to the aerogel structure by the incorporation of zein. The obtained dual-porous aerogels were evaluated in terms of composition as well as morphological, textural, and mechanical properties. Moreover, stability of aerogels was evaluated at mid-term mimicking the zone II (25ºC, 65 % RH) according to the International Council for Harmonization guidelines. Zein incorporation showed a preventive effect on the morphological changes during the storage period while induced remarkable changes in the mechanical performance [2].

Experimental Methods
Cylindrical aerogel specimens were obtained by a previously reported procedure [1]. A series of starch-aqueous dispersions (10% w/w) with varying ratios of zein as the porogen (Figure 1; Z0-Z4). After the solvent exchange (gel-alcogel transition) and zein leaching, a supercritical drying process (6 g/min, 40ºC, 130 bar) was performed for 4 h. Aerogel probes were collected and characterized in morphological, textural, and mechanical terms. Zein residues were quantitatively determined by high-resolution tandem-mass spectrometry analysis.

Results and Discussion
Starch aerogels with a novel macropore population were obtained with the presented method (Figure 2). Zein residues in the 3-24% range were found in the aerogel products, affecting the entire properties of the aerogel. For instance, aerogels with lower residues (Z1, Z2) were lighter and more porous than the unmodified starch aerogels (Z0), whilst those with higher residues (Z3, Z4) behaved the opposite way. Zein presence strongly influenced the stiffness of the aerogels, although specimens exhibited a good strain memory during the cyclic loading tests.

The exposition to storage conditions induced remarkable morphological and textural changes on the aerogels, but the mechanical behavior remained unaltered. Aerogels with higher zein residues (Z3, Z4) preserved better their features after 3 months of storage.

Conclusion
Highly porous starch aerogels (85-92%) with integrated macropores in the mesoporous starch backbone were obtained, encouraging their use as scaffolds for tissue engineering. Zein incorporation induced remarkable changes in the mechanical performance of the aerogels. The storage period (1 and 3 months) induced morphological modifications, but the presence of zein had a preventive effect on it.

Integrated process of supercritical extraction of hemp seed flour and impregnation on starch xerogel and aerogel

Ivana Z. Lukic¹, Jelena M. Pajnik², Stoja L. Milovanovic¹

¹ University of Belgrade, Faculty of Technology and Metallurgy, Belgrade, RS; ² University of Belgrade, Innovation Center of the Faculty of Technology and Metallurgy, Belgrade, RS

Introduction

Hemp seed flour, a by-product of oil production, is a good source of polyunsaturated essential fatty acids, linoleic (omega-6) and α-linolenic (omega-3), with the balanced ratio between 2:1 and 3:1, which is considered optimal for healthy human nutrition. Beside, flour is rich in other bioactive compounds from the polyphenol group, vitamin E, amino acids and minerals, with well-established health benefits including an anti-allergenic, anti-inflammatory, anti-microbial, and cardioprotective effects which make extract obtained from hemp seed flour suitable for the wide range of possible applications, such as nutraceutical, biomedical and pharmaceutical [1,2]. Prolonged shelf-life, stability and bioavailability of bioactive components could be accomplished by its impregnation on/in a polymeric carrier. Aerogels, a special class of porous materials, appear to be promising candidates for this purpose, having open pore structure and high surface area thus enabling high amount of extract to be loaded [3]. Among them, starch aerogels are biodegradable, biocompatible and obtained from renewable resources in an environmentally friendly manner. Therefore, they can be used as carriers for drug delivery systems. Excellent technique for loading of natural bioactive compounds from plant materials into the polymeric carriers with minimal extract losses is integrated process accomplished by merging the supercritical fluid extraction (SFE) and supercritical solvent impregnation (SSI) into the one process. The aim of this study was to prepare starch gels and functionalize them with hemp seed flour extract using integrated SFE-SSI process.

Experimental Methods

Starch gels were prepared starting from hydrogel formed from an aqueous solution of cornstarch (1:10 w/v) which was stirred for 3 h at 95 °C. After replacement of water with acetone by successive increase of its concentration until 100% was achieved, acetogel was formed and further subjected to drying. Aerogels were prepared by supercritical CO₂ (scCO₂) drying at 45 °C and 10 MPa, using combined static and dynamic drying mode. For comparison, a part of acetogel was dried in the oven at 60 °C to obtain xerogel. Integrated SFE-SSI process was performed on laboratory scale unit (High Pressure Extraction Adsorption (HPEA) 500, Eurotechnica, Germany) at 60 °C and 30 MPa for 4 h. Detailed equipment description is presented elsewhere [4].

Results and Discussion

Starch aerogels prepared by scCO₂ drying at 45 °C and 10 MPa, using combined static and dynamic drying mode, are highly porous material with porosity determined to be 81% and low density of 273 kg/m³. On the other hand, porosity of xerogel was only 10%. Scanning electron microscopy (SEM) analysis also confirmed that air drying was not able to preserve the morphology of wet gels contrary to scCO₂-drying which prevented the collapse of the pores. The amounts of impregnated hemp seed flour extracts using integrated SFE-SSI process were 9.2 and 29.8% for xerogel and aerogel, respectively, showing the great influence of the textural properties of carrier on its loading capacity. The presence of the extract of hemp seed flour on the surface of impregnated samples was confirmed by FTIR analysis. Release study revealed initial faster release of extract into PBS solution from xerogel due to the extract position mainly on material surface, while in the case of aerogel extract was distributed through whole carrier matrix.

Conclusion
Starch gels were successfully impregnated with hemp seed flour extract using the integrated SFE-SSI process at 30 MPa and 60 °C. It was shown that impregnation efficiency is highly dependent on morphology and textural properties of polymeric carrier.

Impregnation of starch aerogels with eugenol in supercritical carbon dioxide

Jelena M. Pajnik¹, Ivana Z. Lukic², Stoja L. Milovanovic²

¹ University of Belgrade, Innovation Center of the Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, RS; ² University of Belgrade, Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, RS; ³ University of Belgrade, Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, RS

Introduction
Despite the fact that aerogels are well known for decades, they are being still considered as emerging ones due to high technological advancement and fast development of new methods for fabrication of versatile aerogels. Supercritical CO₂-assisted drying enables utilization of an environmentally friendly medium for preparation of aerogels with different morphologies by simple variation in operating conditions (e.g. pressure). One of the polymers that was reported for aerogels preparation is starch, a low-cost polysaccharide obtained from renewable resources. As it is biodegradable and highly biocompatible, it can be successfully applied in various fields, including pharmaceutical and biomedical. Beside use of supercritical CO₂ for aerogel preparation, this study was aimed to investigate possibility of supercritical solvent impregnation (SSI), for loading of starch aerogels with eugenol.

Experimental Methods
A starch hydrogel was formed from an aqueous solution (cornstarch to water mass ratio 1:10) at 95 °C. Afterwards, water was gradually replaced with acetone during several days to form an acetogel. Starch acetogels were dried at 45 °C and pressures of 10 and 20 MPa. Scanning Electron Microscopy (SEM) was used to evaluate textural properties of the aerogels. Obtained aerogels were impregnated with eugenol at 35 °C, 20 MPa during 5 and 18 h in a high pressure view cell using green medium, supercritical carbon dioxide. Aerogels before and after the SSI were analyzed by Fourier transform infrared (FTIR) spectroscopy.

Results and Discussion
Porosity of the aerogel dried at 10 MPa was 82%, while increased pressure (20 MPa) led to the formation of less porous structure (48%). The difference in morphology of the starch aerogels was clearly visible on SEM images. Morphological properties of aerogels greatly influenced the SSI (Figure 1). The amounts of loaded eugenol were in the range of 25.3 - 31% and 2.8 – 7%, for aerogels dried at 10 and 20 MPa, respectively. FTIR analyses confirmed presence of eugenol on the surface of the impregnated starch aerogels. Desorption tests of eugenol from the impregnated aerogels in PBS showed controlled release profile.

Conclusion
Proposed SSI technique was found effective in impregnation of starch aerogels with eugenol. Given that eugenol has proven antioxidant, anti-inflammatory, and antimicrobial activity, obtained results indicate various possible application of eugenol loaded starch aerogels.

Sol-gel Derived Carbon Microspheres by Continuous Ultrasonic Spray Pyrolysis

Anna Liisa Peikolainen¹, Mai Uibu², Alvo Aabloo¹

¹ University of Tartu, Institute of Technology, Tartu, EE; ² Tallinn University of Technology, Department of Materials and Environmental Technology, Tallinn, EE

Introduction
Sol-gel derived materials are unique type of porous materials because their structure and porosity can be tailored according to its application by the choice of precursors and synthetic conditions. In addition to synthesis of monolithic materials, preparation of sol-gel materials in the powder form via bottom-up routes have been introduced, such as inverse emulsion polymerization [1], electrospraying [2], inkjet printing of microspheres [3]. Here, the fabrication of sol-gel derived carbon microspheres via ultrasonic spray pyrolysis is reported. Ultrasonic spray pyrolysis has been used for fabrication of spherical carbon particles from organic salts. [4] Synthesis of carbon from a colloidal solution via ultrasonic spray pyrolysis, enables to reduce the number of steps in the fabrication process compared to abovementioned methods while enabling continuous synthesis of carbon particles.

Experimental Methods
Aqueous 5-methylresorcinol-formaldehyde solution with Na₂CO₃ as a catalyst with predetermined concentrations was prepared and stirred vigorously at 25°C for 24 h. The aerosol droplets of colloidal solution were generated with ultrasonic nebulizer and transported through a tubular furnace (MTF 12/38/400, Carbolite) at temperature 900°C by a flow of N₂ (0.025 l/min). The carbon particles formed were trapped into water reservoir and then collected by centrifugation.

The particles obtained were investigated using scanning electron microscopy (SEM) (TM-3000, Hitachi). The elemental composition was analysed using energy-dispersive X-ray spectroscopy (EDX) (a Hitachi TM-3000 SEM that was coupled with a SwiftED 3000 EDX analyser, Oxford Instruments). The porosity of the carbon microspheres was determined using N₂ sorption analysis (KELVIN 1042 Sorptometer, Costech Microanalytical SC).

Results and Discussion
Sol-gel derived carbon microspheres obtained were with the maximum particle diameter of 3 µm (Figure 1). The spheres consisted of 95.5 atomic% of carbon which is a high level of carbonization during rapid pyrolysis in flow. Specific surface area calculated based on Brunauer-Emmet-Teller theory was 12 m²/g, and a total pore volume the material reached 137 mm³/g.

Conclusion
The results of elemental analysis, the specific surface area of 12 m²/g and total pore volume of 137 mm³/g suggest that ultrasonic spray pyrolysis enables to produce fine carbon powder for applications where moderate specific surface area is required.

**C.elegans** as animal model for cardiac arrhythmia - the case of Polypyrrole Nanoparticles

**Sumithra Y. Srinivasan**¹, Nuria B. Cases², Dmytro Kukhtar³, Pilar A. Illera⁴, Julián C. Madrigal³, Mayte M. Zoccola⁴, Rosalba Inés F. García⁴, Anna Laromaine¹

¹ Universitat de Autonoma de Barcelona, Institut de Ciència de Materials de Barcelona (ICMAB), Bellaterra, ES; ² ALBA Synchrotron, Cerdanyola del Vallès, ES; ³ Hospital Duran i Reynals, Institut d'Investigació Biomèdica de Bellvitge (IDIBELL), Barcelona, ES; ⁴ Universidad de Valladolid, Instituto de Biología y Genética Molecular (IBGM), Valladolid, ES

**Introduction**

Cardiac arrhythmia (CA) is characterized by irregular beating of the heart cells, caused by improper propagation of cardiac impulse among cardiac cells, prevalent in 90% of CVD patients [1]. Conducting polypyrrole nanoparticles (Ppy NPs) attempts to regulate the electrical impulse propagation across cardiac cells [2]. In our present work, we aim to study the potential of Ppy nanoparticles in synchronizing irregular heart rhythm. In order to evaluate it, we use Caenorhabditis elegans as a small animal model. *C. elegans* are worms with 60% genetic homology to humans, optically transparent, exhibiting short life span and fast reproduction cycle. Notably, the pharynx of *C. elegans* is a continuously pumping organ, the molecular mechanism of which is similar to humans´ cardiac pumping [3]. We are exploring *c.elegans*´ pharynx as a model system for cardiac arrhythmia, to test the potential of Ppy in regulating irregular pumping. Some studies have shown that Ppy has the ability to enhance transient Ca$^{2+}$ signal conduction across voltage gated calcium channels [2].

**Experimental Methods**

Ppy NPs were synthesized reproducibly using chemical oxidative polymerisation method [4]. Physicochemical characterizations, size and morphology and electrical conductivity were measured for the NPs. Ppy NPs were orally administered to *C. elegans* and systemic toxicity and pharynx pumping measurements were carried out. Racepinephrine and propranolol were used as positive and negative control CA drugs, respectively. We employed nanopore sequencing to elucidate the genes that are affected upon Ppy exposure. Further, calcium measurements and electrophysiological measurements from the pharynx are under progress.

**Results and Discussion**

Ppy NPs were found to be spherical with ≈100 nm diameter and a conductivity of ≈0.8 S/cm. We found that Ppy NPs do not show any adverse toxic effects through initial toxicity studies survival %, body length and reproduction. Ppy NPs causes an increase in pharynx pumping rate in *C. elegans*, similar to the positive control racepinephrine. Whereas, propranolol shows a decrease in the pumping rate. We further studied effect of the controls and Ppy NPs on pumping rate through different parameters such as duration time and pumping rate after excretion. Genetic studies to understand which genes are affected upon Ppy exposure, and how those genes can play a role in CA are currently under progress. Taking forward, we are also planning to evaluate cardiac contraction in the cells, we aim to study the transient Ca$^{2+}$ conduction across the voltage-gated calcium channels to understand the exact mechanism of Ppy in changing the pumping rate through calcium imaging in cells as well as *C. elegans*.

**Conclusion**

Application of Ppy in cardiovascular treatments is still at its beginning stage and the molecular mechanism of conducting materials in regulating cardiac synchronization is poorly studied. We believe that our initial screening, as well as genetic and molecular studies with an *in-vivo* small animal model *C. elegans* can greatly accelerate the progress of this material for cardiac therapies.

Bacterial Nanocellulose-Polypyrrole (BC-Ppy) composites as scaffolds for cardiac resynchronization

Sumithra Y. Srinivasan, Osnat Zapata, Mariano Campoy, Anna Laromaine

Universitat de Autonoma de Barcelona, Institut de Ciència de Materials de Barcelona, Barcelona, ES

Introduction
Myocardial Infarction (MI) is a major cause of heart failures. The ischemic muscle death impairs electrical impulse propagation, causing abnormalities in heart rhythm, resulting in cardiac arrhythmia and conduction disorders [1]. Biomaterial scaffolds for cardiac tissue engineering is therefore an active subject of interest. Conducting polymers are able to communicate cardiac impulse across the tissue, facilitating synchronization. Especially, Ppy is the most popular candidate among CPs for tissue engineering applications owing to its easy synthesis, aqueous stability and biocompatibility [2]. In order to improve the structural properties, we have designed a nanocellulose-py composite scaffold. Cellulose is the most abundant bio-polymer with excellent biocompatibility. Bacterial nanocellulose (BNC) displays high purity compared to plant derived cellulose. The fibrous structure of BNC mimics the ECM environment and BNC films are flexible with high mechanical strength to withstand chronic shear stress, making them ideal as cardiac scaffolds [3]. Herein, we have designed and will be investigating cardiac cell attachment and contractions on BNC-Ppy scaffolds.

Experimental Methods
BNC were produced from the bacterial strain Komagataeibacter xylinus (K. xylinus) [4] and BC-Ppy via in-situ oxidative polymerization. The scaffolds were characterized by FT-IR, SEM, TEM, TGA and 4-probe keithly instrument to study their size, structure, morphology and conductive properties.

Results and Discussion
BNC-Ppy scaffolds were successfully synthesized and characterized, wherein the fiber diameter was found to be ≈ 70 nm and that of Ppy NPs were found to be ≈ 85 nm. The conductivity of BC-Ppy films were found to be proportional to the concentration of initial monomer added, and was ≈ 2 S/cm. In-vitro cell culture experiments with BNC-Ppy scaffolds are at the initial stage studying the cell attachment and morphology of cells seeded on scaffolds. Following this, we plan to evaluate the contraction of cells seeded with and without scaffolds and in the presence and absence of external stimulation.

Conclusion
Only a handful studies have shown the efficacy of composites with Ppy as cardiac tissue engineering scaffolds and BNC has not been explored as an effective composite material for this purpose till date. Considering the potential and properties of these materials, BC-Ppy is a promising cardiac tissue engineering scaffold material. To the best of our knowledge, this will be a first of its kind study the use of BNC-Ppy as a scaffold for cardiac cells.

Development of lignin-based aerogels

Mihkel Koel, Piia Jõul, Tiit Lukk

Tallinn University of Technology, Department of Chemistry and Biotechnology, Tallinn, EE

Introduction
The conversion of lignin to higher-value products has been a topic of interest for many years. The idea of substituting phenol in phenol-formaldehyde (PF) resins and resorcinol in resorcinol-formaldehyde (RF) aerogels leads to new, bio-based lignin materials. The low reactivity and heterogeneity of lignin are challenges that can be overcome by lignin modification or cleavage.

Lignin that is cleaved from the lignocellulosic materials and dissolved by organic solvents is known as organosolv lignin. Usually, organosolv lignin is closer in structure to natural lignin, compared to other technical lignins. Lignin can be separated from lignocellulosic biomass with molten salts (ionic liquids and deep eutectic solvents). This kind of treatment is increasing the reactivity of lignin.

The preparation of aerogels from lignin is derived from its phenolic character of chemical structure; it is possible to substitute resorcinol with lignin and use the polycondensation of lignin and formaldehyde for aerogel production. Resulting aerogel is versatile material for value-added applications such as insulation and adsorber materials and raw material for carbon aerogels which can be used as super-absorber or materials for supercapacitors.

Experimental Methods
In current study, organosolv lignin extracted from bleached chemi-thermomechanical aspen pulp (BCTMP) using ethanol and hydrochloric acid was utilized as one of the precursors for the preparation of hydrogels with different lignin/5-methylresorcinol (5-MR) weight ratios to obtain homogeneous lignin-5-MR-formaldehyde (F) hydrogel. After the solvent exchange step, the resulting gel was atmospherically, supercritically or freeze-dried.

Results and Discussion
Chemical and physical properties of obtained xerogels, aerogels and cryogels were evaluated to determine the proper lignin/5-MR weight ratio and the maximum percent of the 5-MR, which could be replaced with BCTMP organosolv lignin.

Conclusion
The heterogeneous and complicated phenolic-rich structure of lignin what differs among lignins of different origin results development lignin-based materials complicated. Chemical extraction / treatment of lignin with molten salts is challenging way to get homogenous and uniform porous aerogels.

Fabrication of bi-functional drug-laden 3D printed aerogel-based scaffold from antibacterial and biocompatible RGD-AMP modified silk fibroin-silica hybrid ink

Yan Demidov, Hajar H. Maleki

University of Cologne, Institute of Inorganic Chemistry, Köln, DE

Introduction

Scaffold-mediated tissue engineering has become a golden solution for the regeneration of damaged bone tissues that lack self-regeneration capability. A successful scaffold in bone tissue engineering comprised of a multitude of suitable biological, microarchitectural, and mechanical properties that are acting as different signaling cues for the cells to mediate the new tissue formation. Therefore, careful designing of bioactive scaffold macro and microstructures in multiple length scales and biophysical properties fulfilling the tissue repair demands are highly required yet very challenging to achieve.

Experimental Methods

In our study, we have synthesized an antibacterial and biocompatible gel-based ink and processed it as three-dimensional (3D) hybrid aerogel based scaffolds with exploiting from the novel yet simple chemical approaches of sol-gel processing and self-assembly approaches with a controlled microstructural design e.g. micro-extrusion based 3D printing and unidirectional freeze casting approaches [2]. As the main constituent of our biocompatible scaffold of this study, we used the silk fibroin (SF) extracted from B. mori cocoon [3]. However, to increase the cell responsivity and bactericidal efficiency, thiol-ended antibacterial, and cell adhesive peptide sequences (SH-AMP-RGD) have been conjugated to the SF polymer through a covalent attachment using a spacer molecule (Fig. 1). This was followed by processing the AMP-RGD-SF as a 3D printable hydrogel. In the next step, the hybrid hydrogel was successfully assessed in terms of printability and viscosity parameters and 3D printed into the construct with interconnected porous structure with hierarchically organized porosity and a combination of several useful properties.

Results and Discussion

Thanks to the covalent linkage of the antibacterial peptide to the SF, the scaffold indicates potent bactericidal efficiency toward gram-positive and negative bacteria. Besides, for the sake of osteoconductivity and osteogenicity, and mechanical strength, we loaded the hydrogel with inorganic components such as 3D silica nanostructures so that SF and silica could intertwine together through parallel sol-gel and self-assembly processing to support the mechanical structure in the final scaffold.

Conclusion

Finally, this study supports the promise of 3D printed anti-infective silica-SF-based hybrid aerogel constructs for repairing the bone defect.
AMP-RGD modified silk fibroin silica aerogel based scaffold designed by a synergistic combination of sol-gel reaction, self-assembly, and 3D printing approaches

Textural and biological evaluation of 3D-printed alginate-hydroxyapatite aerogel scaffolds

Ana Iglesias-Mejuto, Carlos A. García-González

Universidade de Santiago de Compostela, Department of Pharmacology, Pharmacy and Pharmaceutical Technology, I + D Farma Group (GI-1645), Faculty of Pharmacy, and Health Research Institute of Santiago de Compostela (IDIS), Santiago de Compostela, ES

Introduction

3D-printing technology allows the automated and reproducible fabrication of functional, scalable and customized 3D-structures for personalized medicine with high-precision (Boga et al., 2018). Alginate is a natural polysaccharide commonly employed as bioink in 3D-printing due to its biocompatibility, biodegradability, non-immunogenicity and low cost. However, alginate based structures usually lack bioactivity and should be combined with other admixtures for bone tissue engineering. Hydroxyapatite (HA) is an excellent bone substitute because it is bioactive and osteoconductive (Luo et al., 2018). Gel scaffolds prepared with well-defined internal structure and dual-interconnected porosity is essential for tissue engineering and feasible by 3D-printing (Boga et al., 2018). An adequate extraction method of the solvent of a gel is the supercritical CO$_2$-assisted drying as long as it preserves the internal gel structure in terms of its porosity and specific surface area (García-González et al., 2015). In this work, 3D-printed alginate aerogel scaffolds were obtained by the novel combination of 3D-printing and supercritical CO$_2$ drying and evaluated regarding their textural and biological properties aimed to personalized bone regenerative medicine applications.

Experimental Methods

Scaffolds of dimensions 20x20x1 mm were printed from different alginate- HA solutions with a grid pattern and 3 layers. After the printing process, all scaffolds were put directly in contact with CaCl$_2$ aqueous solutions for gelation. The 3D-aerogels were obtained after solvent exchange to ethanol and supercritical drying (120 bar, 40 °C, 3h). The effect of alginate (6-10 wt.%), CaCl$_2$ (0.1-1M) and HA (8-24 wt.%) concentration was evaluated on the textural parameters of the final scaffold (specific surface area, total porosity, mean pore diameter) by BET and SEM analyses. Biological properties (cell viability and adhesion) were assessed in BALB cells after 24 and 48h and the bioactivity tests were performed in simulated body fluid (SBF) at different time periods.

Results and Discussion

Homogeneous 3D-structures formed by filaments arranged in layers with alginate concentrations in the 6-10 wt.% range and HA concentration in the 8-24 wt.% range were successfully obtained after crosslinking with CaCl$_2$ concentrations in the 0.1-1 M range (Fig. 1). The highest BET surface area (438 m$^2$/g), pore size (22 nm) and total pore volume (3.14 cm$^3$/g) were found in aerogels obtained with an alginate concentration of 6 wt.%. Nevertheless, the BET analysis of alginate/HA aerogel scaffolds has shown an important decrease in the surface area and total pore volume while the pore diameter is almost maintained with respect to scaffolds fabricated only with alginate. Overall, the 3D-structure and porosity of all structures were maintained after all processing steps, with mesopores and macropores clearly recognized in all aerogel types (Fig. 1). Furthermore, excellent results on BALB cells viability were found for all aerogel formulations, without observing statistical significance (t-test, p >0.05) with respect to the positive controls, thus confirming the lack of toxicity or other negative effect on the normal cell environment. Finally, cell attachment (Fig. 2) and spreading in terms of nuclear staining was revealed with a proliferation tendency observed in all aerogels formulations, since more nuclei were stained after culturing scaffolds for 13 days than after
6 days. This feature indicated that scaffolds were suitable for tissue growth and able to promote cell adhesion (Fig. 2) and proliferation, as well as the cell colonization of the aerogel scaffold.

**Conclusion**

Macroporous alginate-HA aerogel scaffolds printed in a precise and customized way were obtained by the technological combination of 3D printing and supercritical drying method. Alginate, HA and CaCl₂ concentrations determined the scaffold end nanostructure. The cell viability tests revealed no toxicity effect or negative impact caused by the thus manufactured structures while adhesion assays show cell attachment and spreading with a proliferation tendency throughout the days.

Ethyl cellulose composites with polylactic acid in tissue engineering

Gabrijela Horvat, Klara Žvab, Zeljko Knez, Zoran Novak

University of Maribor, Faculty of Chemistry and Chemical Engineering, Maribor, SI

Introduction
Aerogels and foams are promising materials for bone implants since they could be used as scaffolds for mimicking the natural tissue. Those materials show interconnectivity of pores and are hence interesting materials for cell growth. Additionally, their porous structure and high surface areas enable the incorporation of active agents such as anti-inflammatory agents and antibiotics [1,2,3]. Mechanical properties of polysaccharide aerogels are however poor, leading to a development of new, polymer based composites with polylactic acid (PLA). From a mechanical engineering point of view, moduli of elasticity of implant material and bone materials should be as close as possible (e.g. modulus of elasticity for bone material is around 18 GPa). [4]. Materials, prepared from PLA can reach modulus of elasticity up to 14 GPa, which is very similar to bone. PLA degradation rate in a biological environment is slow, and the combination of polysaccharide aerogels with PLA may result in final biodegradable material with desired mechanical properties and suitable degradation rate for new bone formation.

Experimental Methods
Ethyl cellulose (EC) and polylactic acid (PLA) composites were prepared by dissolving raw materials. Different concentrations of both solutions were prepared and then combined in various ratios in order to obtain composites of various compositions regarding EC and PLA content. Composites were dried by supercritical CO_2 and final materials were characterised by nitrogen adsorption analysis, SEM, DSC-TGA analysis, DMA and swelling. Headspace GC method was used in order to determine the residuals of organic solvents in final materials.

Results and Discussion
Prepared aerogels showed good mechanical properties, however, their surface area was rather low. The surface area decreased by increasing the PLA content, leaving material polymer-like. Supercritical drying of materials showed to be a good method for eliminating the organic solvents from composites as there were no residuals above the toxic level.

Conclusion
The preparation of EC and PLA composites is a promising method for the formulation of bone scaffold materials. Various combinations of EC and PLA gives materials with various properties, however it is noteworthy that the addition of PLA drastically increases the mechanical strenght and elastic modulus of prepared scaffolds. EC-PLA composites are completely biodegradable and biocompatible and there is no residuals of organic solvents.

In vitro and in vivo biocompatibility and biodistribution screening of aerogel products

Gabor N. Szeman¹, Jozsef Kalmar²

¹ University of Debrecen, Department of Molecular Biotechnology and Microbiology, Debrecen, HU; ² University of Debrecen, Department of Inorganic and Analytical Chemistry, Debrecen, HU

Introduction

Development of aerogel products raises the need for fast and effective evaluation of their biointeractions from the cellular level up to the ecological level. Here we propose a methodological pipeline for fast, yet effective screening of broad-range biological interactions. The experimental setup was optimized for the usage of limited quantities of aerogel samples gained from the early stages of experimental production. Parallel data can be obtained from the very same sample, regarding effects on cellular viability, cell-cycle, cellular surface interactions and genotoxicity. Furthermore, quantitative data can be acquired about ecological interactions using just milligrams of aerogel. In vitro data then will be used to set the in vivo tests on mice for biocompatibility/toxicity and biodistribution. Migration of aerogel particles on lymphatic pathways can be characterized in the same set of experiments reducing the number of animals. The proposed workflow of combined methods can reduce the required efforts for testing in the terms of labour and resources.

Experimental Methods

96-well microtiter plates were used for observing the effects of increasing concentrations of aerogel microparticles (10-100μm) on cultured human keratocyte HaCat cell line and human colorectal carcinoma CaCO2 cell line. Cellular responses were monitored via long-term (one week), non-invasive near-infrared (940nm) time-lapse microscopy inside a CO2 incubator under standard cell breeding conditions. Acquired image sequences were analyzed via customized algorithms of NIH ImageJ software. [1-3] Dynamic cellular parameters like size, motility, uniformity, cell-cycle, divisions were quantified on the single cell and population level against time. The same microtiter plates used for imaging were used for MTT cellular viability tests for determination of average living cell number. In the animal experiments 10 (5M/5F) C3H/HeJ mice were injected intraperitoneally with aerogel microparticles suspended in phosphate-buffered saline solution. After one and two weeks the animals were sacrificed and subjected to autopsy for macroscopic investigation and organ harvesting for histopathological examination. Liver, spleen, kidneys were fixed and embedded in paraffin blocks for hematoxylin-eosin staining and immunohistochemistry. Thymus and parathyrmhical lymphatic nodes were also collected for the evaluation of the aerogel microparticles distribution on lymphatic pathways. [4] Ecological and environmental interactions were investigated using custom-built hardware for time-lapse macroscopic image acquisition of 10 parallel capillary (100μl natural water) containing Paramecium Caudatum model organisms in the presence of Hg-specific aerogel absorbent. [5]

Results and Discussion

Silica-based, silica-gelatin hybrid and silica-casein hybrid aerogels did not cause cytotoxicity in a wide concentration range, although the physical presence of the particles interfered with the cellular migration on the breeding substrate surface. [1-3] Smaller particles about 10 μm are often collected by the cells due to the negative charges of the aerogel, similar to the breeding surface. The size discrimination of the cellular surface attached particles can be used to estimate the strength of cell-aerogel binding. Also, in the case of gelatin-containing aerogel, significant positive chemotaxis, chemotraction were observed while cells migrated toward large chunks of aerogel. [1, 2] Analysis of dynamic functional-morphology parameters of the cells suggest that these aerogels elongated the cell-cycle due to their mechanical presence. The MTT viability test results exhibited a good endpoint correlation with these results.
The animal experiments outlined the non-toxic nature of hybrid aerogel microparticles at low concentration (52 mg per kilogram body weight), while high dose (104 mg kg⁻¹) induced low to moderate hepatotoxicity. Fluorescently labelled silica-gelatin aerogel particles were found in the parathymical nodes, suggesting the spread of these particles in lymphatic pathways. The immunohistochemical staining of CD68 and CD163 demonstrated the activation of monocytes / macrophages by aerogel microparticles. In the ecological tests, Hg(II)-binding aerogels (0.1 mg/ml) protected the _Paramecium Caudatum_ up to 500 ppb Hg(II) concentration. [5]

**Conclusion**

Data obtained from image sequences, viability test and genotoxicity test justified the sensitivity of the experimental methods in the evaluation of cell-aerogel interactions. _Paramecium_-based ecological tests indicated the non-toxic nature of aerogels under natural conditions and also exhibited their potential in mercury-detoxification.

Structure and properties of silk fibroin based aerogel particles prepared by emulsion-gelation followed by supercritical CO2 for wound healing

Beatriz G. Bernardes¹, Clara López-Iglesias², Raquel Costa³⁴⁵, Carlos A. García-Gonzaléz², Ana L. Oliveira¹

Introduction

Chronic wounds are one of the major therapeutic and healthcare challenges. The wound healing process is divided in three important stages (haemostasis, inflammation and proliferation/maturation) that deploy a series of biochemical reactions which induce the repair of the injury. During wound healing, a fluid (exudate) can be produced as a natural response towards healing. However, its excessive production can be detrimental, once it is an excellent culture medium for bacterial growth, delaying the inflammatory phase. Nowadays, the design and development of biocompatible, biodegradable and adaptable materials that promote the tissue repair, prevent the infection and inflammation and ensure the management of exudate are a constant need for wound management.

Aerogels are nanostructured dry materials with high porosity, large surface and low bulk density [1]. They can provide advanced performance for wound healing due to their high porosity and large surface area, which can be tailored for a fast and directional fluid transfer of the exudate. They can also act as carriers for bioactive compounds and can present an adequate biological performance to provide the required wound physiological environment. Silk fibroin (SF) protein, obtained from Bombyx Mori, is an excellent carrier of bioactive compounds while supporting cell proliferation, being presently used in wound healing and regeneration. In this work, we propose the use supercritical CO₂ technology to develop SF aerogel particles as a controlled release system of adenosine, a protein that is herein proposed for the first time being expected to trigger the healing process of chronic wounds, promoting angiogenesis, reducing inflammation and accelerating wound closure (Figure 1).

Experimental Methods

Silk fibroin extracted from Bombyx mori cocoons was used to prepare SF aerogel particles by emulsion-gelation from SF aqueous solutions at different concentrations (3% and 5% (w/v)) as aqueous phase in water-in-oil emulsions followed by supercritical CO₂ drying (Figure 2A). The oil phase was prepared by using paraffin oil with different percentages of Span 80 surfactant. For the characterization of the SF particles, Fourier Transform Infrared with Attenuated Total Reflectance (FTIR-ATR) spectroscopy were used to investigate the secondary structure formation and conformation. The chemical structure and crystallinity of the produced matrices were analysed by FTIR-ATR and X-Ray Diffraction (XRD). Textural properties were assessed by helium pycnometry and N₂ adsorption-desorption (BET) tests. The drug loading capacity and release of adenosine in SF aerogel will be evaluated. In vitro tests will be performed using human skin cells to access the cell viability and therapeutic effects of the developed systems.

Results and Discussion
SF gel particles were produced with an emulsion-gelation method using different concentrations of SF, stirring velocity (600 and 1100 rpm) and Span 80. Namely, the SF particles with a stirring velocity of 600 rpm were more spherical and homogeneous (Figure 2B). The diameter of the particles (Dv10 and Dv90) was 509 ± 3 µm and 1073 ± 91 µm for 5%SF (w/v) aerogel particles and 368 ± 2 µm and 1075 ± 22 µm for 3%SF (w/v) aerogel particles, considering the average size of all the methodologies adopted.

The obtained aerogels were characterized in terms of textural and chemical properties. Analysis of the surface area of 5%SF (w/v) and 3%SF (w/v) by BET. All aerogels had high surface area being the 5%SF (w/v) solution higher than 3%SF (w/v) solution at the same conditions, 3%Span80 and 600rpm (515 ± 26 m²/g and 458 ± 23 m²/g, respectively). The surface area was lower at 5%SF and 3%SF with 3%Span80 and 1100rpm (147 ± 7 m²/g and 177 ± 9 m²/g, respectively. The surface area of 5%SF (w/v) particles with 10%Span and 600 rpm was 160 ± 8 m²/g. According to ATR-FTIR analysis, it was possible to verify the presence of the main characteristic bands of SF assigned to the presence of β-sheet structure, characterized by strong bands on amide I and II regions (Figure 2C). Also, it was detected the presence of Span80. The non-complete removal of Span80 may explain why the surface area of the SF aerogels with 10%Span is lower. According to XRD analysis, it is possible to verify the existence of a broad peak referring to SF (Figure 2D).

**Conclusion**

Physicochemical and textural characterization of the SF aerogels showed excellent properties and low particle size deviation, suggesting that the method is suitable for the production of particles for wound healing applications. In the future, we intend to load these particles with pharmaceutical drugs relevant for wound healing applications.

Gold nanoparticles as a part of a photothermal therapy system

Tânia Ferreira-Gonçalves, Eduardo Costa, João M.P. Coelho, Maria Manuela Gaspar, Lia Ascensão, Pedro Faisca, Isabel V. Figueiredo, Carlos A. García-González, David Ferreira, Hugo Ferreira, Catarina P. Reis

Introduction
Photothermal therapy (PTT) is attracting increased attention for the treatment of superficial localized tumors, relying on the induction of local hyperthermia of tumor cells upon their irradiation with light beams. PTT efficacy depends, however, on the heat generated and, on the depth reached by the light. Some strategies to improve PTT efficacy includes the use of the near infrared (NIR, 650 to 900 nm) radiation to enhance the penetration depth of the light, combined with gold nanoparticles (AuNPs) to enhance the photothermal effect.

Experimental Methods
Core AuNPs were synthesized by a novel method using tetrachloroauric acid and a mixture of reducing agents, and subsequently coated with a combination of hyaluronic and oleic acids, for improving the NPs biocompatibility, biodegradability, and lifetime. This coating also promotes the binding of specific cell receptors of the tumor cells. The particles were physico-chemically characterized, and in vitro and in vivo tests were carried out in breast cancer models to assess their safety and efficacy, when applied alone or combined with NIR irradiation.

Results and Discussion
AuNPs presented a predominant spherical morphology with sizes under 350 nm, polydispersity index lower than 0.4 and enhanced absorbance in the NIR. The particles showed no toxicity in vitro and promising efficacy in vivo when administering the NPs in situ and later irradiating them externally. Histopathological analysis of tumors treated with both AuNPs and laser irradiation showed the presence of necrosis in most of the tumors and no effect or practically absence in healthy surrounding cells, which are very encouraging outcomes.

Conclusion
The results are promising, however, there is still room for improving the system, namely by reducing even more the invasiveness of the treatment through the combined use of aerogels structures. Aerogel’s unique properties make them ideal candidates to minimize the exposure of healthy tissues to laser radiation, acting as light and thermal insulators, as well as to incorporate the nanoparticles into their skeletal structure and thus potentiating a topical application of the particles. For these reasons, some exploratory methods were carried to produce and design aerogels structures for PTT applications.

IBU/ZIF-8@Graphene Oxide Aerogels as scaffolds for bone tissue regeneration.

Alejandro Borrás, Ana M. López-Periago, Concepción Domingo

ICMAB-CSIC, SFFM, Campus UAB, ES

Introduction
Graphene Oxide (GO) has become a very promising and studied material in all the biologically related fields given its biocompatibility. Furthermore, its high mechanical strength paired with a high elasticity and flexibility and the possibility to be formed into a porous aerogel [1] elevates this material to the position of a highly qualified candidate for 3D scaffolding. In addition, the oxygen functionalities present in the 2D flakes allow for the anchoring of any wanted molecule or structure. In this case we are anchoring ZIF-8. ZIF-8 is also a very well-studied MOF with a high surface area and porosity [2] that has been considered as a drug delivery system for its high loading capacity and low toxicity [3]. In this case, the ZIF-8 has been heavily impregnated with Ibuprofen, a well-known drug that is used worldwide for its anti-inflammatory properties.

Experimental Methods
The fabrication and impregnation of the composite is fully carried out in a one-pot synthesis under supercritical CO₂, which implies the use of a green solvent on top of the cheap and easily accessible other reagents, such as the MOF precursors, the ibuprofen and the GO.

Two approaches are being followed, in the first one, all the reagents (Zn(acac)2, Hmim, GO and Ibuprofen) are dissolved in ethyl acetate inside a glass vial and placed inside a 100 mL autoclave filled with supercritical CO2 at 200 bar and 40 ºC.

On the second approach the composite is formed beforehand following the same procedure as before and is afterwards impregnated with Ibuprofen following a typical CO₂ impregnation.

Results and Discussion
The state of the project is still on its early stages. However, we have obtained 3D aerogels of GO fully covered with ZIF-8 nanocrystals. In addition, we have successfully impregnated ZIF-8 crystals with ibuprofen.

Conclusion
In this work we are focusing on the preparation of a Zeolitic Metal-Organic framework (MOF) ZIF-8@Graphene oxide (GO) hybrid aerogel. This composite is structured as a hierarchical porous system formed by the macroporous GO aerogel and the microporous ZIF-8 MOF. Therefore, the presented composite could function as a dual therapy agent, firstly with the 3D GO scaffold as a growing media for the generation of new cells and secondly with the controlled release of ibuprofen on the desired area through the ZIF-8 nanocrystals.

Introduction
Scaffolds composed of biopolymers as extracellular matrix (ECM) have received significant attention for their potential therapeutic applications. Physical, mechanical and electrical properties of the substrate in cell culture may affect the cellular behaviors like migration, and stem cell differentiation [1,2]. In this work, an electrical conductive interconnected composite was synthesized [3], using starch/κ-carrageenan/poly(vinylalcohol)/poly(vinylalcohol)-g-N-methyl-4(4’-formylstyrlyl)pyridinium methosulfate acetal, and it has been crosslinked by gamma radiation. The biopolymer, κ-carrageenan, was added to the formulation in order to enhance the biocompatibility and the electrical response and the poly(vinylalcohol)-g-N-methyl-4(4’-formylstyrlyl)pyridinium methosulfate acetal has been incorporated to covalently bond the synthetic and the natural polymers. The physicochemical, mechanical and electrical properties of the Poly(3,4-ethylenedioxythiophene) (PEDOT) composite and the templates were characterized. The mechanical and solubility responses of the porous materials at macroscale were tuned by the starch/κ-carrageenan/PVA/PVA-SbQ biopolymers composition and the material properties were evaluated at nanoscale using atomic force microscopy. The electroactive nanostructures were formulated in order to evaluate its potential application as extracellular matrix in biological cell culture.

Experimental Methods
Starch aqueous dispersions with varying concentrations of κ-carrageenan, PVA and PVA-SbQ (0–1.0 wt.%) were prepared in deionized water. The resulting clear and homogeneous solutions were stirred for 20 s and then immediately transferred to cylindrical moulds. The moulds were, once gelified, stored at 4°C during 48 h for retrogradation. Then, the simples were lyophilized for 4 hours to dry them. A sterilization process, using gamma radiation doses of 25 kGy, was applied in order to promote the crosslinking reaction of the PVA-SbQ. The PEDOT was produced by adding 150 mg of the starch/κ-carrageenan/PVA/PVA-SbQ cryogel template to 2.5 mL of iron chloride (III) in ethanol. Subsequently, 2.5 mL of EDOT in 2-propanol (0.5 M) was added to the template. After 24 h of reaction, a homogenous blue color was obtained.

The compressive strength of the aerogel specimens was evaluated with a universal testing machine and a dynamic mechanical analyzer (DMA). The recorded force was divided by the initial length of the specimen to determine the compressive strain at 10% deformation. The conductive cryogel surface topography, adhesion, and tunneling-atomic
force microscopy (TUNA) electrical conductivity were obtained simultaneously atomic force microscope (AFM) operating in peak force tunneling mode. A 1 V DC bias was applied between the sample and the electrically conductive tip as the tip scanned the sample in contact mode.

**Results and Discussion**

Compression performance tests were used to evaluate the mechanical properties of the cryogel templates as a function of the PVA-SBQ presence. The highest value for the elastic modulus was obtained for the St-κCa-PVA-SbQ (3.25±0.56 MPa) and the lowest was for the St-κCA cryogels (1.95±0.60MPa). The elastic behavior is dominated by the elastic deformation of the porous structure and the macropores freely deform by bending into their open space. The polymerization of the PEDOT into the cryogel templates resulted in an enhancement of the mechanical properties. Similar mechanical properties but with higher κ-Ca and PVA-SbQ contents were denoted as structurally stable materials with high mechanical strength. It can be concluded that the mechanical properties were improved by the incorporation of the crosslinking agent.

The conductive porous material was investigated by electrochemical AFM to obtain the surface topography, adhesion, and electrical conductivity images. The topography of St-κCA cryogel showed a rough morphology and the conductivity analysis confirmed that the regions of high conductivity were found regardless of the mechanical properties. In similar studies, the current differences in some places were attributed to the high charge carriers due the doped-PEDOT areas, which tend to be concentrated in specific areas.

**Conclusion**

The conductive porous PEDOT-based composites were prepared through a nanostructured template-assisted processing approach using starch (S)/κ-carrageenan (κ-C)/poly(vinylalcohol) (PVA) and poly(vinylalcohol)-g-N-methyl-4(4'-formylstyryl)pyridinium methosulfate acetal (PVA-SbQ) cryogel as templates. S/κ-C/PVA/PVA-SbQ cryogels presented an attractive combination of mesoporosity and macroporosity. The mechanical and electrical properties at macro and local scale were evaluated proving the suitability of the PVA-SbQ and the κ-carrageenan in the formulation. The unique combination of properties obtained for this conductive nanoporous material is of high relevance in the biomedical field as an electroactive extracellular matrix for cell stimulation and it will be the subject of further studies.

Fabrication of chitosan/alginate aerogels with antibacterial properties

Jelena M. Pajnik¹, Ivana Z. Lukic², Jelena K. Dikic¹, Svetolik N. Maksimovic², Stoja L. Milovanovic²

¹ University of Belgrade, Innovation Center of the Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, RS; ² University of Belgrade, Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, RS

Introduction
Natural polysaccharides such as chitosan and alginate are broadly utilized for various biomedical applications due to their biocompatible/biodegradable properties and ability to act as carriers for different drugs enabling their controlled release. Chitosan and alginate are both water-soluble polymers and capable to form hydrogels under defined conditions. Process of elimination of a fluid from a hydrogel, in which liquid phase is replaced with a gas by preserving the gel structure, results in a formation of an aerogel. The type of extraction of the liquid phase i.e. drying of hydrogels defines the synthesis of this innovative porous material. This step can be performed with the application of supercritical CO₂-assisted drying. This study was dedicated not only to investigate application of supercritical CO₂ for preparation of chitosan/alginate aerogels, but also to test supercritical solvent impregnation (SSI) as a technique for loading of obtained aerogels with compounds with proven antimicrobial properties.

Experimental Methods
Chitosan/alginate aerogel preparation was performed in several steps. First, chitosan and alginate 1.5 mass% solutions were prepared by dissolving chitosan and alginate powder in 2% (v/v) acetic acid and water, respectively. Hydrogel was formed by mixing chitosan and alginate solutions at room temperature for 24 h. Then hydrogel was poured in plastic mold and immersed into the 5% (w/v) aqueous solution of CaCl₂ during 30 min. Subsequently, water was gradually replaced with ethanol during several days to form an alcogels. Obtained alcogels were cut into disc shape (diameter ~10 mm) and dried at 45 °C and pressures of 100 bar. Scanning Electron Microscopy (SEM) was used to evaluate textural properties of the aerogels. Obtained aerogels were impregnated with thymol/carvacrol mixture at 35 ⁰C, 30 MPa during 5 and 18 h in a high pressure view cell using green medium, supercritical carbon dioxide. Mass ratio of thymol/carvacrol was set to 1/1. Aerogels before and after the SSI were analyzed by Fourier transform infrared (FTIR) spectroscopy. The antibacterial activity of impregnated aerogels was tested towards Gram-negative bacterium Escherichia coli strain DSM 498 and Gram-positive bacterium Staphylococcus aureus strain ATCC 25923. The disk diffusion method was used for a qualitative assessment of antibacterial activity, which was reported as the presence/absence of the inhibition zone.

Results and Discussion
Porosity of the obtained samples was 86%. Highly porous structure of the chitosan/alginate aerogels was confirmed by scanning electron microscopy. As expected, loading of thymol/carvacrol mixture into aerogels increased with an increase in process time. Namely, amounts of loaded thymol/carvacrol mixture were 31 and 43.7% for time intervals of 5 and 18 h, respectively. Presence of thymol/carvacrol on the surface of the impregnated chitosan/alginate aerogels was confirmed by FTIR analyses. As it can be seen from the Figure 1, thymol/carvacrol impregnated aerogels exhibited strong antibacterial activity towards tested bacteria strains while controlled samples (pristine aerogels) had no antibacterial activity.

Conclusion
Chitosan/alginate aerogels were successfully loaded with high amounts of thymol/carvacrol mixture with the application of SSI. Functionalized material exhibited strong antibacterial effective towards both Gram-negative and Gram-positive bacteria, indicating various potential application.

Antibacterial activity of impregnated aerogels towards E. coli (a) and S. aureus (b)
Initial number of bacteria (t₀): E. coli = 3.7 • 10⁸; S. aureus = 4.7 • 10⁸ CFU cm⁻³
Introduction
Aerosol administration of therapeutic drugs is the most efficient pathway for lung inflammatory diseases, such as asthma and chronic obstructive pulmonary disease (COPD). Indeed, β2-agonists like salbutamol sulfate (SS) are quick-acting bronchodilator drugs administered as an aerosol formulation. Aerogel microparticles (aerogel/MPs) hold a great potential for this administration route, thanks to their high surface area, low density, high porosity and drug loading efficiency [1]. The light weight of aerogels allow for large particle size with suitable aerodynamic diameters, which improves their flow properties and resistance to phagocytosis by pulmonary macrophages [2]. For this reason, the biological effect of SS-loaded alginate aerogel/MPs produced by inkjet printing followed by supercritical drying [3] were herein evaluated in vitro. The cytocompatibility and the anti-inflammatory effect were evaluated in lung epithelial cells and macrophages, respectively.

Experimental Methods
The SS loading was carried out in three different ways to achieve different drug distributions within the particles: (1) by incorporating SS in the 0.35 wt.% alginate ink at a concentration of 12 wt.% (Aero-SS-i), (2) by dissolving it in the gelation bath of CaCl₂ at a concentration of 0.4 wt.% (Aero-SS-b), and (3) by combining both loading strategies (Aero-SS-ib). After gelation and solvent exchange to ethanol, supercritical drying was performed (120 bar, 40 ºC, 3.5 h) to obtain the aerogels used for the cytocompatibility tests. Unloaded alginate aerogel/MPs, raw alginate and free salbutamol were also tested as controls. Morphology of the aerogels was evaluated using scanning electron microscopy (SEM) and textural properties were tested by nitrogen adsorption-desorption analysis.

The cytocompatibility of the aerogel/MPs was measured in the human pulmonary epithelial A549 and NCI-H460 cell lines, as model cells of the alveolar and lung epithelium, respectively. The cells were incubated with the aerogel/MPs at different concentrations and the viability was determined by the MTS colorimetric assay. The potential release of reactive oxygen species (ROS), which can contribute to exacerbate inflammatory diseases, was also evaluated in A549 cells incubated with the SS-loaded aerogel/MPs or the control samples. Finally, the therapeutic potential of the formulation was tested in an in vitro model of inflammation by using lipopolysaccharide (LPS) pre-treated human monocytic (THP-1) cells. The anti-inflammatory potential of the SS-loaded aerogel/MPs was based on their capacity to reduce the levels of the proinflammatory cytokines MCP-1 and TNF-α, in comparison with cells treated only with LPS, as described before for SS [4].

Results and Discussion
Aerogels were obtained in the form of a white, free-flowing powder. The SEM images showed particles with high sphericity and sizes between 10–25 mm (Fig. 1). The particles presented excellent textural properties, with surface areas in the 200-300 m²/g range and mean pore diameter of ca. 4.0 nm for the three aerogel processing strategies tested.

After incubation of the aerogel/MPs with the pulmonary epithelial cell lines at different concentrations, no significant reduction of the cell viability or increase in ROS levels were detected for the aerogel/MPs or the individual components, even at the highest concentrations tested (500 µg/mL for aerogel/MPs and 15 µg/mL for SS and SS-
loaded aerogel/MPs). Induction of ROS in the lung is one of the mechanisms that can contribute to exacerbate inflammatory diseases such as asthma or COPD, and even contribute to the fibrotic and carcinogenic process [5]. Thus, the aerogel/MPs showed a good cytocompatibility for pulmonary administration to treat inflammatory diseases. All the SS-loaded aerogel/MPs were able to inhibit the release of MCP-1 and TNF-α in LPS-stimulated THP-1 cells, but only Aero-SS-b and Aero-SS-ib reduced significantly both cytokine levels (Fig. 2). In fact, Aero-SS-ib produced the highest cytokine inhibition, even in non-stimulated cells and similar to the free SS. Hence, SS-loaded aerogel/MPs prepared by combining both techniques, incorporation in the ink and dissolution in the gelation bath, could induce a more controlled drug release in the physiological media in comparison with the individual drug loading strategies. The higher drug load in these aerogels was observed in the SEM images with the presence of SS precipitates in their surface (Fig. 1).

**Conclusion**

Alginate aerogel/MPs prepared by inkjet printing and loaded with SS showed a good cytocompatibility and a safe profile for pulmonary administration. All the SS-loaded aerogel/MPs tested were able to reduce the inflammation in an in vitro cell model. Yet, Aero-SS-ib seems to be the best processing candidate for the treatment of lung inflammation because it produced the highest cytokine inhibition. The combination of both drug loading strategies induced the highest therapeutic efficacy in an in vitro inflammation model.

Introduction

Conductive polymers are a new generation of smart materials extensively used in organic bioelectronics and in active controlled release systems. PEDOT, a conductive polymer synthetized from EDOT, has been recently studied for the incorporation of charged drugs during the electropolymerization process. Numerous aerogels from dierent sources have been used as extracellular matrices for cell colonization in implantable devices, many of them are loaded with bioactive agents such as anti-inflammatory molecules (i.e., dexamethasone) to improve the therapeutic efficacy and safety of the drugs, playing important roles in treatment of several chronic diseases, avoid immune responses, and provide a potential stimulation of dierent types of cells.

In this work, a method to induce the loading of dexamethasone into PEDOT films during the polymerization process onto gold electrodes was established. The polysaccharide κ-Carrageenan (κC) was also incorporated to maintain the electrochemical stability and biocompatibility of the PEDOT matrix and the subsequent drug release using electrical stimulation. Therapeutic doses of dexamethasone appropriate for mesenchymal stem cells diferentiation were achieved during the electrical stimulation of the bioelectronic device.

Experimental Methods

κC (0.2% w/v) in deionized water was prepared and sonicated before adding the monomer EDOT and Dx at three different concentrations. The deposition of the dispersion was carried out on the surface of gold bare electrodes through an electropolymerization process. Profilometry analysis were made in order to study the electrode topography. Thus, the arithmetical mean roughness of the surface (Sa) was calculated by using a 2 μm tip radius and a force of 1 mg. Raman spectroscopy analysis was carried out using a confocal µ-Raman microscope with a 532nm excitation laser. The presence of PEDOT and Dx/κC was confirm at the relative wavenumber of 1435 cm⁻¹ and 1625 cm⁻¹, respectively.

Drug release experiments from the modified electrode were studied using cyclic voltammetry sweeps over a period of 300 min at room temperature. A second release event, without electrical stimulation, was performed as negative control to quantify the passive drug release process. Dexamethasone concentration in the extracted samples was determined using a quadrupole time of flight (Q-tof) mass spectrometer coupled with an UPLC system. Quantification of the drug was carried out using Multiple Reaction Monitoring (MRM) acquisition method with the optimized transition of 471.1584 m/z for the precursor ion and 78.9585 m/z for the product ion.

Results and Discussion

The roughness data of the electrodes surfaces before and after drug release did not show significant differences between them. The lack of significative variation during the delivery of dexamethasone may indicate the reliability of
electroactive composite for cell culture studies since no additional mechanism may be seemed due to the topography changes.

Qualitative composition analysis of the coating using confocal µ-Raman spectroscopy during electrical stimulation showed a strong signal in the spectral range of 1421–1442 cm\(^{-1}\), associated with PEDOT presence. Additionally, a relative intense band at 1625 ± 30 cm\(^{-1}\) was detected, corroborating the qualitative existence of Dx and κC in the conductive film.

The electrochemical controlled release studies from PEDOT:κC:Dx showed a characteristic reduction potential signal range at −100 to −400 mV. This signal indicates the release of the drug from the stimulated electrode, which disappeared completely after 160 cycles of electrical stimulation, confirming the complete dexamethasone migration from the conducting composite.

HR-mass spectrometry was used to calculate the accumulative concentration of the released Dx. The amount of drug released on stimulated electrodes using 1 mM and 5 mM initial formulations were 300 nM and 600 nM, respectively. These values are relevant therapeutic dosages for the mesenchymal stem cell cultures differentiation or during anti-inflammatory treatment.

Finally, the surface area of the unstimulated electrode is associated with promoting larger amounts of passive drug release, yet, in our case, the electrode surface and total area are maintained virtually constant. A low diffusion value was identified in the beginning of the process, maybe it depends on the slow penetration of supportive electrolyte into the polymeric film. Nevertheless, after 80 min, the diffusivity of the passive Dx release process is reflects.

**Conclusion**

Therapeutic doses of dexamethasone were successfully delivered using an electroactive controlled system. Incorporation of κ-carrageen as doping agent in the matrix avoided delamination and changes in the film roughness. The formulation and method established along with a proper active electrochemical stimulation profile allowed the delivery of the drug at adequate concentrations to induce differentiation in mesenchymal cell cultures and in anti-inflammatory responses.

Bioaerogels prepared using the Pressurized Gas eXpanded liquid (PGX) process as delivery systems for hydrophobic bioactives

Feral Temelli¹, Ricardo Couto¹², Bernhard Seifried², Byron Yépez², Paul Moquin²

¹ University of Alberta, Department of Agricultural, Food and Nutritional Science, Edmonton, CA; ² Ceapro Inc, 7824-51 Avenue, Edmonton, CA

Introduction
The global market for functional foods and natural health products is expected to grow by US$ >12 billion within the next decade according to marketing experts. These products are formulated with various bioactives, which are mostly isolated from natural sources. In general, bioactives are sensitive to heat, light and oxygen and can degrade easily. Many bioactives are hydrophobic and some are crystalline in nature, making them poorly bioavailable and challenging to incorporate into aqueous-based products. Such hydrophobic bioactives include coenzyme Q10 (CoQ10), vitamin D (VitD), and vitamin E (VitE). CoQ10 and VitE are antioxidants, associated with reducing the risk of cardiovascular diseases and cancer, while VitD plays an important role in calcium absorption and bone health. CoQ10 and VitD are crystalline powder, but VitE is a viscous liquid. Delivery systems are needed for such bioactives for ease of handling, incorporation into aqueous-based formulations, enhance their stability and maximize their health benefits.

Experimental Methods
Bioaerogels prepared using water-soluble polysaccharides, including oat β-glucan (BG), gum arabic (GA) and sodium alginate (SA) can be utilized as delivery systems for the hydrophobic bioactives to overcome some of the challenges. Conventional methods of aerogel production are slow and expensive as they involve several steps: preparation of hydrogel, conversion to alcogel by lengthy solvent exchange, and drying, preferably by supercritical CO₂ (SC-CO₂) to prevent collapse of the network. Pressurized Gas eXpanded liquid (PGX) Technology is a faster more affordable way to manufacture bioaerogels. The aqueous biopolymer solution is contacted with the PGX fluid (CO₂+Ethanol at 100 bar, 40°C) through a co-axial nozzle to precipitate the biopolymer while removing the water. Then, flushing with CO₂ removes residual ethanol and impurities. Resulting bioaerogel powders have unique morphologies of micro/nano-sized particles as shown in Fig. 1 and large specific surface areas, ranging from 24.1 m²/g for BG [1], to 65 m²/g for GA [2] and 164.5 m²/g for SA [3].

Adsorptive precipitation using SC-CO₂ was employed to load the PGX-processed bioaerogels with the hydrophobic bioactives under different processing conditions followed by fast depressurization. CoQ10 was loaded on BG, GA and SA, while VitD and VitE were loaded on GA and SA. The loaded powders were characterized in detail (loading content, morphology, thermal behavior, crystallinity, release kinetics, stability) in an effort to understand their potential as delivery systems.

Results and Discussion
Helium ion microscopy images demonstrated uniform coating of the bioaerogels by the bioactives. Loading levels varied depending on the biopolymer and the bioactive. CoQ10 loading (w/w) was 3.6% on GA [2], 17.5% on BG [4] and 46.9% on SA [3]. However, CoQ10 loading per unit area was 0.56, 7.2 and 7.5 mg/m² for GA, BG and SA, respectively, demonstrating the higher level of interaction between CoQ10 and the fibrous networks of BG and SA (Fig. 1). A similar trend was observed with the vitamins with SA resulting in higher loading compared to GA (4.4 and 7.1 mg/m² on SA vs 3.2 and 4.8 mg/m² on GA for VitD and VitE, respectively) [5]. The long hydrophobic tail present in the structures of CoQ10 and VitE seems to enhance their interactions and loading on the fibrous network of the negatively charged SA as opposed to the spherical network of GA.
Differential scanning calorimetry and X-ray diffraction analysis demonstrated a reduction in the crystallinity of CoQ10 and VitD after loading on the bioaerogels. Release kinetics in simulated intestinal fluid (SIF) showed a sustained release of the vitamins from GA of up to 20% of the original amount over 4 h but it was limited (up to 5%) from SA, indicating a higher level of interaction. For CoQ10, its sustained release from SA in SIF and simulated gastric fluid (SGF) was at 11.5%, whereas its release from BG and GA was higher in SGF reaching 7.4% and 30.5%, respectively. Considering that the release of pure bioactives was ≤3%, their loading on the bioaerogels resulted in a substantial increase in their availability under simulated digestive tract conditions. In addition, the stability of CoQ10 on BG, GA and SA powders was demonstrated over 1 mo of storage. The aqueous dispersions of CoQ10-loaded BG and GA were quite stable for 6 mo and 1 mo of testing, respectively.

Conclusion
The findings of the studies on adsorptive precipitation of hydrophobic bioactives on the PGX-processed polysaccharide aerogel powders demonstrated the great potential of this technology. The different combinations of bioactives and biopolymers studied provided insight on the development of customized delivery systems for potential targeted applications with anticipated enhanced bioavailability and ease of incorporation into aqueous-based product formulations.

Protective and Functional Coatings of Alginate Aerogel Particles as a Drug Carrier

İşık S. Akgün¹, Enis Demir², Murat İşik², Nadin Ekmekçiyan², Erkan Şenses¹, Can Erkey¹

¹ Koç University, Chemical and Biological Engineering Department, Istanbul, TR; ² Ashland Specialty Ingredients, Istanbul, TR

Introduction
Due to their open pore structures, very high specific surface areas and pore volumes, aerogels in the form of particles are attracting increasing attention for a wide variety of applications such as drug delivery. In general, aerogels provide immediate release due to the adsorption of drugs in the amorphous state and due to the large surface area in contact with the body fluid [1]. Coating the surface of aerogel particles with a thin polymer layer may act as an armor to protect the aerogel matrix and provide prolonged and controlled release of drugs [2]. Coating is an essential component of particle formulations in various industries, particularly in the pharmaceutical industry. However, coating of aerogels based on current technologies in pharmaceutical industry is a challenging task since tablets and aerogels have quite different properties such as very different densities, porosities, and mechanical strength [3].

Experimental Methods
The main target of this study was to successfully coat aerogel particles via keeping their porous structures and understanding drug release mechanism from both coated and uncoated aerogels. Spherical alginate aerogel particles were synthesized by dripping an alginate solution from a nozzle into a CaCl₂ solution followed by solvent exchange and drying with supercritical CO₂ in an Applied Separations Speed SFE. The mean particle size and the mean particle density were 4.20 ± 0.02 mm and 0.05 ± 0.01 g/cm³, respectively. Subsequently, ibuprofen was loaded via supercritical deposition at 40°C and 220 bars. A Wurster fluidized bed was used for both protective and functional coating of alginate aerogel particles. Copovidone based ultrahigh solid film coating system, Aquarius™ Genesis by Ashland Specialty Ingredients, was applied as protective coating around the unloaded aerogel particles whereas methacrylic acid-ethyl acrylate copolymer based Aqueous Control ENA by Ashland Specialty Ingredients was used for functional coating of ibuprofen loaded aerogels. Gastric resistance of functional coated aerogels was tested in 0.1 M HCl. Drug release was measured in phosphate buffer at pH 7.2. Release profiles were determined using HPLC.

Results and Discussion
For protective coating, variations occurring in coating layer thickness (CLT) around alginate aerogel particles and changing coating layer surface morphology with process time, bed temperature, atomizing air pressure and polymer rheology were investigated. Three bed temperatures which were 30°C, 50°C and 70°C and three atomizing air pressures (AP) which were 1.3, 1.5 and 1.7 bars were studied. In all three bed temperatures, aerogel particles were successfully coated. As an example, photographs of uncoated aerogels and coated aerogels with high level of coating uniformity at 50 °C bed temperature and 1.7 bar AP after 30 minutes are given in Figure 1. Coating time for all the runs ranged from 5 minutes to 40 minutes and the CLT ranged from 12.4 ± 4.6 μm to 170.6 ± 43.3 μm. The smoothest coating layer surface and the highest coating efficiency which was 69.2 ± 0.4 % with a linear increase in coating layer thickness were achieved at 50 °C with 1.7 bar. Due to the moderate polymer viscosity and elastic modulus, the lowest contact angle as ~118° was achieved at 50°C which indicating a good droplet spreading on an aerogel surface. An increase in atomizing air pressure from 1.5 bar to 1.7 bar resulted in a smoother coating layer. A high mean coating polymer solution droplet velocity with a narrow droplet size distribution led to a homogeneous spreading and less variance in CLT at 1.7 bar. Coatings at 50°C were very similar in smoothness and morphology to coatings on pharmaceutical dosage forms demonstrating the suitability of Wurster fluidized bed for successful coating of aerogel
Ibuprofen loaded aerogels were also successfully coated for enteric release without damaging the pores of aerogels. SEM images of both outer surface and cross-section of a functional coated ibuprofen loaded aerogel at 50 °C, 3 hours are given in Figure 2. Almost 94% of the ibuprofen was released from uncoated aerogels within 120 min. at a pH of 1.0, whereas ibuprofen release from aerogels coated with methacrylic acid-ethyl acrylate copolymer-based solution was prevented at the same pH with 160 ± 21 µm CLT. The change of the release medium from acid to PBS buffer at a pH of 7.2 resulting in a release of all the loaded ibuprofen in less than 10 min.

**Conclusion**

Highly porous alginate aerogel particles which has very high potential in pharmaceutical industry as drug carriers were successfully coated with a copovidone and methacrylic acid-ethyl acrylate copolymer-based solutions, separately. Based on the results presented, bed temperature was a more important parameter for CLT whereas both AP and bed temperature affected coating layer surface morphology and coating polymer rheology. Moreover, enteric coating of ibuprofen loaded aerogels improve pH specific release of ibuprofen which is a poorly water-soluble drug.

Whey protein aerogel particles as templates to produce oleogels with tailored digestibility

Sonia Calligaris, Stella Plazzotta, Marilisa Alongi, Lara Manzocco

University of Udine, Department of Agricultural, Food, Environmental and Animal Sciences, Udine, IT

Introduction

Oleogels are defined as gels in which the continuous liquid oil phase is immobilized into a supramolecular network of molecules known as oleogelators. A lot of research efforts has been dedicated to developing oleogels intended as fat substitutes in foods to create healthier foods with reduced content of saturated/trans fatty acids. Today, oleogels seem to be promising also for the delivery of bioactive lipophilic molecules and as modulators of the gastrointestinal lipolysis, opening novel opportunities not only in foods but also for pharmaceutical and cosmetic applications. Oleogels can be obtained by exploiting the network-forming ability of lipophilic molecules upon self-assembly in oil or by generating scaffolds made of hydrophilic components able to entrap oil. Recently, aerogels made of hydrophilic food polymers, such as carbohydrates and proteins, have been suggested as potential templates for oleogel preparation, by simple absorption of the oil in the aerogel dried network. Up to now, limited information is available on these novel oleogels, especially considering their gastrointestinal behavior. Based on these considerations, the aim of the present study was to explore the possibility to prepare oleogels from whey protein (WP) aerogels by using different oils and evaluate the digestibility of the obtained systems.

Experimental Methods

To this aim, protein aerogel particles were prepared by supercritical-CO$_2$ drying (SCD) of heat treated and ground WP hydrogels (20% w/w, pH=5.7). The particles were then dispersed into edible oils (castor, cod liver, corn, extra virgin olive, flaxseed, MCT, peanut and sunflower oil) and collected by centrifugation. The obtained oleogels were analyzed for oil content, microstructure, and rheological properties. Some selected oleogels were then subjected to in vitro digestion, conducted according to the INFOGEST protocol.

Results and Discussion

Optical microscopy showed that aerogel particles formed a homogeneous network in all the tested oils, probably due to hydrophilic inter-particle interactions, so that the oil was efficaciously embedded both in the pores of the particles and in the interparticle spaces, as also confirmed by confocal microscopy. Solid-like materials containing up to 80% oil and with mechanical properties comparable to those of conventional fats were obtained. Interestingly, the oil type did not affect the oleogel structure. The only exception was observed for castor oil, whose high polarity probably hindered particle networking. The digestion trials showed that, differently from native WP, which were completely digested in the stomach, circa 50% of the WP aerogel particles remained undigested after gastric digestion, being then fully digested in the intestinal phase. At the same time, the lipolysis degree of the oil contained in the oleogel was significantly different as compared to that of the bulk oil. It can be hypothesised that the protein network embedding the oil was able to modify the lipase action at the interface.

Conclusion

This work demonstrates that WP aerogel particles could be regarded as versatile oleogel templates allowing the structuring of many edible oils into solid-like materials. The developed structure could have peculiar delivering capacity of health-promoting lipophilic components not only in foods but also in human body, modulating their release.

Potential of whey protein aerogels as delivery systems in food: structural characterization and physical stability

Stella Plazzotta, Sonia Calligaris, Lara Manzocco

University of Udine, Department of Agricultural, Food, Environmental and Animal Sciences, Udine, IT

Introduction
During the last years, a lot of research has been focused on natural biopolymer-based aerogels, which can fulfill the requirements for food applications. Being based on food-grade polysaccharides and proteins, these aerogels are claimed to provide new opportunities for food applications, including edible delivery systems for bioactive and labile components. In both cases, the stability of the loaded molecule might be increased not only during food processing and storage, but also during digestion, allowing for a controlled release after intake. The aerogel loading may be easily performed by immersing the aerogel into a liquid, which permeates into the aerogel and saturates the internal volume. The embedded liquid may interact with the aerogel polymer chains and either reinforce or weaken their architecture. Structural integrity upon liquid loading strongly affects the feasibility of exploiting aerogels as delivery systems in foods, since influencing the effective entrapment and release of the loaded components during food processing, storage, and in vivo delivery. Both composition and process can be adjusted to get aerogels showing specific structural response to contact with hydrophilic or lipophilic liquids. In this regard, protein aerogels appear promising in the light of their compatibility with food components. As well known, the drying technique strongly affects the aerogel micro-structure by steering pore size and distribution, and thus its loading and liquid retention capability. While supercritical-CO₂ drying (SCD) generally preserves the original network, leading to homogeneous pores with low dimension, freeze-drying (FD) commonly results in macropores and cracks upon sublimation.

Experimental Methods
Based on these considerations, the aim of this study was to investigate the potential of whey protein (WP) aerogels as delivery materials in foods. To this aim, WP monolithic hydrogels (20% w/w, pH 5.7) were dried by FD or SCD. The obtained aerogels were firstly characterized for their structural features (density, volume contraction, firmness, SEM microstructure), adsorption isotherm and glass transition temperature. Subsequently, the FD and SCD aerogels were used as templates for absorption of water and oil by immersion.

Results and Discussion
Heat treatment of 20% WP solutions near their isoelectric point resulted in white monolithic hydrogels, whose microstructure consisted in the association of spherical hydrated protein particles, called microgels. The hydrogels were subjected to FD and SCD. SCD resulted in denser aerogels (d=0.29 g/cm³), which underwent a greater volume contraction (ΔV=39%) as compared to the FD samples (d=0.22 g/cm³; ΔV=15%). Accordingly, the SEM microstructure of the two samples appeared different. The FD aerogels showed an open protein matrix with large pores (2-5 µm), in which the microgel particles appeared fused together. A more compact and homogeneous matrix was observed in the SCD samples, which showed lower-dimension pores (< 1 µm) and a particulate network in which the structure and organisation of the original microgel particles were maintained. Despite these differences, both aerogels showed a type III isotherm upon water vapour absorption, indicating a limited capacity of interacting with water molecules, and similar glass transition at 161 °C. An ERH of circa 80% was identified as the maximum humidity value below which both samples maintained their porosity at 20 °C.

A slower uptake of both water and oil was observed in the SCD aerogel as compared to the FC one. Water absorption caused destructuring of both aerogel samples. By contrast, the aerogels retained their integrity upon oil-loading.
generating materials containing 75% (w/w) oil, independently on the drying technique applied for their preparation. However, the SCD sample presented higher firmness (F=29.5 N) and oil holding capacity (OHC=96.3%) than the FD one (F=18.5 N, OHC=44.7%).

Conclusion
The results acquired in this work demonstrate the potential of WP aerogels to be used as innovative delivery systems in foods, and the possibility to steer their properties by changing the drying technique. Based on their fast dissolution in water, FD aerogels would be optimal candidates for rapid release of loaded compounds; by contrast, the SCD aerogels should be selected for the delivery and controlled release of oil and lipophilic compounds.

Ultrasonic Detection of Aerogel coupons for Biomedical Applications

Firouzeh Sabri

UofM, Physics and Materials Science, Memphis, US

Introduction
Ultrasound imaging is a non-invasive rapid diagnostic technique with no known biological risks to tissue or to the patient. We have previously shown that polyurea crosslinked silica aerogels can be easily identified in vivo and are distinguishable from the surrounding bone and tissue scanned at 13MHz[1]. The aerogel implants demonstrated hyperechoic behavior and significant posterior shadowing. The impedance mismatch contributes to a clear outline of the aerogel coupon and visibility of structural details is expected to be frequency dependent and was not explored in our earlier study. In this study we expand the library of ultrasonic properties available for aerogels and investigate other types of aerogels, beyond silica-based aerogels and as a function of frequency.

Experimental Methods
Six different types of aerogels were evaluated. Coupons of a similar size were extracted from each aerogel type and scanned under different conditions. An Edan U50 Prime ultrasound unit with a linear probe array was used for this study. Aerogels were scanned systematically from 8Mhz upto 13.5 MHz. Image analysis and processing was performed by means of NIH open-source ImageJ software. Attenuation coefficient was calculated using linear regression of pixel intensity from the acquired images.

Results and Discussion
Submuscular and subcutaneous positioning of aerogel coupons investigated as a function of frequency showed unique characteristics influenced by the porosity and the Young's modulus of each aerogel type.

Conclusion
Diagnostic ultrasound techniques can be readily used to detect Aerogels both in vivo and in vitro. The unique structure of aerogels allows for a clear distinction from surrounding tissue and depends on acoustic impedance and attenuation coefficient. Some frequency dependence in the range of 8-13.4 MHz was also observed. Further studies in other frequency ranges will be performed in the next phase of our study.

GW AW02-01
Development of fiber-reinforced composites for dental and medical reconstructive biomaterial

Pekka Vallittu

University of Turku, Biomaterials Science / Institute of Dentistry, Turku, FI

Development of dental and medical biomaterials has been limited to use only isotropic bulk materials until recently, when first clinically applicable fiber-reinforced composites (FRC) have become to the clinical use in late 1990s. Present applications of FRC can be found in all disciplines of clinical dentistry and in applications of bone reconstructive surgery. All of these applications are having fibers of glasses in the biostable resin-based matrix of FRC. Orientation of fibers in the polymer matrix may vary from unidirectional to bidirectional weaves and random fiber oriented mats. On the other hand, fibers can also vary in terms of length. Continuous and discontinuous (short) fibers are both utilized in clinical dentistry nowadays. Other properties of FRC in relation to the direction of fibers, like optical properties and bonding properties are also having their implications in dentistry, where transmission of polymerization light is a desired property. Due to bone like biomechanical properties and high toughness, FRCs have found their implications in bone surgery too: FRC with bioactive glass is already in clinical use as bone growth inducing implant for large bone defects in cranium. Biological mechanism of action of the implant is based ion dissolution from the bioactive glass which influence the cells differentiation to osteogenic cells and the simultaneous physicochemical modification of the FRC surface. Lecture will show clinical examples of the use of glass fibers in prosthetic applications, and give an insight to bioactive surgical FRC implants.
10:15 a.m. – 11:00 a.m.

**Klaas de Groot Award: Some reflections on scientific progeny**

**Clemens A. van Blitterswijk**  
*Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL*

We are all products of our past. This is no different for scientists as for the species seen in Darwin’s tree of life. There is a difference still, a species is moulded over time by a combination of chance and the influence of its environment, on which it, usually, has little influence. A scientist, though, is a conscious being that should at least be partially able to select its own environment and possibly even its scientific ancestry, thus controlling its own development.

As the Klaas de Groot award is on mentorship and guidance I thought that, as its recipient, rather than highlighting some of our group’s research, it might be more interesting to reflect on how our scientific predecessors may and should, even today, still affect our careers and scientific choices. I will try to do this by mixing some personal anecdotes with historical examples and a few biological metaphors on scientific organizations.

Perhaps, these reflections may be of some use to younger scientists to make the right choices early in their career and not make the mistakes of their predecessors. For those for which this advice comes too late (my generation) it will at least recall some memories on the inspirational impact of Klaas de Groot on the early generation of biomaterial scientists.
11:30 a.m. – 1:00 p.m.

Plastic antibodies for (bio)sensing

M. Goreti F. Sales

University of Coimbra, Chemical Engineering Department of the Faculty of Sciences and Technology, Coimbra, PT

(Bio)sensors have evolved in recent years and generally meet point-of-care (POC) requirements. They are compact analytical devices that can be built from low-cost materials in a suitable size and in a portable manner as required for POC applications. Electrochemical biosensors are at the forefront of such developments, easily recognisable from blood glucose monitoring strips. Optical biosensors are also popular devices, implemented in the population mainly through pregnancy tests and the rapid antigen/antibody tests in COVID-19 management.

In terms of development, biosensors require a biorecognition element that selectively binds to the target biomolecule. Various compounds can be used for this purpose, with antibodies playing the main role. Their operation is effective and similar to an ELISA test, but with a different transduction mode. However, all procedures for the production of natural antibodies in the laboratory are still very complex and expensive. They require highly skilled personnel, special handling and storage conditions, and complex facilities/equipment that often require the use of animals [1]. Moreover, handling antibodies in the commercial solutions is a difficult task. These biological materials are unstable and change their functionality due to slight variations in temperature, pH or solution composition. Antibodies may also become unusable once bound to the antigen, as this binding cannot be reversed without altering the 3D antibody assembly.

In contrast, plastic antibodies are synthetic “analogues” capable of selectively targeting a specific analyte, offering greater stability and lower cost than natural antibodies, as well as the possibility of scaling [2]. Such interaction between the antibody and its target analyte can even occur in direct contact with complex samples, avoiding sample pretreatment and opening doors to POC applications. The most successful synthetic route for obtaining plastic antibodies uses molecular imprinting technology [3], in which a polymeric material facilitates antigen-antibody interactions through simulated Fab regions. Briefly, an imprinted polymer is made by growing a rigid polymeric network (of individual monomers and crosslinkers to precisely tailor a molecular shape in a 3D imprinted site) around a target molecule; the imprinted sites are generated as the template emerges from the polymer matrix and theoretically matches the size and shape of the target.

Polymer antibodies have already been used in biosensors for a variety of biomolecules, such as various proteins that signal cancer or cardiovascular disease or extracellular vesicles, among others [4,5]. Several examples of these specific applications will be presented, coupled to the processes involved in their production. Interestingly, plastic antibodies also open up for a wide range of other applications in tissue engineering.

Introduction
The free radical theory of infertility is derived from the more general free radical theory of ageing. It states that free radicals are the reason why sperms become dysfunctional. Some free radicals are also needed to maintain crucial functions in sperms including sperm capacitation, the acrosome reaction, and sperm-oocyte fusion. However, despite their undeniable importance we know relatively little about where free radicals are generated exactly, which ones play a role or if we can alter their generation. Unfortunately, free radicals are short lived and thus very difficult to detect with the state of the art methods. As a result, detecting radicals is despite the enormous potential barely used as clinical marker.

Experimental Methods
We have used commercial 70nm oxygen terminated FNDs (Adámas Nano, Raleigh, NC, USA). Boar sperm commercially available from Varkens KI Nederland BV was separated using Ficoll gradient, and selected motile sperm cells were plated on fibronectin or hyaluronic acid coated dishes. Sperm cells were treated with FNDs suspension in Human Tubal Fluid (HTF) for capacitated state and modified-HTF (HTF medium without bicarbonate, calcium salts and serum) for uncapacitated state. Biocompatibility tests like MTT assay, DCFDA and membrane integrity assay was performed. Confocal and scanning electron microscopy were performed on fixed cells to characterize the location of FNDs on sperm cells. We have applied diamond magnetometry (the fluorescent nanodiamonds are used as sensors) to visualize free radical generation in real-time in single cells with nanoscale resolution, which is not possible with other methods. We have used our home-built magnetometers to perform a specific type of diamond magnetometry called relaxometry. These measurements reveal a signal, which is equivalent to T1 from conventional MRI but from nanometer sized voxels around the diamond particles (rather than millimeter to micrometer as in conventional MRI). T1 is a measure for spin noise and (after calibration) allows quantifying free radical generation.

Results and Discussion
In this studies we have developed novel approach to detect free radical in sperm cells. To prove our concept, we first tested the biocompatibility of FNDs and the effect of them on sperm cells metabolic activity, reactive oxygen species formation and membrane permeability. The results of this set of experiments indicated no significant difference compared to the control group for FNDs in both capacitated and uncapsacitated sperm cells. Confocal and scanning microscopy images have shown that FNDs attached preferentially to the head of sperm cells. The fluorescent nanodiamonds have been used in the relaxometry measurements to detect real-time changes of free radicals level in the sperm transition between the uncapacitated and capacitated stage. We have been tracking capacitation progress for two hours using one selected nanodiamond and observed gradual shortening of relaxation time. Decrease of T1 values corresponds to an increase in free radical concentration near the nanodiamond sensor, which was expected for the capacitation process. In the further experiments we have investigated how chemical stressors and antioxidants influence the free radicals generation by the sperms on a different maturation stages.

Page 653 of 2028
Conclusion
We have shown for the first time that fluorescent nanodiamonds can be used for innocuous selective labelling and localized, real-time measurements of free radical in single sperm cells using diamond magnetometry. Our research lay the foundation for further work with human clinical samples.

Introduction

Lung cancer (LCa) remains the leading cause of cancer-related mortality, worldwide, with late diagnosis and limited therapeutic approaches still constraining patient’s outcome [1,2]. Liquid biopsies have been introduced as a minimally invasive way to retrieve multiple cancer biomarkers for tumor characterization and microfluidic devices have shown promising results regarding biomarkers isolation efficiency and specificity [3]. In this work, we proposed a microfluidic chip for size-based isolation of circulating tumour cells (CTCs) from plasma samples of LCa with downstream circulating cell-free DNA (cfDNA) methylation analysis.

Experimental Methods

The microfluidics layer was developed in polydimethylsiloxane (PDMS) via soft-lithography and bonded to coverglass by plasma cleaning, creating the final chip. A total of 22 LCa plasma samples (2mL) were processed through the chip and CTCs were isolated through size in chambers with sequential rows of micropatterns with varying interspacing, followed by cfDNA extraction from the processed plasma. CTCs were identified in-chip as DAPI+/EpCAM+/CD45− in non-small cell lung cancer patients (NSCLC) and DAPI+/CD133+/CD45− for small cell lung cancer (SCLC) samples. A collection of samples was further stained for Vimentin (VIM). Promoter methylation levels of ADCY4me, MIR129-2me and HOXA11me were assessed in ctDNA by multiplex quantitative methylation-specific PCR.

Results and Discussion

CTCs were detected in a total of 18 samples. CTC count increased according to disease progression, with a higher average count in late-stage samples (3.7 ±2.0) compared to a lower (1.3±1.8) in early-stage patients. A total of 8 DAPI+/EpCAM+/CD45− negative cells were identified, highlighting the limitations associated with EpCAM identification of CTCs in LCa.

Results regarding cfDNA extraction and quantification revealed that samples processed in-chip showed a tendency for higher DNA concentration than the respective unprocessed samples. A trend was also observed for higher cfDNA concentration in late-stage samples as well as higher number of methylated genes. HOXA11me displayed the highest individual LC detection.

In the 4 samples with no CTCs detection, at least one gene promoters’ methylation was identified in all early-stage samples (n=3) and cfDNA methylation of all 4 genes was observed in the late-stage sample (n=1).

Conclusion

The designed chip showed efficacy in CTCs isolation from a minute sample volume (2 mL), with increased detection in late-stage samples and higher cfDNA concentration levels and number of methylated genes. Plasma processing
through the microfluidic device allowed for a combinatorial analysis of both cancer biomarkers, showing a promising approach for LCa diagnosis and assessment.

Electrochemical behaviour of the nanotubular TiAlV surface in the presence of bacteria

Jaroslav Fojt, Eva Pruchova, Vojech Hybasek, Jitrenka Jiru, Ludek Joska

University of Chemistry and Technology in Prague, Department of Metals and Corrosion Engineering, Prague, CZ

Introduction
Biofilm-related infections (BRI) are an overwhelming issue for health care systems in Europe and worldwide. Common examples of biofilm-related infections include implant-related infections, like those that may follow joint replacement, osteosynthesis, mechanical heart valves, breast implants, indwelling catheters, ventriculo-peritoneal shunts etc. BRIs are characterized by chronic behaviour or frequent recurrences, antibiotic resistance, complex and prolonged treatment, poor prognosis, high social and economical costs and difficult diagnosis. In vitro experiments showed that young biofilm could be easily eliminated by antibiotic treatment compared to the matured biofilm. Therefore, early and aggressive antibiotic treatments are recommended for biofilm infections. However, early diagnosis of BRI is currently difficult and most of the clinical biofilm infections are actually matured biofilms that are usually difficult to eradicate with antibiotic treatment. The ability to acquire real-time measurements of environmental parameters of interest including within the implant surface in situ would significantly enhance the information available to medical professionals to detect and effect early inflammation. The titania nanotubes have a big ratio of the real/geometric area and thus with a relatively small dimension of the sensor provide a large active surface. This surface could provide changes in the electrochemical response, which reflects changes caused by bacteria presence.

Experimental Methods
The nanotubular surface of Ti-6Al-4V alloy was prepared by anodic oxidation in fluorides containing electrolyte and covered by several bacteria strains: E. Coli, S. Aureus and P. Aeruginosa. The sample with bacteria were cultivated in agar with nutrient and electrochemical impedance spectra, open circuit potential and polarisation resistance were measured throughout 48 hours exposure.

Results and Discussion
The presence of bacteria was detected during up to 24 hours. The open circuit potential decreases reflecting the oxygen consumption by bacteria. The electrochemical impedance spectra showed several frequency windows, which reflects processes on the surface. The first one was at high frequencies and corresponds to the fast reactions such as nitrate metabolism and also reflecting surface coverage by bacteria. The slow reactions were detected at middle-low frequencies. One of the possible reaction candidates is iron ions oxidation/reduction. The impedance spectroscopy showed increasing sensitivity to used bacteria strain E. Coli, P. Aeruginosa and S. Aureus, respectively.

Conclusion
The results indicate that nanostructured Ti-6-Al-4V surface should be a possible candidate for bacteria detection sensors.

Development of *in vitro* flow model to test antimicrobial coatings for blood-contacting materials

Juliane Valtin$^{1,3}$, Stephan Behrens$^2$, Manfred Maitz$^1$, Lars D. Renner$^1$, Frank Sonntag$^2$, Carsten Werner$^{1,3}$

$^1$Leibniz Institute of Polymer Research Dresden, Institute of Biofunctional Polymer Materials, Dresden, DE; $^2$Fraunhofer Institute for Material and Beam Technology IWS, Micro- and Biosystems Engineering, Dresden, DE; $^3$TU Dresden, Center for Regenerative Therapies Dresden, Dresden, DE

**Introduction**

Serious medical consequences and cost-intensive management of catheter-associated blood stream infections have led to an increased interest in antimicrobial coatings. Many candidate materials show promising performance in standard microbiological assays, but fail in clinical trials [1]. This circumstance highlights the need for more realistic *in vitro* models to test antimicrobial coatings in a relevant physiological environment. The realistic emulation of shear forces is of particular interest as bacterial adhesion and proliferation *in vivo* are strongly dependent on the hydrodynamic flow conditions.

**Experimental Methods**

*Flow model setup:* Our microfluidic model consists of two main components: the pumping chip connected to a controlling unit regulating the speed of the blood flow (previously described in [2]), and the microchannel chip for the detection of bacterial adhesion and proliferation (Figure 1). The microchannel chip is made of three layers: (1) the upper layer with Luer-Lock connections for in- and outlet (polycarbonate), (2) the middle layer which determines the shape of the channels (3M™ Adhesive Transfer Tape 94714 LE), and (3) the bottom layer with customizable surface material. Most experiments were performed with a bottom layer made of thermoplastic polyurethane.

*Incubation conditions:* Human whole blood, anticoagulated with 5 µM hirudin, was stored in a blood bag reservoir, slowly drawn through the microfluidic system and collected in small caps after passing the pumping and microchannel chip. The collected blood samples were analyzed for inflammation (e.g. complement component 5a) and hemostasis parameters (e.g. prothrombin fragment F1+2, platelet factor 4). Bacterial adhesion was detected via fluorescence microscopy through the microchannel chip. All experiments have been performed at 37°C and 5% CO$_2$ incubation. Pumping speed of the flow model can be adjusted in the range of 0.09 and 13.5 µL/s corresponding to wall shear stresses from 0.07 to 10.5 dyne/cm$^2$ (channel height of 300 µm).

*Antimicrobial surfaces:* The microchannel surfaces were coated with PEGylated copolymers which are further equipped with antimicrobial components (e.g. hexetidine).

*Bacteria:* Gram-positive bacterial species *Staphylococcus aureus* (RN4220) and Gram-negative bacterial species *Escherichia coli* (MG1655) were used for bacterial colonization. Both strains are labeled with green fluorescent protein. A bacterial solution (OD$_{600}$ = 0.1) was applied to microchannels before blood incubation for 1 hour at 37°C.

**Results and Discussion**

Initially, the flow model was optimized to reduce inflammation and hemostasis of pumped blood cells. By broadening in- and outlets, adjusting channel height and optimizing bonding procedure for Luer-Lock ports, hemocompatibility was improved significantly and is comparable to our well established quasi-static whole blood screening chamber [3].

Using the novel flow model, the antimicrobial efficiency of copolymer coatings was shown. Pre-tests with lysogeny broth media displayed a reduction of bacterial surface coverage up to 50 % for both bacterial strains. Whole blood...
experiments revealed lower inflammation response due to the reduced bacterial adhesion and proliferation on the surface. Fluorescence microscopy images of the microfluidic chip after incubation confirmed this observation.

**Conclusion**

The reported results suggest that our developed flow model allows evaluation of antimicrobial coatings under physiological conditions. By adjusting the wall shear stresses, the model can be adapted for defined test conditions.

A Long-Range Sensing Mechanism of Cell Sensing of Substrate Nanotopography

Julien Gautrot, Stefania Di Cio

Queen Mary, University of London, School of Engineering and Materials Science, London, GB

Introduction
The mechanical properties and nanotopography of the extracellular matrix have an important impact on cell phenotype. Such physical cues have been shown to regulate cell adhesion and spreading, cell motility, proliferation and differentiation in a wide range of cells, stem cells and in cancer. However, detailed mechanisms underlying mechanical and nanotopography sensing remain unclear. We developed nanoscale engineered extra-cellular matrices to study such mechanisms. In particular, we show that focal adhesions, typically regarded as essential mechanosensors, are not primary sensors of the nano-scale geometry of the ECM and that the dynamics of the microscale acto-myosin network acts instead as a global sensor of the ECM nanoscale geometry.

Experimental Methods
We used nanopatterned polymer brushes to control the nanoscale geometry of the ECM and cell adhesions. We characterised cell and focal adhesion morphology via confocal microscopy. We studied actin dynamics via live imaging and study the dynamics of regulators of actin assembly and disassembly. We use engineered protein expression, siRNA and inhibitors to explore the imapct of focal adhesion formation, actin contractility and dynamics on nanotopography/nanogeometry sensing.

Results and Discussion
Here, we use nanotopographical patterns of polymer brushes generated via electrospun nanofibre lithography (ENL) to investigate the mechanisms of nanotopography sensing by cells. We observe the dysregulation of actin dynamics, resulting in the surprising formation of actin foci. This alteration of actin organisation is regulated by myosin contractility but independent of adapter proteins such as vinculin. This process is highly dependent on differential integrin expression as β3 integrin expressing cells, more sensitive to nanopattern dimensions than β1 integrin cells, also display increased perturbation of actin assembly and actin foci formation. We propose that, in β3 integrin expressing cells, contractility results in the destabilisation of nanopatterned actin networks, collapsing into foci and sequestering regulators of actin dynamics such as cofilin that orchestrate disassembly.

Conclusion
In contrast to the sensing of substrate mechanics and ECM ligand density, which are directly orchestrated by focal adhesion assembly, we propose that nanotopography sensing is regulated by a long-range sensing mechanism, remote from focal adhesions and mediated by the actin architecture.

*Tissue engineering aims at the reproduction of cell-biomaterial interactions sensed by cells in vivo. The symposium will highlight recent evidences on the influence of biophysical and biochemical cues of biomaterials in mediating cell phenotype or response to treatment. Such knowledge is fundamental for tissue regeneration and modelling.*

*The keynote speaker will introduce the subject of the symposium, by highlighting how biomaterials properties may affect the mechano-chemical processes occurring at cell-biomaterials interface. The selected abstracts will cover innovative approaches in studying biomaterial impact on cell fate and behaviour, covering different biomaterials composition and architectures and different cell types.*
S09-KL01

Mechanochemical processes at the cell/material interface

Manuel Salmeron-Sanchez

University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB

The physical properties of the extracellular matrix (ECM) and the use of growth factors are powerful tools to control cell behaviour, including fundamental processes such as cell migration and (stem) cell differentiation. Integrins are mechanotransducers that feel and respond towards the viscoelastic properties of the ECM. Growth factors are important molecules that trigger signalling cascades that control e.g. osteogenesis and vascularisation. The field has moved from soluble administration/release of growth factor from biomaterials to solid-phase presentation of growth factors, recapitulating aspects of the ECM. We have developed material systems that allow simultaneous stimulation of integrins and growth factors receptors. We have engineered polymers and 3D hydrogels that unfold and assemble proteins to allow exposure of the integrin and growth factor binding regions. For example, we show the use of BMP-2 in synergy with α5β1 integrins to promote osteogenesis and regeneration of critical-sized defects and VEGF to promote vascularisation. Using laminin-based hydrogels we have demonstrated the combined effect with NGF to trigger neural processes.

In parallel, we have also engineered dynamic systems that allow control over temporal release of adhesion molecules and growth factors. Unconventionally, we have used non-pathogenic bacteria in co-culture with stem cells that have been engineered to control release of a fibronectin fragment and BMP-2 in a dynamic way. We present bacteria-based materials in which symbiotic bacteria/mammalian cell interactions occur and their use for stem cell engineering. We have first genetically modified L. lactis to produce a fibronectin fragment (FNIII7-10) that allows integrin binding and cell adhesion to the bacteria biofilm and then stimulation of osteogenesis by inducing the expression of BMP-2 in a dose-controlled manner.

Introduction

How adhesive forces are transduced and integrated into biochemical signals at focal adhesions (FAs) is poorly understood. Using cells adhering to deformable micropillar arrays, we demonstrate that traction force and FAK localization, as well as traction force and Y397-FAK phosphorylation, are linearly coupled at individual FAs on stiff, but not soft, substrates. Similarly, FAK phosphorylation increases linearly with external forces applied to FAs using magnetic beads. This mechanosignaling coupling requires actomyosin contractility, talin-FAK binding, and full-length vinculin that binds talin and actin. Using an in vitro 3D biomimetic wound healing model, we show that force-FAK signaling coupling coordinates cell migration and tissue-scale forces to promote microtissue repair. A simple kinetic binding model of talin-FAK interactions under force can recapitulate the experimental observations. This study provides insights on how talin and vinculin convert forces into FAK signaling events regulating cell migration and tissue repair.

Experimental Methods

Cells: eGFP-WT vinculin, eGFP-VH vinculin, eGFP-A50l-vinculin, and vinculin-null MEFs were generated. WT GFP-FAK, E1015A GFP-FAK, K454R GFP-FAK (kinase-dead), Y397F GFP-FAK, and FAK-null MEFs were derived by transducing FAK−/− MEFs with lentiviral constructs for FAK variants.

mPADs analyses: Microfabricated post array detectors (mPADs) device silicon masters were fabricated using PDMS replica molding.

Western blotting: Equal amounts of protein (10 μg) were boiled (95° C) in Laemmli sample buffer for 5 min, separated by SDS-PAGE. Membranes were incubated with antibodies overnight at 4°C and imaged with a LI-COR Odyssey Imager (LI-COR Biosciences).

Magnetic bead experiments: Fibronectin was coupled to tosyl-activated paramagnetic Dynabeads M-450 (At 6 mm distance, the force on a single bead was 30 pN or 10 pN

Microtissue fabrication and experiments: Cells (1.2 x 10⁶) were suspended in 1.75 mg mL⁻¹ neutralized rat tail collagen type I (Ibidi) and seeded in the device.

Results and Discussion

By analyzing individual FAs in cells adhering to deformable micropillar arrays, we demonstrate that traction force and FAK localization and traction force and Y397-FAK phosphorylation are linearly coupled at individual FAs on stiff, but not soft, substrates. Importantly, disruption of talin binding to FAK using the E1015A FAK mutant eliminates force-
FAK localization and force-Y397-FAK phosphorylation. We further demonstrate that force-FAK coupling regulates two important cellular responses: (i) signaling in response to applied external forces using magnetic beads, and (ii) coordinated cell migration and tissue-scale forces driving microtissue repair using an *in vitro* 3D biomimetic wound healing model of fibrous tissue. Consistent with the results on micro post arrays, mutation of talin-binding site in FAK significantly disrupts these two cellular processes. Using a conventional wound scratch assay, Lawson et al. reported reduced wound closure for FAK E1015A-expressing cells compared to wild-type FAK-expressing cells, and no differences between FAK E1015A-expressing cells and FAK-null controls [1]. In contrast, fibroblasts migrating in 3D collagen matrices do not display a lamellipodium, and migration is driven by mechanosensitive proteins that rely on actomyosin contractility [2]. We used a biomimetic 3D *in vitro* model of fibrous tissue repair with cells dispersed within a collagen construct in which wound healing involves coordinated tissue-scale forces, matrix assembly, and cell migration to restore 3D tissue architecture. In contrast to the reduced cell migration reported by Lawson et al., we observed increased cell speed, straightness index, persistence time, and diffusivity for FAK E1015A-expressing cells compared to wild-type FAK-expressing cells. Furthermore, we observed higher contractile forces in microtissues containing wild-type FAK-expressing cells compared to microtissues seeded with FAK E1015A-expressing cells. Finally, we present a simple kinetic binding model of talin-FAK binding interactions under a force that recapitulates the experimental observations. Our model proposes force-dependent structural changes in talin that regulate its interaction with FAK. Although talin at FAs is stretched by forces [3,4] and stretching modulates vinculin binding [5] to our knowledge, there is no direct experimental evidence showing that FAK binding to talin requires a mechanical stretch.

**Conclusion**

These experimental and modeling analyses provide insights into how talin, FAK, and vinculin convert forces into early signaling events regulating mechanotransduction. This conceptual framework is relevant to adhesive force-signaling coupling at migratory cell fronts, force-regulated morphogenesis, and stem cell lineage commitment in response to matrix stiffness. Furthermore, this fundamental understanding of mechanosignaling can ultimately be exploited to design cell-biomaterial interactions.

Introduction
With over 2.5 million people affected worldwide, multiple sclerosis (MS) represents a serious health, economic and social burden with no long-term suitable treatment. Remyelination failure in MS is a longstanding problem that remains to be solved. The formation of a glial scar containing reactive astrocytes overexpressing altered extracellular matrix (ECM) proteins contributes to a complete alteration of the microenvironment surrounding these cells. We hypothesize that oligodendrocytes (OLs) respond to these dynamic biomechanical changes altering their differentiation capacity, and in turn the remyelination is compromised. By tuning glial scar-mechanosensing mediated pathways one expects to be able to promote remyelination.

Here we propose a novel fully three-dimensional tissue-engineered model to study the impact of mechanical properties changes of the ECM on OL differentiation. The platform consists of an array of polydimethylsiloxane (PDMS) microstructures with biologically relevant dimensions and low stiffness designed to act as surrogate axons, embed within a modified alginate (ALG) matrix to fully recreate the 3D environment of the ECM. PDMS possesses advantageous characteristics as optical transparency that allows the user to follow live myelination, biocompatibility, and easiness of production. ALG was chosen as the polymer to mimic the extracellular milieu due to its biocompatible, non-toxic and tunable matrix mechanical properties.

Experimental Methods
PDMS microstructures were fabricated through replica moulding by mixing PDMS base and curing agent in a weight ratio of 10:1. PDMS stiffness was varied by adding to the PDMS mixture a low viscosity PDMS.

ALG hydrogels were produced by combining modified ALG formulations containing the cell adhesive peptide RGD (GGGGRGDSP) or the matrix metalloproteinase sensitive peptide PVGLIG (GGYGPVG↓LIGGK). Primary rat oligodendrocyte precursor cells (OPCs) growth and differentiation were optimized by varying the alginate content (0.5–1.5 wt/v%), PVGLIG (130–400 µM) and RGD concentration (40–200 µM) and polymer chain oxidation status.

Results and Discussion
Axon surrogates were produced using a low viscosity PDMS, corresponding to an advance in the creation of structures with a great aspect ratio and reduced stiffness. OPCs not only adhere and differentiate but also generate spread myelin sheaths when cultured on the PDMS microstructures. Interestingly automated image analysis (using open-source image analysis software – Fiji, Ilastik and Cell Profiler) suggested that softer PDMS structures (Young’s modulus of 1250 kPa vs 364 kPa) promoted higher expression levels of OL differentiation markers.

Alginate hydrogels were non-toxic to OPCs and differentiation status was favoured in matrices with high PVGLIG and oxidation content (Figure 1). The impact of the mechanical properties’ changes on OL differentiation was assessed by culturing OPCs in increased alginate content hydrogels (1%, 2% and 3% wt/v). OL metabolic activity and differentiation (assessed by the expression of the myelin basic protein, MBP) was favoured in softer matrices.
(shear modulus, $G^* \sim 100$ Pa) in comparison with low expression of MBP and decreased cell volumes for $G^*$ around 350 Pa and 1300 Pa. Additionally, impaired OL differentiation was verified in hydrogels with similar stiffness values but with increased stress-relaxation times, which indicates an enhanced cellular behaviour in matrices with augmented capability of dissipating cell-induced forces.

To recreate a glial scar in vitro, primary rat astrocytes were also embedded within the ALG matrices and found to extend long processes, with increased cellular complexity for high PVGLIG matrices (Figure 1). Activation with LPS/IFN-γ lead to an increase of Lcn2 and Col4 expression, strongly indicating that astrocytes acquire an astrogliosis-like phenotype.

**Conclusion**

In this work we have established an in vitro platform that can function as a toolbox to dissect (de)myelination processes occurring under differential mechanical conditions. OLs respond to alginate matrices mechanical properties alterations (stiffness and stress-relaxation properties) by changing their differentiation pattern. By combining the culture of OLs and activated astrocytes within the ALG hydrogels we are expecting to understand the crosstalk between these cells and investigate the effects of matrix alterations provoked by astrogliosis processes on OL differentiation.

Influence of culture substrates on morphology and function of pulmonary alveolar cells in vitro

Chiara Emma Campiglio1, Marina Figliuzzi2, Sara Silvani2, Matteo Tironi2, Sara Conti2, Federica Boschetti3, Andrea Remuzzi1

1 University of Bergamo, Department of Management, Information and Production Engineering, Dalmine, IT; 2 Istituto di Ricerche Farmacologiche Mario Negri-IRCCS, Department of Biomedical Engineering, Bergamo, IT; 3 Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering, Milan, IT

Introduction

Cell’s microenvironment has been shown to exert influence on cell behavior. In particular, matrix stiffness and cell interaction strongly impacts cell morphology and function. The alveolar epithelium is a dynamic tissue normally undergoing a slow, but constant renewal [1]. It is predominantly composed of alveolar Type I (ATI) and Type II (ATII) epithelial cells. ATII pneumocytes basically secrete the surfactant proteins implied in the regulation of alveolar surface tension during gas exchange, in alveolar fluid balance and in host defense. However, isolated ATII pneumocytes cultured in vitro lose their specific features and acquire ATI epithelial cell characteristics, stopping surfactant production [2]. Continuous cell lines are an alternative to primary ATII epithelial cell cultures. A representative cell system used to investigate ATII epithelial cells is the A549 lung epithelial adenocarcinoma cell line. A549 cells are usually cultured in conventional two-dimensional (2D) systems. Under such conditions, A549 cells flatten, lose differentiated Type II cell morphologic characteristic, and stop synthesis and secretion of biochemical markers of surfactant.

The purpose of this study was to analyze the influence of different culture substrates on phenotype and functional properties of A549 cells in order to understand in which in vitro culture condition these cells are able to acquire and maintain ATI or ATII phenotypes.

Experimental Methods

Two different substrates were used for A549 cell culture: a rigid surface of cell culture treated Thermanox™ Coverslips, and a polydimethylsiloxane (PDMS) artificial elastic membrane (Elastosil® Film). Firstly, the two substrates were characterized by a tensile testing and, to provide a more suitable substrate for cell adhesion, they were coated with fibronectin. For cell culture experiments, A549 cells were seeded at concentration of 1 x 10⁴ cells/cm² on Thermanox™ Coverslips and Elastosil® Film, and maintained in culture for 72 h. Metabolic activity was quantified by resazurin assay, while the morphological characterization was performed by optical and scanning electron microscopy (SEM). In order to characterize A549 cell functional changes, an immunofluorescence analysis was performed for YAP-1 and surfactant protein C expression, focal adhesion and actin filaments organization.

Results and Discussion

A549 cells were successfully seeded onto Thermanox™ Coverslips and Elastosil® Film, substrates with elastic modulus of 1,350 ±290 and 0.85 ±0.01 MPa, respectively (Figure 1A). The resazurin assay showed that there are no statistically significant differences in the metabolic activity measured on cells seeded on different substrates (Figure 1B). However, the two substrates influenced cell morphology and the actin cytoskeleton organization. The morphology and distribution of A549 cells on Thermanox™ Coverslips and Elastosil® Film substrates were examined by SEM analysis. We observed that cells grown on Thermanox™ Coverslips remained flat, expressing a low number of microvilli while cells cultured on Elastosil® Film maintained the typical ATII cell morphology, with rounded shape and large number of microvilli on cell surface (Figure 1C-D). The different distribution of F-actin filaments was also associated with a different expression of focal adhesions identified in A549 cells cultured on Thermanox and Elastosil.
substrates. The acquired sections (z-axis) confirmed a different profile in cell organization: cells remained round-shaped on Elastosil® Films (19 μm thickness), while appeared flat in a thinner layer on Theranox™ Coverslips (9 μm thickness) (Figure 2). Further, the Yes-associated protein (YAP) and its transcriptional coactivator PDZ-binding motif (TAZ) were translocated to the nucleus in A549 cells cultured on the more rigid polyester substrate, yet it remained mostly cytosolic in cells on soft PDMS substrate. Immunofluorescence staining for surfactant-C revealing a high expression of surfactant-C in cells cultured on Elastosil® Film, but not in cells cultured on Theranox™ Coverslips. Therefore, A549 cells grown onto soft Elastosil® Film exhibited morphology and functionality that suggest retention of alveolar epithelial Type II phenotype, while A549 cells grown onto more rigid substrates acquired an alveolar Type I phenotype.

Conclusion
The presented results suggest that different substrates induced important changes in cell morphology and cytoskeleton organization. A stiffer substrate led to nuclear YAP/TAZ formation in lung epithelial cells and to a reduction of surfactant C expression, inducing cells to acquire ATI phenotype, while soft substrate induced to retain an ATII phenotype. The results from this study bring us a step closer to understand how cell substrate and, in particular, substrates stiffness influence morphology and function of alveolar epithelial cells.

The Visco-Elasticity of 2D Protein Networks Regulates Stem Cell Expansion at Liquid-Liquid Interfaces

Julien Gautrot, Dexu Kong, Lihui Peng

Queen Mary, University, School of Engineering and Materials Science, London, GB

Introduction
The mechanical behaviour of the extracellular matrix has an important impact on cell phenotype. Despite the importance of mechanotransduction in regulating a wide range of phenotypes, we recently reported the surprising observation that cells (keratinocytes and mesenchymal stem cells) can adhere, spread and proliferate at the surface of liquids\(^1\)-\(^3\). This observation is particularly surprising as the reinforcement of cell adhesion is thought to require a solid elastic or viscoelastic substrate that can resist cell-mediated contractile forces. Our work has evidenced the formation of protein nanosheets, self-assembled at the liquid-liquid interface, displaying strong mechanical properties that can provide a sufficient mechanical scaffold to promote cell adhesion and expansion. We showed that this is sufficient to regulate stem cell phenotype. However, the parameters controlling the self-assembly and the mechanical properties of protein nanosheets remain poorly understood. In this work we investigate the assembly of polymers and proteins at liquid-liquid interfaces, and the impact of pro-surfactants with a wide range of chemistries. We identify structural features that control the visco-elastic properties of the resulting nanosheets and regulate associated cell phenotype.

Experimental Methods
Assembly at liquid-liquid interfaces is studied using interfacial rheology. Protein nanosheets are characterised by scanning electron microscopy, atomic force microscopy and X-ray photoelectron spectroscopy. Cell adhesion and phenotype was characterised by fluorescence microscopy and qPCR.

Results and Discussion
In this work, we show the importance of parameters such as pH and concentration on protein self-assembly and the impact it has on interfacial mechanics. Importantly, we demonstrate the impact that pro-surfactant-protein interactions play on regulating the assembly and the interfacial mechanical properties of the corresponding interfaces. In addition, we show how these parameters regulate interfacial viscoelasticity over a wide range, and ultimately regulate cell adhesion and proliferation. Finally, we demonstrate the proof-of-concept of using such liquid substrates, in the form of emulsions, for stem cell culture in 3D bioreactors, and their simple recovery by centrifugation.

Conclusion
Overall, our results suggest that nanoscale mechanical properties of biomaterials may dominate over bulk physical properties. This concept has important implications for the design of biomaterials in the field of regenerative medicine and allow the rational design of liquid substrates for tissue engineering.

Introduction
Reproducing interaction between cells, and between cells and extracellular matrix (ECM), remains a challenge when developing biomimetic materials. In vivo, cells are surrounded by a constantly changing microenvironment, which regulates many cell functions such as differentiation, migration and cell death.¹ Without the natural microenvironment, some of the biological cell functions can be lost or altered, thus there is a need for developing novel materials for improved in vitro models.² Smart stimuli-responsive materials are an emerging group of materials, which can react to external stimuli. Light is an interesting energy source for stimuli-responsive materials, as it can be localized over a substrate, it is non-invasive, and its properties can be finely tuned. One of the primary molecules used for photosensitive materials are azobenzenes. The molecular process behind the photoinduced motions in azobenzene-based systems is the isomerization of the azobenzene molecule between the thermodynamically stable trans isomer and metastable cis isomer. Azobenzenes can be incorporated into glass-forming materials, which can be surface patterned via light-induced mass migration to form sinusoidal surface relief gratings (SRGs).³ The aim of this research is to combine the dynamic nature of living tissue with in vitro cell culturing. Here we have developed a dynamic platform, which enables the control of cell alignment and migration in a non-invasive way.

Experimental Methods
Disperse Red 1-glass (DR1g) was spin coated on clean glass coverslips to obtain a 500 nm-thick layer. Then, a solution of Sylgard 184 was diluted in n-hexane and spun over DR1g to form DR1g-PDMS bilayer. Samples were photopatterned using laser interference lithography (488 nm light), and the formation and erasure of SRGs on the bilayer was studied with diffraction measurements and with atomic force microscopy (AFM). Microcontact printing (μCP) technique was used to print FITC-conjugated gelatin and collagen I on flat and surface patterned bilayer surface. Cell alignment on the bilayer was studied with Madin-Darby canine kidney type II epithelial cells (MDCK II), which were seeded on top of surface and protein patterned samples and cultured for 72h. Microcontact-printed samples were passivated with Pluronic F-127. The alignment of MDCK II cells was analyzed with confocal microscopy and image analysis.

Results and Discussion
The results show that SRGs were efficiently produced on DR1g-PDMS bilayer. Compared to plain DR1g film, the SRG formation and erasure on the bilayer was slower and the dynamics depended on the PDMS film stiffness. MDCK II cells cultured on DR1g-PDMS bilayer with SRGs showed elongated morphology after 24h from cell seeding (Figure 1a), as confirmed by image analysis conducted on focal adhesions. The focal adhesions were oriented in the same direction as SRGs, whereas on flat areas they had a random orientation. 72h post-seeding focal adhesions were still oriented along the SRGs, thus the SRG topography provides strong guidance for the cells. These results are consistent with our previous studies.⁴ DR1g-PDMS bilayer was also chemically patterned with proteins, to assess the chemical functionalization of the platform.⁵ Protein patterns with uniform and micropatterned areas were achieved. MDCK II cells were seeded on top of the protein patterned DR1g-PDMS bilayer and their attachment and alignment on the pattern was studied (Figure 1b). Cells adhered well on the protein patterned areas and aligned according to the pattern (24h post-seeding), until cells spread to the passivated areas (72h post-seeding). To study
the different effect of topographical and chemical cues over cell migration, MDCK II cells were also seeded on bilayer with combined surface topography and protein pattern. Cells attached to areas with the protein pattern, however, after 24h from cell seeding the cells aligned along the topography rather than the protein pattern. This indicates that the surface pattern is dominating the cell orientation over the protein pattern in longer cell culturing times, probably due to protein adsorption from cell medium and passivation reduced effect. The results showed that the DR1g-PDMS bilayer can be surface patterned dynamically and further modified by protein patterning, which enables the tunability of the platform for different applications.

Conclusion
Azobenzene-containing DR1g was chosen as light-responsive material to study collective cell migration on purely topographical versus purely chemical cues. The presence of a biocompatible PDMS coating did not inhibit the SRG formation and erasure but altered the dynamics. Based on the results, the light patterned DR1g-PDMS bilayer can guide cell alignment and, interestingly, the topographical signal was able to drive cell migration for longer culture times. The possibility to control material properties non-invasively and remotely with light will open new ways to design next-generation smart materials for biomedical research.

Clickable microgels with hydrophobic topographical domains and in situ tunable matrix properties as dynamic cellular microenvironments

Mariana I. Neves¹,²,³, Ana L. Torres¹,², Lorenzo Moroni⁴,⁵, Cristina C. Barrias¹,²,⁶

¹ Universidade do Porto, i3S - Instituto de Investigação e Inovação em Saúde, Porto, PT; ² Universidade do Porto, INEB - Instituto de Engenharia Biomédica, Porto, PT; ³ Universidade do Porto, FEUP - Faculdade de Engenharia, Porto, PT; ⁴ Maastricht University, MERLN - Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; ⁵ Università del Salento, CNR NANOTEC - Institute of Nanotechnology, Lecce, IT; ⁶ Universidade do Porto, ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Porto, PT

Introduction

The extracellular matrix (ECM) is a key component of a cell microenvironment, regulating many cellular processes through biochemical and mechanical signaling. Hydrogel systems have been widely used to build artificial cellular niches, which should allow mimicking both the structure and the dynamic properties of the native ECM. Strain-promoted azide-alkyne cycloaddition (SPAAC) is a biorthogonal conjugation strategy, involving a specific reaction between strained cyclic ring-containing alkynes and azides, which proceeds under mild, copper-free, biocompatible conditions. For this reason, SPAAC has been widely used for biomolecules and living cells labelling [1]. While in polymer chemistry SPAAC emerged as an attractive strategy for (bio)functionalization and/or network formation [2,3], here, we further exploited the ability of pendant cyclooctyne groups to undergo physical crosslinking via hydrophobic interactions. By taking advantage of this feature, we formulated dual-crosslinked alginate microgels that present hydrophobic microdomains and can be functionalized with azido-functionalized compounds, in situ and in the presence of cells, in a time-controlled fashion. This microgel system provides topographical cues to entrapped cells and may sequester molecules with hydrophobic moieties, while allowing on-demand dynamic switch of matrix properties.

Experimental Methods

Ultra-pure alginate was functionalized with a cyclooctyne (BCN-amine) by carbodiimide chemistry, and the modification degrees of alkyn-agarates (ALK) were assessed by ¹H NMR. ALK hydrophobicity and hydrophobic-driven self-assembly potential were characterized by contact angle measurements, hydrophobic probes (ANS and Coomassie), scanning electron microscopy and viscometry. ALK microgels (acellular and cell-laden) were prepared by ionic crosslinking with Ca²⁺ using a coaxial airflow droplet extrusion device [4]. SPAAC conjugation with azide-functionalized compounds was performed at 37°C, in pre-gel solutions (0.9% w/v NaCl) or pre-formed microgels (culture medium). Grafting kinetics and efficiency were estimated using fluorescent azido-tags. Clickable microgels laden with mesenchymal stem cells (MSC) were analyzed throughout culture for cell number, viability (live/dead assay) and metabolic activity (resazurin assay).

Results and Discussion

ALK derivatives with varying modification degrees were successfully produced. Expectably, as the content of grafted hydrophobic octyne moieties increased, ALK derivatives become less hydrophilic, showing decreased wettability, stronger interactions with hydrophobic probes and increased viscosity in aqueous solutions. Also, at higher modification degrees, ALK derivatives become less water soluble and showed ability to spontaneously establish concentration-dependent physical cross-linkages between polymer chains, via pendant cyclooctyne groups, forming filamentous structures. By taking advantage of this property, and further promoting secondary ionic crosslinking, we were able to produce dual-crosslinked ALK microgels with structured hydrophobic microdomains. These not only add topographical features to the otherwise smooth bulk hydrogel, but also provide binding regions for sequestering...
compounds with hydrophobic sites, such as proteins, as verified using an extrinsic hydrophobic fluorescent probe. The ability to multi-functionalize the clickable ALK microgels, in situ and on-demand, was confirmed by performing consecutive SPAAC conjugations with sequentially added azido-functionalized florescent tags of different colors. The kinetic profiles demonstrated that the reactions proceeded rapidly (less than 30 min) and efficiently, under physiological conditions (i.e., in culture medium at 37ºC). The live/dead and resazurin assays performed after SPAAC reaction on MSC-laden ALK microgels showed that cells remained viable and metabolically active throughout 14 days of culture, confirming the cytocompatibility and specificity of the strategy. In situ SPAAC conjugation with fluorescent azido-tags could be successfully performed at different time points, proving that a fraction of octyne groups remained reactive, enabling temporal control of the hydrogel matrix throughout the culture.

**Conclusion**

By taking advantage of the intrinsic hydrophobicity of cyclooctyne groups, which can be conjugated with azido-conjugated compounds via SPAAC, we successfully formulated dual crosslinked microgels with topographical hydrophobic domains that can be (bio)functionalized, on-demand, in the presence of cells.

S10 | Advances in Functionalization and Fabrication of Gelatin Hydrogels for Biomedical Applications

Chairs
- Silvia Faré
  Politecnico di Milano, Dept Chemistry, Materials and Chemical Engineering, Milan, IT
- Nicola Contessi Negrini
  Imperial College London, London, GB
- Susanne Heid (YSF)
  Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, DE

The presentation will provide an overview of pros and cons associated with crosslinking chemistries, both from a processing (laser- versus extrusion-based 3D-printing and electrospinning) and an application perspective. Furthermore, the use of crosslinkable gelatin in vivo will be reported along with the trajectory towards Phase I clinical trials.

The Keynote Speaker will discuss advanced chemistries and fabrication technologies to prepare gelatin scaffolds. The other four speakers will be selected to present specific chemistries and/or fabrication technologies to regenerate different tissues, aimed at clinical applications or advanced in vitro models, to capture the interest of a wide audience.
S10-KL01

Crosslinkable gelatins - From Innovative Chemistry and Valorization of Bioinks towards Human Trials: Utopia or Reality?

Biofabrication is a specific area within the field of tissue engineering which takes advantage of rapid manufacturing (RM) techniques to generate 3D structures which mimic the natural extracellular matrix (ECM). A popular material in this respect is gelatin, as it is a cost-effective collagen derivative, which is the major constituent of the natural ECM. The material is characterized by an upper critical solution temperature making the material soluble at physiological conditions. To tackle this problem, covalent crosslinking is realized by functionalizing gelatin with (photo-)crosslinkable functionalities. In this respect, methacrylamide-functionalized gelatin (gel-MA/gel-MOD) currently is the gold standard. However, gel-MA poses some important limitations with regard to network homogeneity and processing capabilities exploiting laser-based additive manufacturing (AM). As a result, we have developed mono- and bifunctional (patented) crosslinkable gelatin derivatives which offer distinct advantages (e.g. solubility at room temperature) for various AM techniques. The hydrogels support processing with digital light projection, multiphoton lithography (2PP) and extrusion-based additive manufacturing. Furthermore, they are suited to encapsulate a.o. adipose tissue-derived stem cells and to support differentiation into different lineages (e.g. adipogenic and osteogenic). The gelatin derivatives offer a unique opportunity to serve a plethora of tissue engineering (TE) applications (including ocular, adipose, bone, etc.) and some gelatins are currently being valorized by a spin-off company as bioink constituents. In addition to their in vitro biocompatibility assessment, we also performed in vivo animal trials (mice) which indicated that the implanted constructs actively stimulate vascularization. Currently, the regulatory trajectory towards first in-human trials of an injectable crosslinked bifunctional gelatin to serve adipose tissue engineering applications is ongoing.

Introduction
Gelatin hydrogels are promising biomaterials to engineer biomimetic extracellular matrix for tissue engineering and in vitro modelling. However, the development of a cytocompatible crosslinking strategy to stabilize these hydrogels at physiological temperature and simultaneously control physico-mechanical properties to guide a desired cell response is still challenging [1]. Here, we prepare gelatin hydrogels using bioorthogonal click chemistry and demonstrate that the hydrogel properties can be tuned by fixing their concentration and modulating their crosslinking to guide in vitro cell response.

Experimental Methods
Gelatin hydrogels were prepared by bioorthogonal crosslinking reaction (Fig.1, left) between tetrazine (Tz) and norbornene (Nb) [2]. Tz- and Nb-gelatin derivatives (Gel_Tz and Gel_Nb) were synthesised with different degrees of modification (DOM) by decorating gelatin either with Tz or Nb, respectively, using EDC/NHS coupling reaction. ¹H NMR was performed to measure the DOM of gelatin derivatives. Gelatin hydrogels at fixed 8% w/v concentration were prepared by mixing Gel_Tz and Gel_Nb obtained with different DOM (i.e., low, medium, and high), at different Gel_Tz:Gel_Nb ratios R (i.e., 0.5, 1, and 2). The evolution of the rheological properties (storage modulus G' and time required for crosslinking t_cross) of the hydrogels during crosslinking were recorded by a rheometer (Anton Paar MCR302). The swelling of crosslinked hydrogels was investigated by measuring their weight variation after immersion in PBS at 37 °C up to 2 weeks. The compressive mechanical properties of swollen hydrogels were tested by Instron 5900R. Human Dental Pulp Stem Cells (hDPSC) were added to the gelatin derivatives solutions and cell-laden hydrogels were prepared (1·10⁶ cells ml⁻¹). After 1 day of culture, a live/dead staining was performed to evaluate cell viability and distribution in the 3D hydrogels. Cell metabolic activity was measured over 2 weeks of in vitro culture by AlamarBlue™ assay. Cell morphology was evaluated after 14 days by F-Actin/nuclei staining.

Results and Discussion
Gel_Tz and Gel_Nb were successfully synthesised with different controlled DOM (i.e., 5, 10, and 15%). After mixing the gelatin derivatives, an increase in G' was observed with time, confirming the ongoing crosslinking reaction between Tz and Nb to achieve a formed hydrogel (G’>G”). Hydrogels prepared using higher DOM and equimolar Tz:Nb ratio (i.e., R=1) were characterized by a quicker crosslinking reaction and higher G’ values at plateau (t_cross=10-20 min, G’=1000-1500 Pa), compared to hydrogels prepared with lower DOM and defect of Tz or Nb (i.e., R=0.5 and R=2, respectively; t_cross=60-70 min, G’=300-600 Pa). Crosslinked hydrogels were stable in PBS at 37 °C for 2 weeks, and higher weight variation was measured for lower DOM hydrogel and hydrogels prepared with defect of Tz or Nb (i.e., R=0.5 and 2). Compressive mechanical properties of swollen hydrogels were tuned both by varying the DOM and the R ratio (Fig.1, right). Lower Young Modulus E was measured for hydrogels with low DOM and R0.5 and R2 (E<1 kPa), while higher mechanical properties characterized hydrogels with high DOM and R1 (E>1 kPa). Viable hDPSC (viability>85%) distributed in the 3D structure of the hydrogels (Fig.2, left) were observed in all the hydrogel formulations, proving the cytocompatibility of the developed hydrogels. Cell morphology after 14 days of culture heavily depended on the mechanical properties of the hydrogels (Fig.2, right). Elongated cells were observed for hydrogels with lower mechanical properties, while less elongated cells were observed in hydrogels with higher mechanical properties.
mechanical properties, proving the importance of modulating the hydrogel properties to guide a desired cell response [3]. Cell metabolic activity increased over time in all the hydrogel formulations; elongated cells showed higher metabolic activity values compared to less elongated cells. Hydrogels prepared with excess Nb or Tz were successfully adhered and remained in contact over culture, potentially allowing for future use as compartmentalized cell co-culture platforms.

**Conclusion**

Cytocompatible gelatin hydrogels with tuneable properties were successfully developed by varying the DOM and Tz:Nb ratio of the hydrogels. All hydrogel formulations can be used to culture viable and metabolically active cells. Tuning the properties of the hydrogels allowed successful modulation of cells response.

Introduction
Hydrogels are hydrated networks able to mimic the natural Extra Cellular Matrix (ECM) and are widely used for different applications, including biomedicine and soft electronics. [1] Nervous tissue is an excitable system, with poor self-healing ability when damaged by trauma and diseases. Recently, great attention has been focused on developing electroconductive hydrogels to support recovery of the degenerated nervous tissues, [2],[3] by enhancing cell adhesion, cell growth and formation of functional neuronal networks in the scaffold. [4],[5] Among neural cells, glial cells, called astrocytes, play a critical role in nervous system recovery and in the response of the damage tissue to the implanted scaffold. In the present work, an electroconductive scaffold is prepared and characterized and its biocompatibility with different cell types including astrocytes are evaluated.

Experimental Methods
Hydrogels were fabricated by using three different components, namely \(i\) gelatin, a biomimetic polymer, \(ii\) genipin, a crosslinking agent and \(iii\) different amounts of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT/PSS), an electroconductive polymer. Rheological analyses were performed to investigate the gelation time and mechanical properties at the end of the gelation. Mechanical properties were also investigated with compression tests using Dynamic Mechanical Analysis (DMA). Electroconductive properties of resulting hydrogels were assessed by Electrochemical Impedance Spectroscopy. Furthermore, swelling and degradation after hydrogels incubation in media able to mimic physiological conditions of temperature, pH and osmolarity were considered. Finally, hydrogels biocompatibility was investigated by using different cell types, including primary rat astrocytes. Alamar blue assays was used to this aim.

Results and Discussion
Genipin was able to promote homogenous gelation of the resulting composite networks. Gelation time of the system without the conductive polymer was close to three hours, whereas in the presence of PEDOT/PSS it was reduced down to 30 minutes. Hydrogels fabricated in the presence of PEDOT/PSS displayed an increase of the shear and elastic modulus but resulted to be less resistant to deformation. This behavior was attributed to the ability of conductive polymer to partially prevent networks bending and stretching. All hydrogels displayed an excellent stability. Additionally, the presence of PEDOT/PSS enhanced the electroconductivity of resulting hydrogels. Hydrogels resulted to be biocompatible towards different cell lines, including primary rat astrocytes.

Conclusion
The presence and the amount of PEDOT/PSS resulted to finely tune some pivotal physical-chemical features – including gelation time, mechanical performance, electroconductive properties, swelling and degradation – of resulting hydrogels. These electroconductive hydrogels can be proposed as electrically conductive interfaces with human tissues, e.g. as neural probes and skin electrodes. Resulting hydrogels can be also potentially proposed as \textit{in-vivo} injectable biomaterials for regeneration of electroconductive tissues, e.g. muscular and neural tissues. Furthermore, this system is promising for development of 3D bio-printed electroconductive biomaterials for regenerative medicine.

Cell proliferation and morphology of NIH/3T3 cells are influenced by stress-relaxation behavior which can be modified by pre-crosslinking in alginate-gelatin-based hydrogels

Jonas Hazur1, Nadine Grummel2, Dirk W. Schubert3, Ben Fabry2, Aldo R. Boccaccini1

1 University Erlangen-Nürnberg, Institute for Biomaterials, Erlangen, DE; 2 University Erlangen-Nürnberg, Department of Physics, Erlangen, DE; 3 University Erlangen-Nürnberg, Institute for Polymer Materials, Erlangen, DE

Introduction

Synthetic and natural hydrogels are widely used as extracellular matrices in biofabrication, 3D cell culture and tissue engineering. Their physical and chemical properties sensitively influence the behavior of the embedded cells, and it is therefore of considerable interest to understand how these hydrogel properties must be optimized to achieve desired cell functionality. In an ideal matrix, attaching cells are able to establish cell-material interactions, e.g. via integrin-binding and are able to elongate, proliferate and migrate. Alginate hydrogels show good biocompatibility, but do not offer binding-sites for cellular attachment. In this study, we investigated the influence of a priorly established pre-crosslinking technique on the mechanical behavior of alginate-gelatin-based hydrogels and the resulting changes of cell morphology, proliferation and migration of embedded NIH/3T3 cells.

Experimental Methods

The materials used in this project were alginate-gelatin-based hydrogels. On the one hand, native alginate (Alg) and on the other hand oxidized alginate (ADA) was mixed with gelatin (GEL) in the same ratio. After that, the hydrogels were crosslinked with adjusted Ca\(^{2+}\) concentrations, as well as 5 % microbial Transglutaminase (mTG). In order to characterize the mechanical properties, uniaxial compression tests of cylindrical samples were performed in order to determine the Young’s moduli. Furthermore, samples were compressed to 5 % strain and the stress-relaxation was measured over a time period of 10 min. For the biological characterization of NIH/3T3 cells, their morphology was evaluated with Fiji ImageJ and Clickpoints Software and roundness values were compared. Apart from that, migration distance and motility of the cells was investigated with a custom Clickpoint-based Python script. Lastly, the viability of cells was determined with a formazan salt (WST-8) assay, which indicates high cellular activity by a color change upon bioreduction.

Results and Discussion

First of all, we were able to prepare 3D hydrogel matrices with similar Young’s moduli, while substituting ADA with alginate, by adjusting the Ca\(^{2+}\)-crosslinking concentration. With these samples we could show that by the substitution of ADA with alginate, the stress relaxation behavior is altered. The native alginate polymer has an increased molecular weight compared to its oxidized form. Our hypothesis is, that this reduction of the molecular weight leads to the slower stress-relaxation behavior as observed. Furthermore, a significant effect on the cell behavior of NIH/3T3 cells could be observed. Embedded in ADA-GEL samples, cells proliferated a lot more. Accompanied by that, distinctly more elongated cells were observed in these hydrogel matrices.

Secondly, our previously described pre-crosslinking technique [1] was investigated thoroughly within this study. From a mechanical point of view, we observed significantly faster stress relaxation behavior within pre-crosslinked hydrogels. This lead to significantly enhanced cell proliferation, increasingly stretched morphology of the cells, as well as an increased fraction of motile cells in ADA-GEL hydrogels.

Conclusion
In this study, we could emphasize the importance of mechanical stress-relaxation behavior for 3D cell culture *in vitro*. The positive effects of stress-relaxation on a variety of critical cell characteristics, such as morphology, proliferation and migration behavior could be observed. Furthermore, the pre-crosslinking of ADA-GEL-based hydrogels did enhance these positive effects, by rendering the matrix with a faster stress-relaxation behavior. Our hypothesis is that due to the pre-crosslinking, micro-gel particles form within the matrix, which are rather stiff and consist of high alginate content. These micro-gel particles are thought to be surrounded by a rather soft, gelatin rich matrix. In the latter, cells can elongate, migrate and proliferate easily, while the stronger crosslinked parts are impenetrable, but stabilize the structure before being post-crosslinked, which can be advantageous for 3D biofabrication approaches.

Chitosan/gelatin/k-carrageenan sponge-like scaffolds for bone tissue engineering

Konstantinos Loukelis¹, Danai Papadogianni¹, Maria Chatzinikolaidou¹²

¹ University of Crete, Department of Materials Science and Technology, Heraklion, GR; ² FORTH, IESL, Heraklion, GR

Introduction

Since there is an increasingly high demand for optimal biomaterials for a variety of different bioengineering applications, researchers around the globe are constantly trying to fabricate new biofunctional scaffolds that can facilitate and support cell growth and tissue formation. Two of the most prominent biomaterials are chitosan and gelatin, whose chemistry allows for extensive biochemical interactions and also present excellent cell adhesion and cytocompatibility capabilities [1]. Kappa carrageenan is another natural biomaterial, mainly used in the food industry as preservative, which possesses two biologically important chemical groups per subunit, one hydroxyl and one negatively charged sulfur trioxide group. These two groups contribute to its great biological response, when combined with other biomaterials [2,3]. Taking this into consideration, we currently aim to produce kappa carrageenan/chitosan/gelatin scaffolds, reinforced with potassium chloride and covalently crosslinked with glutaraldehyde, in order to subsequently assess their physico-chemical and biological properties. This idea is based on the fact that a polyelectrolyte complex (PEC) can be formed between the negatively charged sulfur trioxide group of kappa carrageenan and the positively charged amino group of chitosan, leading to a sponge-like formation. Moreover, potassium chloride is being used to negate the sulfur trioxide groups that have not participated in the polyelectrolyte complex, allowing for the transition of the non-reacted kappa carrageenan chains from coil to helix formation, endowing the scaffolds with a more robust structure.

Experimental Methods

Four different scaffolds compositions have been prepared: (i) chitosan/gelatin/kappa carrageenan, (ii) chitosan/gelatin/kappa carrageenan enriched with potassium chloride, (iii) chitosan/kappa carrageenan, and (iv) chitosan/gelatin (as control). For all the scaffolds containing kappa carrageenan, three different concentrations have been used, 1% w/v, 0.75% w/v and 0.5% w/v, while keeping chitosan/gelatin concentration the same. Chitosan/gelatin blend was prepared following an established protocol [1]. 2.5% w/v chitosan solution was prepared in 0.25 M acetic acid for 1 h at 50 °C and 5% w/v gelatin solution was prepared in deionized water for 20 min at 50 °C as well. Then, the two solutions were mixed in a volume ratio of 2:1 chitosan:gelatin. Another chitosan solution was prepared without gelatin, in order to be used for the construction of kappa carrageenan/chitosan scaffolds. The same procedure was followed for the preparation of the kappa carrageenan/chitosan/gelatin scaffolds enriched with potassium chloride, with the only difference being that 0.2 M potassium chloride was added in each kappa carrageenan solution prior to the mixing with the chitosan/gelatin blend. The final solutions, independently of their composition, were allowed to mix for 4 h at 60 °C under stirring. Finally, 10 ml of the mixture were transferred into a 15 ml falcon and after addition of 50 μl of 0.25% v/v glutaraldehyde, 800 μl of the blend were cast onto the wells of a 24 well-plate and allowed to freeze-dry for 24 h. Mechanical analysis of the materials was conducted by employing a CellScale UniVert unit (tension, compression and bending testing), while the measurement of swelling ratio, degradation, pore size distribution and FTIR characterization of the different scaffold types were performed. The pore size and morphology has been examined by means of scanning electron microscopy. Swelling ratio and degradation rate at 37 °C in PBS were addressed. Cell viability and proliferation assessment has been performed by means of the PrestoBlue cell viability assay using MC3T3-E1 pre-osteoblastic cells.
Results and Discussion
The scaffolds enriched with potassium chloride demonstrated the highest Young modulus while the non-enriched 1% kappa carrageenan/chitosan/gelatin had comparable Young modulus to that of chitosan/gelatin (control). Kappa carrageenan/chitosan combinations presented the lowest values. All materials had high swelling ratios above 2500% and degradation times with a mass loss of 30% after 21 days. In addition, all kappa carrageenan-containing materials depict big pores above 120 μm, while chitosan/gelatin scaffolds presented lower values. FTIR analysis indicated that the polyelectrolyte formation has occurred and crosslinking with glutaraldehyde occurred for covalent binding. Cell viability and proliferation increased up to 14 days in culture, validating the excellent biocompatibility of all the scaffold compositions. Ongoing osteogenic differentiation assays including the ALP activity, calcium mineralization and collagen secretion are in progress.

Conclusion
The kappa carrageenan/chitosan/gelatin scaffolds demonstrated high mechanical properties, high swelling ratio, 30% mass loss after 3 weeks, and an excellent biocompatibility, rendering them promising candidates for bone tissue engineering.

Introduction
In the last decades, bone tissue engineering aimed at developing smart bioactive biomaterials and constructs able to direct cell activity and to provide alternative strategies to the standard pharmacological and surgical approaches \([1]\). Especially in the case of diseases such as osteoporosis, biomimetic three-dimensional (3D) scaffolds, reproducing the chemical composition and morphological features of native bone tissue, can provide key stimuli to support a suitable balance between osteoblast (OB) and osteoclast (OC) activities. More recently, cell co-culture systems have been demonstrated to be a useful tool for the pre-screening of innovative biomaterials and scaffolds for bone regeneration, enabling the simulation of the natural cell crosstalk mechanisms, and reproducing a more effective in vitro bone model \([2]\).

In this study, 3D scaffolds were produced by extrusion printing of a bioactive hybrid formulation combining type I collagen, strontium containing mesoporous bioactive glasses (Sr-MBG) and rod-like hydroxyapatite (HA) nanoparticles. Subsequently, the ability of the resulting constructs to promote cell adhesion, proliferation and differentiation was assessed by means of human co-culture of OBs and OCs.

Experimental Methods
A hybrid bioactive biomaterial ink was obtained by combining Sr-MBGs and rod-like HA nanoparticles with a 1.5 wt% collagen solution. 3D printed scaffolds were fabricated by using a commercial 3D Bioprinter (BIOX, Cellink) equipped with a temperature controlled pneumatic extrusion printhead and exploiting the freeform reversible embedding of suspended hydrogels (FRESH) method \([3]\). After incubation at 37 °C, the resulting scaffolds were chemically crosslinked with 0.5 wt% genipin solution in 70% ethanol (GEN/EtOH). After the physico-chemical and morphological assessment, the scaffolds were cultured in presence of human OBs derived from trabecular bone samples and human peripheral blood mononuclear cells (PBMCs) isolated from fresh buffy coat as OC precursors. The indirect co-culture was set seeding OBs onto the scaffold surface, while PBMCs were placed onto the transwell device, to be cultured in a medium free of osteogenic inducers, up to 21 days. Cell viability was detected by means of Alamar Blue and Live/Dead assays, while cell adhesion and morphology were investigated by Scanning Electron Microscopy (SEM). Alkaline Phosphatase, Alizarin Red S and von Kossa stain were used to investigate OB maturation, while Tartrate-resistant acid phosphatase, Phalloidin-FITC and Hoechst 33258 staining enabled the detection of PBMC differentiation towards pre-OCs.

Results and Discussion
3D printed bioactive composite scaffolds were successfully obtained by processing a hybrid formulation combining type I collagen, Sr-MBGs and HA nanoparticles. The resulting constructs (10x10x1 mm\(^3\)) were characterized by a mesh-like pattern and 1 mm pores. The subsequent chemical crosslinking with GEN/EtOH led to the increase of the overall material stiffness and stability. The indirect co-culture system using human OBs and PBMCs demonstrated the ability of the designed scaffolds to promote cell adhesion and high proliferation rates up to 21 days, while by colorimetric and fluorescent assays the differentiation of cells between 7 and 14 days after seeding, without the addition of osteogenic inducers in the culture medium, was highlighted.
Conclusion
Bioactive 3D printed scaffolds were successfully designed by processing a novel biomaterial ink combining type I collagen, Sr-MBGs and HA nanoparticles with the aim to mimic the native features of human bone tissue. Human OB/OC co-culture system proved the ability of the designed scaffolds to support cell adhesion, proliferation, and differentiation by paracrine activity in complete medium free of osteogenic inducers, up to 21 days.

Making it stick: A novel approach to bind and present physiological amounts of BMP-2 via collagen-based substrates

Stylianos O. Sarrigiannidis, Oana Dobre, Aleixandre Rodrigo-Navarro, Matthew Dalby, Manuel Salmeron-Sanchez

University of Glasgow, GLASGOW, GB

Introduction
The challenge in utilizing growth factors in tissue engineering is to keep them active and stable within the material for a prolonged period [1]. Collagen type I, a material often used in tissue engineering, does not have a high affinity and binding capacity to growth factors. Researchers have been incorporating growth factors such as Bone Morphogenic Protein 2 (BMP2) into collagen sponges for bone regeneration for several years [2], a system that is FDA approved (INFUSE®). However, very high, carcinogenic concentrations of BMP2 are required for this procedure and BMP2 swiftly leaks out of material [3]. The aim of this study is to incorporate BMP-2 into collagen substrates that can be presented locally to the biological environment. We have genetically engineered bacteria which express new recombinant peptide fragments that combine collagen binding domains (CBD) of fibronectin (FN) or bacterial collagenases (COLG, COLH) and the growth factor binding domains (GFBD) of fibronectin [4]. The fragments can be isolated and incorporated stably into a collagen substrate allowing it to sequester growth factors (e.g. BMP2) and promote osteogenesis.

Experimental Methods
The custom fragments (FN-CBD + GFBD, COLG-CBD + GFBD and COLH-CBD + GFBD) were expressed in BL21Star E. Coli bacteria utilizing a pet100 vector. Bacteria growth conditions were optimized, and the expressed protein was purified using a nickel column. Fragment attachment to collagen was verified by immunostaining and HisTag ELISA in multiple collagen hydrogel/scaffold systems (2D – on top of collagen-PEG gels, 2.5D – within collagen sponge and 3D – incorporated into collagen-PEG gel). Growth factor absorption - release experiments were conducted by incorporating Alexaflor488 labelled BMP-2 into each hydrogel/scaffold system at different concentrations and then placing it in PBS for up to 7 days. Aliquots of the supernatant were removed and analyzed at different time points. Human Mesenchymal Stem Cells (hMSCs) were cultured and seeded on the collagen hydrogel systems to conduct cell viability, morphology and differentiation experiments.

Results and Discussion
The fragments successfully bind to collagen substrates and allow for the sustained release of BMP-2 from 2D, 2.5D (fig 1) and 3D collagen hydrogel systems. The COLG-CBD+ GFBD peptide showed the highest affinity for collagen and naturally retained more BMP2 compared to the other groups (figure 1). Osteogenic differentiation experiments showed that the collagen substrates (2D, 2.5D and 3D) treated with the peptide and BMP-2 show upregulation of osteogenic markers. The translocation of Runx-2 to the nuclei of hMSC after 7 days cultured in a 2.5D collagen systems can be seen in fig. 2 (1μg/mL of BMP2 was used for the BMP2 conditions). When the nuclear intensity was quantified the COLG-CBD+GFBD+BMP2 showed the highest translocation of Runx-2 to the nucleus. This is consistent with other osteogenic differentiation experiments such as upregulation of osteopontin (OPN) in 2D after 21 days and von Kossa studies after 28 days.

Conclusion
This system is an innovative method of absorbing and retaining physiological amounts of BMP-2 to promote osteogenic differentiation of hMSCs, which can be expanded to other GFs in the future for other tissue regeneration.
An in vivo experiment (critical defect murine model) will be conducted this summer to further showcase the validity of this system.

Nucleic acid delivery systems for RNA therapy and genome editing

Daniel G. Anderson

Institute for Medical Engineering and Science, Cambridge, US

RNA nano formulations have received much attention for their role in bringing the covid pandemic under control. However, vaccines are only a small part of the broad potential use of RNA in human therapeutics. Here we describe our work developing nanoformulations for RNA therapy and genome editing. Libraries of degradable polymers and lipid-like materials have been synthesized, formulated and screened for their ability to delivery RNA payloads inside of cells. These nanoformulations facilitate in vivo delivery to a range of tissues, and can enable targeted gene suppression with siRNA, gene expression with mRNA, or even permanent genetic editing using the CRISPR/Cas9 system. We will describe the development and use of this technology, and describe their potential as therapies for a range of different diseases.
S11-KL02

Leveraging polymer biomaterials to improve the design of nanomedicines

Clara Mattu, Giulia Brachi, Gianluca Ciardelli

Politecnico di Torino, DIMEAS, Torino, IT

Nanomedicines, i.e., nano-encapsulated drugs, have demonstrated great potential in the treatment of several hard-to-tackle diseases, including cancer. When properly designed, nanomedicines are able to negotiate with several biological barriers, enhancing the delivery of the encapsulated drugs at the target location. [1]

Among the design parameters, the choice of the constituent material for nanomedicines plays a fundamental role, as it dictates the encapsulation efficiency, the release kinetics, and the interactions with the biological milieu. [2,3]

This presentation will discuss the role of the materials in the design of drug delivery systems, including nanomedicines for combinatorial drug delivery and for the localized treatment of site-specific pathologies. [3-5]

Introduction

The impact of neurological disorders and the lack of efficient therapies drive an urgent need for development of new treatments. Nucleic acid (NA)-based drugs (siRNA, miRNA, aptamers, antisense-oligonucleotides) can be seen with immense therapeutic potential, however, there is still a need for an effective brain delivery and a specific neuronal targeting [1], [2]. DNA-based nanostructures (DNA-NS) can be promising NA drugs carriers for brain and neuronal delivery, application for which DNA-NS potential is still largely unexplored.

Using principles of DNA nanotechnology for seamless bottom-up self-assembly, we are engineering a novel multifunctional DNA-NS integrating different NA drugs and functionalized with multiple ligands, aiming at three outcomes: an effective brain delivery, a specific neuronal targeting and a neuroprotective therapeutic effect.

In the present work, we have functionalized the DNA-NS with a neurotrophin-mimetic aptamer conferring neuronal cell targeting. Additionally, we are exploring if the aptamer-functionalized DNA-NS (DNA-NS-Apt) is activating the cognate neurotrophin receptor.

Experimental Methods

DNA-NS are produced by bottom-up self-assembly of four single-strand oligonucleotides and characterized by gel electrophoresis, dynamic light scattering (DLS) and atomic force microscopy (AFM). The functionalization with aptamers is done through direct hybridization of DNA-NS anchors with a reverse complementary DNA sequence included in the aptamer (Fig. 1). The DNA-NS-Apt was characterized by gel electrophoresis and DLS.

DNA-NS-Apt biological functionality was evaluated in terms of neuronal targeting capability and specific neurotrophin receptor activation in neuronal and non-neuronal cell lines (Fig. 2), as well as in primary cortical neuronal cells. Neuronal targeting has been assessed by confocal microscopy and flow cytometry, whereas receptor activation has been evaluated by Western blotting (WB).

Results and Discussion

DNA-NS can be produced with high uniformity, with an assembly yield of 88.3 % ± 2.1 %, according to gel quantifications. A mean hydrodynamic diameter of 19.37 nm ± 0.32 nm was measured by DLS (z-average, ± SD) and height of approximately 5 nm was detected by AFM. Being intrinsically modular, DNA-NS allow spatially and stoichiometrically precise functionalization with ligands, as verified with DNA-NS-Apt, by PAGE and DLS. A mean hydrodynamic diameter of 43.33 nm ± 0.35 nm was measured by DLS.

DNA-NS-Apt showed an enhanced cell binding in neuronal cell lines expressing the specific neurotrophin receptor, in comparison with the DNA-NS and the DNA-NS functionalized with a scrambled aptamer (DNA-NS-scrApt). Accordingly, low cell binding was observed when using non-neuronal cells (not expressing the neurotrophin receptor) (Fig. 2). These results reveal the neuronal targeting potential of DNA-NS-Apt. Internalization routes will be investigated to analyse the DNA-NS-Apt intracellular fate.
Preliminary evaluations of neurotrophin receptor phosphorylation (receptor activation) show a tendency for a low level of activation (partial activation) by DNA-NS-Apt, in comparison with the control DNA-NS-scrApt.

**Conclusion**

In summary, these are the first demonstrations of DNA-based nanostructures capable of neuronal cell targeting, through aptamer functionalization. Work is on-going regarding further multi-functionalization with other NA drugs and ligands. The proposed system will be further characterized both structurally and biologically, aiming to translate it into a unique and efficient nanotechnology to promote brain delivery, neuronal targeting and, ultimately, neuroprotection.

Engineering nanoparticles for targeted delivery of RNA-based therapies

Vitor Francisco¹, Josephine Blersch¹, Catarina Rebelo¹, Artur F. Rodrigues¹, Hugo Fernandes¹,², Lino Ferreira¹,²

¹ Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, PT; ² Faculty of Medicine, University of Coimbra, Coimbra, PT

Introduction
RNA-based therapies are highly selective and affect in many ways the biology that cannot be achieved by small molecules. Non-viral vectors such as nanoparticles are very promising formulations for the delivery of RNA-based therapies but they suffer from limited success in cell targeting, cell internalization and endolysosomal escape. To this end, it is crucial to develop formulations that enable their delivery to a target cell, with potential off-target effects and simultaneously increase their efficacy in the intracellular delivery. The goal of the current work is to obtain biocompatible light-activatable nanoparticles (NPs), allowing precise control of the timing and spatial release of the RNA molecules, in order to accelerate the translation of these therapies.

Experimental Methods
By Michael-type addition chemistry we produce polymers with chemical diversity. Then, the polymers were conjugated with light sensitive molecules to increase their hydrophobicity as well as confer light responsiveness properties. The polymers obtained were precipitated in water to form NPs and then complexed with siRNA and miRNA or directly added to mRNA to form polyplexes. The NP library was characterized for size, zeta potential, light disassembly, siRNA complexation, cellular internalization and gene knockdown activity.

Results and Discussion
Herein, we synthesized a nanoparticle library with more than 250 formulations, based in two different principles with a variety of physico-chemical properties and responsiveness to UV light. We evaluated (i) formulations synthesized with light responsive group in different positions of the polymers structure and (ii) complexation of different RNA molecules, siRNA, miRNA and mRNA (Figure 1). Next, we have performed high-throughput screenings in reporter cells to identify formulations that were rapidly taken up by cells and deliver efficiently RNA molecules (more effectively than the commercial transfection agent lipofectamine RNAiMAX). We have selected candidates for subsequent studies regarding their specificity to skin cells (some NPs were more internalized by a specific type of cell than other), endolysosomal escape and functional studies before and after light activation. This study indicates that the compositional elements of the formulations, other than zeta potential of the NPs, RNA complexation ability, trigger responsiveness, cellular uptake, play a key role in determining an efficient RNA transfection vector. Next, we have confirmed the advantages of one of the candidate formulations in a wound healing animal model, for the delivery of a skin regenerative miRNA identified recently by us.

Conclusion
Using the appropriate cell model allied with high content analysis we can rapidly monitor several parameters, such as cellular uptake, cytotoxicity, intracellular trafficking and RNA delivery efficacy. This strategy allows precise delivery of RNA-based therapies and thus provides an effective design approach to address critical issues in non-viral gene delivery.

High-throughput production of polyethylene glycol-tyramine microcapsules for non-invasive delivery of immunoprotected beta cells

Nuno Araújo-Gomes¹, Barbara Zoetebier Liszka¹, Bas van Loo¹, Suzanne Nijhuis¹, Alexandra M. Smink², Bart de Haan², Paul de Vos², Marcel Karperien¹, Jeroen Leijten¹

Introduction
Type 1 diabetes is an auto-immune disease that results in the destruction of destroys the insulin-producing beta cells of the pancreas. Transplantation of pancreatic islets or beta cells is anticipated as a high potential curative solution for patients suffering from Type 1 diabetes. However, to implanted cells currently require immunosuppressants to evade the host's immune response to the implant, which causes adverse effect such as an increase to susceptibility of collateral and opportunistic infections [1]. To this end, several immunoprotective biomaterial strategies have been developed to protect engrafted beta cells by acting as e.g. semi-permeable microcapsules [2], which prevent the diffusion of molecules larger than 150 kDa (i.e. antibodies) while allowing for diffusion of small sized molecules, such as insulin and glucose. However, clinical translation of these immunoprotective microcapsules is currently challenged by the low-throughput production rate of the currently explored platforms. Here, we describe the development of a novel non-degradable immunoprotective material that allows for continuous high-throughput microfluidic production of beta cell containing microgels.

Experimental Methods
8-arm enzymatically crosslinkable 20 kDa polyethylene glycol–tyramine (PEG-TA) conjugates were synthesized in a two-step reaction: 1) ester activation and 2) amidation. PEG-TA conjugates (2.5%, 5%, and 10% w/v) were used to fabricate microcapsules up to a diameter of 200 µm with a shell thickness of 20 µm. Microfluidic droplet generation was optimized for production of hollow PEG-TA microgels using a delayed outside-in crosslinking strategy based on horseradish peroxidase and hydrogen peroxide diffusion [3]. Microcapsule permeability assessment was performed by incubation with fluorescently labeled immunoglobulin (IgG) and bovine serum albumin (BSA). Cytocompatibility, proliferation, cyto-immunity permselectivity and insulin release profiles were assessed in vitro using MIN6B1, a pancreatic beta cell model and THP1, a monocytic cell line. In vivo analysis was carried out using a C57BL/6 mouse model by: 1) implanting hollow microgels in to confirm the low immunogenicity of the microgels and 2) implanting MIN6B1 laden gels subcutaneously to determine the survival and function of the microencapsulated β-cells.

Results and Discussion
Monodisperse PEG-TA microgels of 150-200 µm diameter containing up were produced on the PMMA on-chip platform at a rate of ~45 Hz allowing for the continuous microencapsulation of ~50 beta cells/min. Microgel permselectivity assessment confirmed that in microgels composed of 10% PEG-TA, molecules of >150kDa could not diffuse into the microcapsules offering immunoprotectivity for at least 30 days (Fig.1a). Moreover, microgels still were permeable to smaller molecules like (BSA), guaranteeing nutrient, hormone, and growth factor diffusion. Immunological assessment revealed that microgel contact with undifferentiated THP1 cells elicited low-to-no immune cell activation and cell attachment to the microgels. Interestingly, multiplexed ELISA of whole blood exposed to microgels demonstrated an inverse dose-dependent response of several pro-inflammatory cytokines with the immunoprotective formulation of 10% PEG-TA thus inducing the lowest inflammatory reaction. Post-encapsulation, beta cells remained viable and glucose responsive, with no loss-of-function. Upon reaching confluency, microgel withstood the growing internal mechanical pressures and remained intact, which allowed the microgels to act as a
proliferation-restrictive barrier yielding non-proliferating monodisperse microencapsulated β-cell spheroids (Fig.1c). In vivo analysis showed that the implantation of hollow microgels on mice elicited the formation of minor fibrotic structures surrounding the material, most likely due to the geometric profile of the microparticles. The implantation of cell-laden gels revealed that the encapsulated cells formed microaggregates that remained viable and glucose responsive after 7 days (explantation day), confirming the immunoprotectivity and semi-permeable character conferred by the PEG-TA microgel (Fig.2).

Conclusion
High-throughput production of beta cell containing PEG-TA hollow microgels represents a promising and innovative approach for the production and delivery of immunoprotected glucose responsive non-autologous beta cells for the treatment of type 1 diabetes.

Biomaterials for cancer models and treatment Cancer is the leading cause of death worldwide, and the Portuguese and Spanish biomaterials scientific community is clearly trying to fight it. This symposium highlights the role of biomaterials for use as cancer models and for use as nanoparticles for targeted therapies, exploring a wide range of applications, including brain, gastric, lung, bone, pancreatic and breast cancers.
Selective targeting of cancer stem cells by hyaluronic acid-coated nanoparticles based on naproxen

Introduction

Cancer Stem Cells (CSC) are a small cell subpopulation within the tumour, with high tumorigenic potential and the ability to self-renew. They are associated with the acquisition of drug resistance and the development of early, aggressive metastatic relapses. In breast cancer, major CSC markers are CD44+/CD24- phenotype and high aldehyde dehydrogenase 1 (ALDH1).

Chronic inflammation has long been linked to carcinogenesis and play a key role in the different stages of tumour development. Non-steroidal anti-inflammatory drugs (NSAIDs), and in particular naproxen (NAP), have shown to be effective in the treatment of breast cancer [1]. NAP anti-cancer properties have been attributed to the reduction of prostaglandin E2 levels (the major product of the activation cascade of both cyclooxygenase isoforms (COX1/COX2)) and COX-independent pathways, being both mechanisms associated to CSC maintenance. However, repeated-administration and efficacy of free forms of NAP are hampered by the drug's high hydrophobicity and dose and time-dependent gastrointestinal side effects.

The aim of this work is the development of NAP-based polymeric nanoparticles (NP) with higher activity and lower side effects than the free NAP. NP were coated with hyaluronic acid (HA) in order to actively target CD44 receptors, overexpressed in breast CSC.

Experimental Methods

NAP-based cationic NP were prepared by nanoprecipitation of poly(HNAP-co-VI)(71:29), as recently described [2]. HA-coating was performed by electrostatic interaction of NAP-based NPs and HA at pH 4.0. Synthesis conditions were optimized and the influence of pH and ionic strength on hydrodynamic properties as well as stability were assessed.

Particle size distribution and zeta potential were determined by DLS and LDE, respectively; Morphology was assessed by cryo-TEM. Esterase-mediated NAP release kinetics was determined by UV spectrophotometry during 14 days.

Haemocompatibility parameters (aPTT, PT and TT) were determined. NP uptake was studied to evaluate CD44-mediated active targeting of CSC and non-CSC populations. For this assay, an in vitro CSC fluorescent model of MCF-7 cell line was used [3]. Cell viability and IC50 of MCF-7 (CD44+) and HepG2 (CD44-) cancer cells in the presence of the NP were evaluated by MTT assay. NP cytotoxicity was also evaluated in cells from the mammary tumor microenvironment (RAW264.7, HUVEC and MCF-7) using AlamarBlue assay. ELISA kits were used to study COX-dependent markers (PGE2 and VEGF) and apoptosis markers (p53 levels) in NP-treated MCF-7. Wound healing assay was performed to evaluate NP capacity to inhibit MCF-7 migration.

Results and Discussion

Page 705 of 2028
HA was physically adsorbed on the surface of NAP-based NPs by electrostatic interaction as confirmed by an inversion in the sign of surface charge and a significant increase in NPs diameter. HA-coated NPs were spherical as observed by cryo-TEM.

HA-coated NP were stable at physiological pH as HA-coating kept the surface charge constant. However, a significant increase in mean size was observed as the pH increased. HA-coating acted as a barrier layer providing a better control in NAP-release. HA-coated NPs caused a lower haemolysis of red blood cells if compared with uncoated NAP-based NPs.

CD44-HA interaction plays a key role in the internalization of the NP, as CSC presented a significantly higher endocytosis rate of coated-NPs than the differentiated breast cancer cells. Uncoated-NAP NPs did not reduce MCF-7 or HepG2 cells viability below 90% at any of the tested concentrations, while HA-coated NPs were cytotoxic at concentrations of polymer above 0.1 µg/mL for MCF-7 or above 1 µg/mL for HepG2. HA-coated NPs are 10 times less effective in cells with low CD44 expression (HepG2) when compared to CD44-overexpressing cells (MCF-7).

HA-coated NPs did not reduce cell viability of macrophages RAW264.7 at doses below 50 µg/mL, however, these NPs affected HUVEC cell viability (66 ± 6% for 50 µg/mL) which is highly desirable in an anti-tumour treatment.

Non or little effect was observed on PGE2 or VEGF, respectively. A significant dose-dependent accumulation of p53 was observed for HA-coated NPs at 12.5 and 25 µg/mL. Cell migration was also inhibited by HA-coated NPs at 12.5 and 25 µg/mL.

**Conclusion**

NAP-based cationic NP were successfully coated by HA that provided superior pH stability, a better control on esterase-mediated NAP release and a better haemocompatibility, than uncoated-NAP NPs. HA-coated NPs are better and faster internalised in CSC than in non-CSC as a direct consequence of the CD44 targeting. This feature coupled to the anti-inflammatory activity from NAP makes HA-coating of poly(HNAP-co-VI)(79:21)-based NPs a potent strategy for targeting CSC subpopulation within breast tumors by either directly attacking CSC or preventing their occurrence derived in response to a pro-inflammatory state. The system also allowed to reduce the dose of NAP needed to achieve pro-apoptotic and anti-migratory activity against luminal breast cancer cells.

Zwitterionic polyphosphazene nanoparticles for the genetic modulation of the glioblastoma niche

Carla Garcia-Mázás1, Elia Bozzato2, Veronique Preat2, Noemi Csaba1, Marcos Garcia-Fuentes1

1 Universidad de Santiago de Compostela, CiMUS Research Center, Santiago de Compostela, ES; 2 Université Catholique de Louvain, Louvain Drug Research Institute, Brussels, BE

Introduction
Glioblastoma cells of high malignancy are protected and supported by their tumoral niche. It is now understood that disruption of this tumoral niche is critical to generate long-lasting and effective antitumoral responses in combinations with standard chemotherapy [1]. Some Bone Morphogenetic Proteins (BMPs) are known to disrupt glioblastoma malignant cells in clinically relevant models [2-4]. In this work we show that BMPs can be delivered in genetic form, as plasmid DNA (pDNA), when associated to suitable nanocarriers. Nanocarriers for pDNA delivery based on polyphosphazene combinations have shown high transfection/toxicity ratio and the capacity to deliver gene therapies in vivo [5]. In this work, we designed new nanocarriers with further transfection capacity based on this technology and tested them in advanced glioblastoma treatments.

Experimental Methods
Polyphosphazenes were synthesized based on a thiol-ene reaction previously reported by us [5]. Four cationic and one anionic polyphosphazene were synthesized. The polymers were characterized by 31P and 1H NMR. Polymeric nanoparticles (NPs) were prepared by ionic complexation of cationic polyphosphazenes with plasmid DNA, with or without the anionic polyphosphazene. The NPs were characterized for particle size, zeta potential, morphology and plasmid association. Their toxicity and transfection efficiency were evaluated in vitro in 2D and 3D U87MG cultures. Therapeutic activity was evaluated in vitro in U87MG neurosphere models. In vivo efficacy was tested in U87MG ectopic models using NMRI nude mice. The animals were treated with the nanoparticles loaded with U87MG either alone, combined with temozolamide, or with a battery of controls. Antitumoral activity was analyzed by measuring tumor size, survival and the expression of malignancy markers in the tumor by qRT-PCR.

Results and Discussion
We obtained several NP prototypes based on the use of cationic polymers alone or associated with the anionic polymer, with a size around 100 nm and positive charge. Nanocomplexes were able to associate effectively the polynucleotides. The in vitro and in vivo toxicity assays showed that the anionic polymer reduces the toxicity of all cationic nanoparticles. Studies performed in vitro showed that an aliphatic cationic polyphosphazene derivative had the best transfection/toxicity ratio, particularly when combined with the anionic polymer. Indeed, this optimized NPs prototype showed 3-fold higher transfection than the experiment benchmark (Lipofectamine 2000). The optimized NPs formulation was used to deliver a BMP encoding plasmid, and this gene therapy was capable of suppressing tumor formation in a neurosphere assay. The NPs combined with temozolamide were capable of inhibiting tumor growth in an in vivo study (Figure), resulting on statistically significant effect as compared with any other groups. Indeed, this antitumoral activity resulted in >50% survival by the end of the study, whereas all other groups had minimal or no animal survival. The study indicated that the presence of BMP in the tumor normalizes the expression of efflux pump MRD, which can be induced by the presence of temozolamide. This normalization of MRD expression results in more effective antitumoral effects for this therapeutic combination.

Conclusion
Optimized nanoparticles based on polyphosphazenes for their use as gene delivery carriers have been synthesized and characterized. These nanoparticles have an excellent delivery/toxicity profile. When loaded with a BMP-encoding
plasmid, these nanoparticles result in synergistic and highly efficient glioblastoma treatments in combination with temozolamide.

Introduction

Gastric cancer (GC) remains a major cause of death worldwide mainly due to late detection in advanced stage. Hence, there is an unmet clinical need for the development of reliable, non-invasive screening methods for early detection and treatment of GC. Cancer-targeting nanoparticles have attracted considerable attention as theranostic tools. Nevertheless, very few de novo expressed molecules specific of GC cells have been identified and, therefore, the development of GC-targeted strategies is only in the beginning. Recently, we demonstrated that CD44v6 is not only de novo expressed in GC¹, but also promotes GC malignancy², suggesting that it may enclose a key marker for the early diagnosis and treatment of GC. Although antibody-targeted NPs have been commonly explored given the innate high-binding affinity and specificity of antibodies, their clinical translation has been hampered by the uncontrolled and random conjugation of antibodies to nanoparticles, resulting in loss of binding specificity³. Here, we designed a modular nanoscale system that specifically targets CD44v6-expressing GC cells by conjugating in a site-specific manner a novel engineered CD44v6 half-antibody fragment to model polystyrene nanoparticles (PNPs) via an efficient bioorthogonal thiol-Michael addition click chemistry⁴.

Experimental Methods

Anti-human CD44v6 antibody was incubated with different concentrations of tris(2-carboxyethyl)phosphine (TCEP) for 3 h and then separated by SDS-PAGE. Binding affinity of generated CD44v6 half-antibody fragments to GC cells was analyzed by flow cytometry using an isogenic human CD44v6-expressing GC cell line, established and reported by our group², ⁵, and its parental cells, lacking CD44 expression, as control. After antibody reduction, 200 nm carboxylated Texas Red-labeled PNPs were functionalized with a heterobifunctional maleimide crosslinker that allowed their ‘click’ conjugation to the native reactive thiol groups of the novel chemically reduced CD44v6 half-antibody fragment by bioorthogonal thiol-Michael addition click reaction. CD44v6 half-antibody conjugated PNPs were characterized by dynamic light scattering and zeta-potential measurements, and their targeting ability to CD44v6-expressing GC cells was evaluated by flow cytometry and further confirmed by immunofluorescence.

Results and Discussion

CD44v6 half-antibody fragments with intact antigen-binding sites to CD44v6-expressing cells and reactive thiol groups were obtained by preferential reduction of disulfide bonds bridging the two half chains of the anti-human CD44v6 antibody in 1 mM of TCEP. Using this optimized antibody reduction condition, our results showed the successful site-specific conjugation of modified-PNPs maleimide groups to half-antibody thiol groups as shown by the increase of particle size and surface charge compared to control conditions. This bioorthogonal click strategy overcomes major pitfalls of current approaches exclusively based on carboxyl-amine coupling of full antibodies, providing superior control over site-oriented ligand conjugation, essential to obtain cell-specific targeting. Notably, our results confirmed the specific targeting ability of the newly engineered CD44v6 half-antibody conjugated PNPs.
that exhibited a significant increased binding to CD44v6-expressing GC cells (1.65-fold) compared with their counterparts, highlighting the receptor-mediated targeting potential of these nanoparticles.

Conclusion
Collectively, by exploring the native reactivity of half-antibody fragments and the bioorthogonal nature of click reactions, our findings not only open new avenues on the use of CD44v6 half-antibody fragments as new targeting ligands, but also highlight the broad significance of our nanoscale system that stands as a promising and clinically relevant tool for the early diagnosis and therapy of GC. Additionally, the rational design of this modular nanoscale system may be explored for the development of several other nanotechnology-based disease-targeted approaches.

Targeting Fatty Acid Synthase in Sensitive and Resistant Lung Adenocarcinoma Models Cultured on Polycaprolactone Electrospun Scaffolds

Emma Polonio-Alcalá¹², Santiago Ruiz-Martínez², Marta Planas³, Lidia Feliu³, Teresa Puig², Joaquim Ciurana¹

¹ Product, Process and Production Engineering Research Group (GREP), Department of Mechanical Engineering and Industrial Construction, University of Girona, Girona, ES; ² New Therapeutic Targets Laboratory (TargetsLab) - Oncology Unit, Department of Medical Sciences, University of Girona, Girona, ES; ³ Laboratori d’Innovació en Processos i Productes de Síntesi Orgànica (LIPPSO), Department of Chemistry, University of Girona, Girona, ES

Introduction

Lung cancer is the first leading cause of cancer-related mortality in men and women. More than 85% of lung cancer patients correspond to non-small cell lung cancer (NSCLC) subtype, of which around 40% are adenocarcinomas. Epidermal growth factor receptor (EGFR) activating mutations are the most common genetic alterations in lung adenocarcinoma. Different EGFR tyrosine kinase inhibitors (EGFR-TKI) have been developed during the past few years, such as gefitinib or osimertinib. Nevertheless, approximately 70% of patients are diagnosed with locally advanced or metastatic disease when the treatment is not curative.

In physiological conditions, cells are enfolded by the extracellular matrix (ECM), a fibrous network that plays a key role in some cellular processes, for instance morphogenesis, differentiation and homeostasis. Three-dimensional (3D) cell culture has burst into oncology field providing structures that serve as a physical support for cancer cells, allowing interactions between cell-cell and cell-matrix. Electrospinning is a technique used to manufacture nanofiber scaffolds with a diameter fiber size close to ECM. Polycaprolactone (PCL) is a suitable synthetic polymer for cell culture purposes due to its biocompatibility, biodegradable, viscoelastic properties and its low cost. Interestingly, using PCL electrospun scaffolds to culture EGFRm lung adenocarcinoma sensitive and resistant to EGFR-TKIs models, we have demonstrated an enrichment of cancer stem-like cells, a tumor subpopulation related to drug resistance, relapse and metastasis.

Fatty acid synthase (FASN) is an enzyme responsible for the synthesis de novo of long-chain fatty acids. The overexpression and hyperactivation of this enzyme have been related to aggressiveness and poor prognosis. We have previously shown that FASN inhibition had cytotoxic effects in sensitive and EGFR-TKIs resistant cell models. Additionally, the FASN inhibitors (-)-epigallocatechin-3-gallate (EGCG) and its derivative G28 synergistically interact with gefitinib or osimertinib in EGFR-TKI resistant EGFRm lung adenocarcinoma models.

The purpose of this study is to determine the role of FASN and its related signaling pathways and compare the effect of FASN inhibitors on cell proliferation of sensitive and EGFR-TKI resistant lung adenocarcinoma models cultured in monolayer and on 15% PCL electrospun scaffolds.

Experimental Methods

PCL was dissolved in acetone at 15% (weight/volume) concentration at 60°C under agitation. Scaffolds were manufactured through the Spraybase® electrosprinning machine using a stainless steel 18G needle. Through the Syringe Pump Pro software, 5 mL of solution were ejected at a flow 6 mL/h and voltage 7kV. mRNA and protein expression of FASN and its related signaling pathways were analyzed through RT-qPCR and Western blot. The cytotoxic effect of EGCG and G28 on EGFRm lung adenocarcinoma cells cultured on electrospun scaffolds were tested by MTT assay.

Results and Discussion

Page 711 of 2028
Sensitive and resistant to EGFR-TKIs lung adenocarcinoma cells cultured in 3D showed an overexpression of FASN mRNA and protein levels compared to monolayer culture. An activation of the related signaling pathways EGFR/STAT3, PI3K/AKT, and MAPK was also observed in 3D cultured cells. Additionally, EGCG and G28 treatments had a similar cytotoxic effect in cells cultured in monolayer and in 15% PCL electrospun scaffolds.

**Conclusion**
The results exhibited in this study using 15% PCL electrospun scaffolds support FASN inhibition as an alternative therapy for sensitive and resistant EGFRm lung adenocarcinoma.

**Stratified 3D Microtumors as Organotypic Testing Platforms for Screening Pancreatic Cancer Therapies**

*Maria V. Monteiro, Vítor M. Gaspar, Luís F. Mendes, Iola F. Duarte, João F. Mano*

*Aveiro University, CICECO-Aveiro Institute of Materials, Aveiro, PT*

**Introduction**

Pancreatic ductal adenocarcinoma (PDAC) is a highly deadly and complex neoplasia with a very low 5-year patient survival. The poor prognosis of this malignancy is related with its unique bioarchitecture in which an abundant juxtatumoral fibrotic stroma shields cancer cells mass hampering anti-cancer therapeutics delivery.\(^1\) A growing evidence has suggested that cancer associated fibroblasts (CAFs), generally localized in periductal/periacinar regions close to the tumor mass, are master players in orchestrating such active desmoplastic tumor microenvironment.\(^2\) To date, few 3D in vitro tumor models have been able to fully recapitulate such PDAC tumor features, resulting in poorly predictive preclinical drug screening data of PDAC candidate therapies. Aiming to recapitulate key disease hallmarks, in this work we bioengineered truly organotypic and physiomimetic 3D microtumor models that recapitulate PDAC unique cytoarchitecture, as well as biomolecular and desmoplastic characteristics. The capacity of such 3D stratified microenvironment spheroid models (STAMS) to emulate various tumor hallmarks including the native spatial stratification of cancer-stromal cells, de novo ECM deposition and secretion of key molecular biomarkers and drug resistance were evaluated.

**Experimental Methods**

3D STAMS were established by using the Human Pancreatic cancer (PANC-1) cell line (ATCC® CRL-1469™) and Human Immortalized Pancreatic CAF-Stellate Cells. STAMS platforms are comprised by a cancer cell-rich core enveloped by stromal CAFs. This cytoarchitecture was established through a two-step strategy. In the first stage, a 3D spheroid core comprising PANC-1 cells was maturated for 6 days under low-adhesion conditions. Afterwards, human pancreatic stellate CAFs were and allowed to attach to 3D PDAC spheroids establishing the stratified model. The cell viability, necrotic regions formation and cellular tracking were all evaluated along time. Moreover, glycosaminoglycans (GAG) and total collagen levels were also analyzed to evaluate de novo ECM deposition. The quantification of soluble biomolecular markers secreted by 3D PDAC microtumor models was performed by ELISA. 3D PDAC models were then used as testing platforms to evaluate different anti-cancer therapeutics (Gemcitabine, Olaparib and Irinotecan). PANC-1 mono-culture 3D spheroids and Random spheroids in which cancer cells and CAFs were randomly distributed within the microtissue were used as controls.

**Results and Discussion**

The engineered 3D STAMS model showed to emulate PDAC key biomarkers and cytoarchitectural hallmarks, namely its cancer-stroma stratification and tumor microenvironment composition, as well as the activated fibrotic stroma that promoted an increased ECM deposition. Interestingly, STAMS reproduced gemcitabine resistance as generally observed in the clinical setting for this standard-of-care therapy, confirming the influence of TME composition and drug sensitivity, emphasizing the importance of mimicking the cytoarchitecture cellular organization of this malignancy in an *in vitro* setting.

**Conclusion**

Overall, 3D STAMS platforms represent a valuable testing tool for evaluating the complex interactions between stromal and pancreatic cancer cells, as well as to accurately perform preclinical drug discovery and screening. The ease of assembly, reproducibility and low-cost of these platforms also highlights their potential inclusion in high-content, high-throughput screening platforms.

Calcium-Deficient Hydroxyapatite Microspheres as Antitumoral Carriers for Bone Cancer

Cédric Labay\textsuperscript{1,2,3}, Linh Johansson\textsuperscript{1,2}, Maria P. Ginebra\textsuperscript{1,2,3}, Cristina Canal\textsuperscript{1,2,3}

\textsuperscript{1} Universitat Politècnica de Catalunya, Biomaterials, Biomechanics and Tissue Engineering Group (BBT), Dpt. of Materials Science and Engineering (CEM), Barcelona, ES; \textsuperscript{2} Barcelona Research Center in Multiscale Science and Engineering, Barcelona, ES; \textsuperscript{3} Research Centre for Biomedical Engineering (CREB), Barcelona, ES

Introduction

To tune the resorption rate of calcium phosphate bone grafts used for bone regeneration, research on calcium phosphate cements (CPC) evolved from the manufacturing of dense macroporous blocks to the synthesis of micro-sized particles [1] or thin filaments for 3D-printed scaffolds. The excellent biocompatibility of CPC-based biomaterials, together with their porosity has fostered interest on enhancing their functionality by including cargos such as stem cells, growth factors or active molecules [2,3]. The development of microporous CPC microspheres with controlled size, topography and porosity allowed important advances these last years, regarding the incorporation of biological moieties or drugs and their subsequent controlled release [4,5]. The novelty of this work is to investigate CPC microspheres as carriers for antitumoral drugs, by loading doxorubicin (DOX) into the microspheres and assessing the \textit{in vitro} biological effects on Sarcoma Osteogenic SaOs-2 cell line. By conferring such added therapeutic value to the proven bone regenerative properties of the CPC biomaterial, the designed DOX-loaded microspheres aim to the refill of a diseased site after a bone tumor removal surgery, in order to enhance bone regeneration while preventing the recurrence of cancer cells.

Experimental Methods

In this work, Calcium-Deficient HydroxyApatite (CDHA) microspheres were synthesized by emulsion from α-TCP coarse powder. Characterization of the CDHA microspheres was performed using: i. Scanning Electron Microscopy (SEM) to analyze the shape and the topography of the microspheres, ii. Dynamic Light Scattering (DLS) to evaluate the size distribution of the microspheres and iii. Mercury Intrusion Porosimetry (MIP) and N\textsubscript{2} Adsorption with BJH to determine the porosity and the specific surface area, respectively.

After selecting the microspheres with diameter size ranged from 100 µm to 150 µm by sieving, the microspheres were loaded with an auto-fluorescent antitumoral molecule by soaking them into a 0.4 M DOX aqueous solution for 4 h. Loading kinetics of DOX into the microspheres was plotted from the monitoring of the absorbance of the loading solution. Penetration of the DOX into the CDHA microspheres was assessed by confocal microscopy (CLSM). Subsequent release experiments from the DOX-loaded CDHA microspheres were performed to PBS release medium to evaluate the release kinetics and the final percentage of DOX released. \textit{In vitro} experiments of the DOX-loaded microspheres were performed with Sarcoma Osteogenic (SaOs-2) and human Mesenchymal Stem Cells (hMSC) to study the cell viability and the selectivity of the loaded microspheres at 24 and 72 h on a cancer and a healthy bone cell line.

Results and Discussion

CDHA microspheres with a size range 100 to 700 µm were synthesized, consisting of needle-like calcium-deficient hydroxyapatite crystals (Figure 1a). We observed that drug loading efficiency was microsphere size-dependent, with the highest efficiency being around 60% for CDHA microspheres with the smallest diameter size range (100 – 150 µm). This was associated with a higher specific surface area of the smaller carriers. Assessment with CLSM of the cross-section of a DOX-loaded microsphere revealed that DOX is adsorbed within the first 15-20 µm of the microspheres (Figure 1b). This was related to the release pattern from the DOX-loaded microspheres, showing a
burst release of the antitumoral with 90% of the final [DOX] released in 1 hour. In views of decreasing the release rate, plasma polymerization with polycaprolactone (PCL) was investigated on the surface of the DOX-loaded CDHA microspheres. In vitro experiments revealed cell viabilities down to 20% with SaOs-2 after 72 h in presence of DOX-loaded microspheres, either uncoated or PCL-coated, while hMSC presents a maintained cell viability around 80% in the same cell culture conditions.

**Conclusion**
The loading of doxorubicin into the CDHA microspheres from an aqueous solution is size dependent. The antitumoral agent mainly adsorbs onto the surface of the microspheres which promotes a fast subsequent release of doxorubicin. Evidence of selectivity of the DOX-loaded CDHA microspheres on osteosarcoma cells (SaOs-2) was revealed by in vitro cell cultures, when compared the cytotoxic effects with those observed on human mesenchymal stem cells (hMSC).

Theranostic hydroxyapatite nanoparticles with intrinsic anti-cancer activity against triple negative breast cancer

Tiago P. Ribeiro, Fernando J. Monteiro, Marta S. Laranjeira

1 University of Porto, INEB-Instituo Nacional de Engenharia Biomédica, Porto, PT; 2 University of Porto, Institute for Research and Innovation in Health (i3S), Porto, PT; 3 University of Porto, FEUP-Faculty of Engineering, Porto, PT

Introduction
Theranostic nanometric systems are compact devices with both therapeutic and diagnostic capabilities. Moreover, materials with intrinsic anti-cancer activity are revealing great promise as co-adjuvants of common cancer therapies such as chemotherapy and radiotherapy [1]. For instance, one material with an unexpected intrinsic anti-cancer activity is hydroxyapatite. This calcium phosphate is a highly biocompatible and biodegradable material, mainly used as a synthetic bone substitute due to its similarity with natural bone apatite [2]. Yet, several studies reported that hydroxyapatite nanoparticles are selectively toxic against certain types of cancer cells, meaning that healthy cells are not affected. Moreover, the unique crystal structure of hydroxyapatite enables it to be modified through ion doping, which creates additional features for biomedical applications, such as magnetism and antimicrobial activity [3-5].

Experimental Methods
In this study, hydroxyapatite and iron doped hydroxyapatite nanoparticles were synthetized, through a wet-chemical precipitation method, characterized and their influence on triple negative breast cancer cells was evaluated. Physicochemical characterization was done with TEM for size and morphology determination, XRD and FTIR for crystallinity, phase purity and chemical composition evaluation and SQUID for the study of the magnetic properties. In vitro toxicity towards MDA-MB-468 human breast cancer cells was determined through metabolic analysis, live-dead fluorescence assay and ultrastructure analysis. Contrast potential for bioimaging was determined in a clinical 3T MRI equipment.

Results and Discussion
The physicochemical characterization of the produced particles, through the wet chemical precipitation method, revealed that both where, in fact, hydroxyapatite with a hexagonal crystalline conformation. Iron incorporation, by calcium substitution, was confirmed through XRD, where a less crystalline structure with a smaller crystallite size was obtained. This occurs because iron ions introduce defects into the crystal structure and size decreases because iron has a smaller atomic radius than calcium. Quantitatively, the produced particles had about 10% iron ions, which provided the material with a saturation magnetization of 0.5 emu/g and a superparamagnetic behaviour. These magnetic properties were further explored, and when the nanoparticles were exposed to an MRI magnetic field, they were able to produce significant contrast, meaning that they could be used as contrast agents for cancer diagnosis. Finally, regarding the intrinsic anti-cancer activity, it was confirmed that both non-doped and iron doped hydroxyapatite nanoparticles were toxic towards triple negative breast cancer cells in a concentration dependent manner, with the iron doped ones being more effective. Through an ultrastructure analysis, the cells were mainly suffering from mitochondrial stress and cell membrane deregulation. These led to the conclusion that the calcium excess was working as a mitochondria disruptor, while iron ions were probably contributing to the formation of reactive oxygen species through the Fenton reaction. The latter being supported by some test conditions where the production of lipid droplets was detected, which are indicators of oxidative stress.

Conclusion
In conclusion, these findings regarding iron doped hydroxyapatite nanoparticles, serve as a foundation for future development of cancer theranostic devices.

Rapid Assembly of Fibrillar dECM-Hyaluronic Acid Hydrogels for 3D Breast Cancer In Vitro Modelling

Luís P. Ferreira, Carole Jorge, Vitor M. Gaspar, João F. Mano

University of Aveiro, CICECO - COMPASS, Aveiro, PT

Introduction
Currently available 3D in vitro breast cancer models focus mostly on the independent recapitulation of either cell population interactions or singular ECM-specific moieties. The influence of tumor microenvironment cellular and extracellular populations is critically inferred and yet mischaracterized in preclinical validation models resulting in a poor correlation between in vitro analysis and clinical trials data [1]. Alternatively, high-throughput compatible models seeking to provide a holistic representation of the tumor microenvironment interplay between cancer cells and their surrounding ECM are underdeveloped [2]. Within this context, decellularized scaffolds provide a new pathway to recapitulate major tumor hallmark characteristics in complex cell-representative coculture models capable of integrating ECM-specific stimuli and bioactive components [3]. Therefore, providing a more biomimetic window into the process of tumor modeling and cell-cell interaction analysis. Seeking to overcome these disadvantages, herein we developed fibrillar dECM/hyaluronic acid conjugate hydrogels for establishing organotypic 3D breast cancer-stromal models which recapitulate the cellular and matrix landscape of the human tumor. These surrogate biomimetic matrices were combined with cancer and stromal cells and rapidly processed into spherically structured 3D tumor models using superhydrophobic surfaces.

Experimental Methods
To this end, ECM derived from porcine adipose mammary tissues was decellularized [2], characterized and homogenized into fibrillar micro-fragments suitable for inclusion in the process of microtumor assembly. High molecular weight hyaluronic acid was modified with methacrylic moieties in accordance with previously established methods [4]. Breast cancer cells (MDA-MB-231) and Breast Cancer Associated Fibroblasts (BCAFs) were directly cultured with conjugated dECM microfibrillar fragments within photocrosslinked hyaluronic acid hydrogels (dECM/HA-MA) assembled in super-hydrophobic surfaces [5]. Obtained microgels ability to recapitulate key solid tumor hallmarks was evaluated through characterization of morphology, viability, and necrotic core formation analysis.

Results and Discussion
The optimized dECM/HA-MA spherically structured 3D microgels supported cancer-stromal cells and 3D spheroids viability, as well as served as unique platforms for evaluating such co-cultures interactions and in vitro maturation along time. The conjugation of HA hydrogels with dECM microfragments better recapitulated the diverse landscape of mammary ECM. Serving as a platform in which tumor-targeting combinatorial therapeutical compounds can be tested.

Conclusion
Overall, the addition of dECM fragments, preserving ECM fibrillar architecture and mammary specific components, within a secondary matrix of HA-MA enabled the development of dECM-enriched scaffolds in which co-culture interactions could be evaluated in a Tumor-ECMs mimetic context capable of partially portraying the ECMs influence in cancer cell behavior.

Univ. Maastricht, NL
Maria Southall
Royal Society of Chemistry, Publishing, Cambridge, GB
May A. Tayyem (YSF)
Queen's University Belfast, School of Pharmacy, Belfast, GB

Biomaterials Science is very happy to be the official journal of the European Society of Biomaterials and sponsor a session at ESB 2021.

Bimaterials Science is published on a not-for-profit basis by the Royal Society of Chemistry and publishes high impact work focused on exploring the design, function, and interactions of biomaterials. Its scope encompasses new concepts in biomaterials design, studies into the interaction of biomaterials with the body, and the use of materials to answer fundamental biological questions. The journal is led by Editor-in-Chief Jianjun Cheng, alongside an international Editorial Board including expert Associate Editors.

This session features presentation of the 2021 Biomaterials Science lectureship to Nasim Annabi (UCLA). We are happy to have Khuloud Al-Jamal as second keynote speaker in the session.
ESB-Biomaterials Science-KL01

Multifunctional adhesive biomaterials for medical applications

Nasim Annabi

University of California, Department of Chemical and Biomolecular Engineering, UCLA, Los Angeles, US

Tissue engineering is an interdisciplinary field incorporating concepts from engineering, biological sciences, and medicine with the goal of engineering biological substitutes to maintain, restore and promote normal tissue function. Polymer-based biomaterials have played an important role in the development of tissue constructs that mimic the structures and physical properties of the native tissues. However, there are still many challenges in micro-engineering biomaterials with tunable physical and biological properties for the development of fully functional tissue constructs. The combination of advanced biomaterials with micro- and nanoscale technologies have been shown to hold great potential to address the current challenges in tissue engineering. Our research focuses on developing biomimetic elastin-based biomaterials and nanocomposite hydrogels, with controlled architecture, and physical and biological properties, utilizing recombinant proteins. These advanced biomaterials are integrated with different micro- and nanofabrication technologies to engineer biomimetic tissue constructs for engineering soft and elastic tissues. Furthermore, we have developed new chemistries to improve the adhesion of these biomaterials to the tissue surfaces and use them as multi-functional bioadhesives for sealing and repair of soft tissues such lung, heart, skin, and cornea. In addition, our group has designed different nano delivery planforms which can be incorporated in these bioadhesives for gene and drug delivery applications. In this presentation, I will outline our recent work on the development of adhesive and elastic hydrogels for tissue engineering along with their clinical applications as tissue adhesives and surgical sealants.
Track to understand or understand to track extracellular vesicles?

Khuloud Al-Jamal

King’s College London, School of Cancer and Pharmaceutical Sciences, London, GB

The ability to track extracellular vesicles (EVs) in vivo without influencing their biodistribution is a key requirement for their successful development as drug delivery vehicles and therapeutic agents[1]. Here, we evaluated the effect of five different optical and nuclear tracers on the in vivo biodistribution of EVs. Exp293F EVs were labelled using either a non-covalent fluorescent dye DiR[2], or covalent modification with 111Indium-DTPA[3], or bioengineered with fluorescent (mCherry) or bioluminescent (Firefly and NanoLuc luciferase) proteins fused to the EV marker, CD63. To focus specifically on the effect of the tracer, we compared EVs derived from the same cell source, and administered systemically by the same route and at equal dose into tumour-bearing BALB/c mice. 111Indium and DiR were the most sensitive tracers for in vivo imaging of EVs, providing the most accurate quantification of vesicle biodistribution by ex vivo imaging of organs and analysis of tissue lysates. Specifically, NanoLuc fused to CD63 altered EV distribution resulting in high accumulation in the lungs, demonstrating that genetic modification of EVs for tracking purposes may compromise their physiological biodistribution. Blood kinetic analysis revealed that EVs are rapidly cleared from the circulation with a half-life below 10 min. Our study demonstrates that radioactivity is the most accurate EV tracking approach for a complete quantitative biodistribution study including pharmacokinetic profiling. In conclusion, we provide a comprehensive comparison of fluorescent, bioluminescent, and radioactivity approaches, including dual-labelling of EVs, to enable accurate spatiotemporal resolution of EV trafficking in mice, an essential step in developing EV therapeutics.

“BeeInspired”: Drug load patches for wound healing

Katia R. Amaral, Lúcia F. Santos, Ana S. Silva, João F. Mano

CICECO - Aveiro Institute of Materials, University of Aveiro, Aveiro, PT

Introduction

Transdermal drug delivery patches are used to improve wound healing. Still, the limited amount of drugs that these patches can carry leads to a frequent patch replacement which can cause reinjury of the wound, thus resulting in pain and delayed wound healing.1,2 Inspired by this limitation and stimulated by the ability of honeybees in transporting large quantities of pollen particles in between their legs’ hairs, we propose the development of an algae-derived micropatterned patch composed of spaced micropillars with high aspect ratio able to transport high quantities of drug particles. After satisfactory results using polydimethylsiloxane 3, methacrylated laminarin is now used to microfabricate the patch, granting anti-inflammatory properties and a moist environment for a faster healing, while improving the delivery of poorly soluble drugs such as ciprofloxacin, used as an antibiotic.

Experimental Methods

Firstly, methacrylated laminarin micropatterned patch (MLMP) was prepared by a soft lithography technique and mechanical characterization was performed. Then, PCL microparticles were produced by an emulsion technique in order to investigate the entrapment efficiency of MLMP by gently pressing the particles onto the MLMP. Herein, we also demonstrated that microparticles could be immobilized in the developed MLMP. For this purpose, ciprofloxacin-encapsulated alginate microparticles (CLM) were produced by an electrospray technique. MLMP entrapping either ciprofloxacin powder (CP) or CLM were investigated. Free MLMP and non-loaded alginate microparticles were used as controls for the different assays. In vitro release studies of the drug were made at pH 7.4 (physiological) and pH 5.5 (wound). Moreover, the cells biocompatibility of the mentioned constructs was evaluated using human-dermal fibroblast. After incubation for 3, 7 and 14 days, analysis of cells viability, mitochondrial quantification and cell proliferation were performed. Finally, growth inhibition of MLMP and the different constructs was investigated using E. coli (gram negative) and S. aureus (gram positive) cultures.

Results and Discussion

We herein report a novel biomimetic structure with spaced micropillars able to physically support the entrapment of drug particles, as proven by the successful entrapment of PCL microparticles in the MLMP. Sustained and controlled releases were evidenced for both constructs (MLMP + CP and MLMP + CLM) at both pHs, with an initial burst release of 10 % of CP from the MLMP in the first hour. Suggested by this initial burst release followed by a more controlled and sustained release evidenced for the CP-MLMP system at both pHs, we hypothesis that MLMP had a probable superficial adsorption of CP, as usually seen in the marketed patches. This event demonstrated that our MLMP could be applied either in wound healing situations or other events that require topical transdermal delivery of a drug, since an initial burst provides immediate relief followed by prolonged release to promote gradual healing. Furthermore, bacterial assays showed that MLMP containing CP manifested remarkable antimicrobial activity against both strains. Interesting, free MLMP and MLMP with non-loaded alginate microparticles shown antibacterial activity against E. coli, but the same result was not evidenced for S. aureus. As reported in literature, the laminarin present antibacterial activity against gram-negative bacterium, corroborating the results of MLMP against E.coli.4 Finally, cellular assays were performed attesting the biocompatibility of our MLMP (free of drug).

Conclusion

The biocompatibility of our MLMP (free of drug) together with an enhanced antimicrobial activity and with the ability to fix high dosages of CP or CP in drug vehicles (alginate microparticles), make these natural-derived hierarchal...
optimized patches valuable systems for clinical applications. Additionally, since the particles’ entrapment can be easily accomplished by simple contact of the patch with any powdered product, these constructs could be a valuable solution for the treatment of diseases that require high drug concentrations, enabling less-frequent dosing and thus significantly improving patient compliance. We also hypothesize that the applicability of these systems could be extended from wound healing applications to other high-value uses, such as the biomedical, biotechnological, environmental and industrial fields, where fixing high content of microparticles could be an added-value.

Multifunctional lipid-based magnetic nanovectors: Combining chemotherapy and magnetic hyperthermia to treat glioblastoma multiforme

Carlotta Pucci, Daniele De Pasquale, Gianni Ciofani

Istituto Italiano di Tecnologia, Smart Bio-Interfaces, Pontedera, IT

Introduction
Glioblastoma multiforme (GBM) is the deadliest brain tumor, with a median survival rate of only 12-15 months and a 5-year survival of around 5%. Difficulties in treating GBM arise from its diffuse nature and genetic variability that makes conventional therapies extremely inefficient. Moreover, most of the drugs cannot easily penetrate the blood-brain barrier (BBB), and have poor selectivity. For this reason, research is focusing on finding more efficient treatments.

In this work, we propose a multimodal approach based on the synergic action between chemotherapy and magnetic hyperthermia. To achieve this, lipid nanovectors (LMNVs) were loaded with a drug (chosen among a library of drugs tested on different glioblastoma cell lines) and superparamagnetic iron oxide nanoparticles (SPIONs), inducing lysosomal membrane permeabilization (LMP) upon interaction with an alternated magnetic field (AMF). Thanks to the functionalization with peptides (angiopep-2) or cancer cell membrane extracts (homotypic targeting), nanovectors can accumulate in tumor tissues, and more efficiently cross the BBB.

Experimental Methods
LMNVs were synthetized by hot ultrasonication, and subsequently functionalized with either angiopep-2 or GBM cell membrane extracts. The physicochemical properties of the nanovectors were studied by DLS, TEM, TGA, whereas the successful functionalization was demonstrated by fluorescence spectroscopy and SDS-PAGE. Drug loading and release was measured by HPLC. The cytotoxicity of the nanovectors was studied in vitro by WST-1 assay and immunocytochemistry, with or without alternated magnetic field (AMF) stimulation. The preferential uptake of the nanovectors by GBM cells was assessed in static and dynamic conditions, and compared with the uptake by healthy cells lines (human astrocytes, endothelial cells, and neuronal-like cells). The intracellular fate of Ang-LMNVs was studied by confocal microscopy.

Results and Discussion
Thanks to functionalization, we were able to selectively target GBM cells, both in static and dynamic conditions, while the uptake by healthy cells was, in comparison, negligible. On the other hand, bare LMNVs uptake was lower and aspecific. Functionalized nanovectors were also found to be more efficient in crossing a fluidic BBB model as compared to bare LMNVs. LMNVs were internalized in lysosomes. Upon interaction with AFM, the SPIONs-mediated heat generation induced destabilization of the lysosomes membrane (LMP effect) and triggered the leakage of lysosomal enzymes, such as cathepsin B, in the cytosol with consequent cell death. Alongside, the drug encapsulated in the nanovectors was able to induce an increase in p53 expression, leading to cell apoptosis. The toxic effect of the drugs increased when the drug was loaded in the nanovectors as compared to the free form, probably due to a higher cellular uptake mediated by the nanovectors. Moreover, the release of the drug was found to be higher at acidic pH conditions, similar to those found in cancer cells and in acidic organelles, such as lysosomes. Therefore, AMF-induced LMP might foster the release of nutlin-3a trapped within lysosomes, increasing its efficiency. The combined effects of chemotherapy and magnetic stimulation, induced a significant reduction of GMB cells viability (<
1\%), and, even after 3 days from the end of the stimulation, no further cell proliferation was detected, proving the high efficiency of the approach.

Conclusion
Thanks to the synergic effect between chemotherapy and magnetic hyperthermia, LMNVs efficiently activates several apoptotic pathways in GMB cells, hindering cell proliferation even after the chronic AMF stimulation protocol. Moreover, the improved BBB crossing abilities and targeting efficiency of functionalized LMNVs make this system a potential candidate for the treatment of GBM.

Particle-coated hydrogels for adhesion to internal tissues

**Maïlie Roquart**¹², Estelle Palierse¹, Nicolas Golse³, Eric Vibert³, Mathieu Manassero⁴⁵, Sophie Norvez¹, Laurent Corté¹²

¹ ESPCI Paris, PSL University, Chimie Moléculaire, Macromoléculaire et Matériaux, Paris, FR; ² Mines ParisTech, PSL University, Centre des Matériaux, Evry, FR; ³ Hôpital Paul Brousse, Centre Hépato-biliaire, Villejuif, FR; ⁴ Ecole Nationale Vétérinaire de Maisons-Alfort, Service de Chirurgie, Maisons-Alfort, FR; ⁵ CNRS, Biologie, Bioingénierie et Bioimagerie Ostéo-articulaires, Paris, FR

**Introduction**

Improving the fixation of hydrogels to the soft and wet surface of internal organs could create opportunities for the development of innovative surgical approaches and implantable technologies. Adhesion by particle bridging appears as an interesting solution to that respect [1]. In this approach, particles are deposited at the tissue-hydrogel interface and adhesion is created by the adsorption of the macromolecules composing the hydrogels and the tissues to the surface of these particles, which can then act as connectors. In vivo experiments on rat models showed that nanoparticles can be used to fix polymer membranes to tissues, onto a resected liver surface and a beating heart [2]. More recently, in vivo experiments on pig models have shown that in the presence of blood, the use of procoagulant silica nanoparticle coatings can further enhance this hydrogel-tissue adhesion by triggering the formation of an interfacial blood clot [3]. In addition to these specific particle bridging mechanisms, intrinsic viscoelastic properties of hydrogels also play an important role in their adhesion to soft internal tissues through the dissipation of mechanical energy [4]. Taking these considerations into account, we investigate here how the adhesion on internal tissues depend on the properties of hydrogel substrates and particle coatings in order to design membranes able to adhere by simple contact and withstand surgical and physiological stresses.

**Experimental Methods**

**Materials:** PEG-based hydrogel membranes of 0.5-2 mm thickness were fabricated using formulations based on photoactivated thiol-acrylate chemistry [5]. Powders of aggregated silica nanoparticles having a 30 nm diameter (Ludox TM-50®) were prepared from aqueous solutions by a series of steps comprising dialysis, drying, grinding and sieving.

**Liver tissue sourcing:** Pig livers were purchased from butcher’s shop or harvested from surgery school (Fer-à-Moulin, AP-HP). They were stored at 4°C and used from 3h to 76h after harvesting.

**Adhesion measurements:** Peeling experiments were performed on a tensile test apparatus (AllAround, Zwick) equipped with a 10 N force cell. For each measurement, a 1cm-wide hydrogel stripe, coated or not, was placed onto either a model glass surface or the surface of porcine liver capsule. Contact was applied for given times and pressures. Peeling was then performed at constant angle (90°) and speed (1 mm/s).

**Surface characterization:** The surface of coated membranes was characterized by SEM on a FEI Nova NanoSEM 450 apparatus. Specimens were sputter coated with a 2 to 4 nm layer of gold/palladium and then observed with a secondary electron TLD detector and a backscattered electron detector (CBS) which gives a chemical contrast image. This analysis was completed with an energy-selective X-ray microanalysis system (EDS) to trace the presence of elements on the surface that are representative of the particles (Si), of the gel (S) and of biological compounds (N).

**Results and Discussion**

To explore these adhesion mechanisms and design clinically relevant adhesives, we synthesized resorbable PEG hydrogel membranes having adjustable topologies and cross-linking densities. The viscous dissipation within these
gels could be greatly modulated. For instance, adhesion energy on model glass surfaces varied from 20 to 250 J.m$^{-2}$ by varying the thiol-acrylate ratio (Figure 1a). Coatings of silica nanoparticle aggregates were deposited on those membranes by a simple brush spreading process. Their adhesive performances and the underlying microscopic mechanisms were characterized by ex vivo peeling tests on the capsule of porcine livers.

Figure 1b shows typical peeling curves after a 5 min contact on the liver capsule for highly dissipative membranes with and without silica particle coating. For the uncoated membranes, a normalized peeling force of about 4 N.m$^{-1}$ is obtained and peeling is accompanied by a small deformation of the liver tissue (Figure 1c). For the coated ones, the peeling force can be 3 to 4 times higher with a noticeably larger deformation of the liver (Figure 1d). SEM observations (Figure 1e) and chemical analysis indicate that silica aggregates remain on the hydrogel surfaces after peeling and are coated with biological compounds.

**Conclusion**

Through ex vivo experiments on porcine liver surfaces, we showed that the adhesion of PEG hydrogels is strongly enhanced by the deposition of silica nanoparticle coatings. Using intrinsically dissipative hydrogels, adhesion energies up to 15 J/m$^2$ were obtained for contact times and pressures that are relevant for surgical practice. These results justify the implementation of on-going in vivo tests to evaluate the robustness of these adhesives in surgical conditions.

Modelling early stage cardiac fibrosis through “bioartificial” scaffolds: an in vitro platform for preclinical validation of new cardiac regenerative therapies

Mattia Spedicati¹,², Gerardina Ruocco¹,², Irene Carmagnola¹,², Alice Zoso¹,², Valeria Chiono¹,²

¹ Politecnico di Torino, Department of Mechanical and Aerospace Engineering, and POLITO BioMedLab, Turin, IT; ² Interuniversity Center for the promotion of the 3Rs principles in teaching and research, Centro 3R, Politecnico di Torino Unit, Turin, IT

Introduction
Myocardial infarction, the leading cause of mortality and morbidity worldwide, provokes the loss of billions of cardiomyocytes and the deep remodelling of cardiac extracellular matrix (ECM) with the progressive formation of a stiff and dysfunctional fibrotic tissue, rich in crosslinked collagens. Post-infarct microenvironment is mainly populated by activated cardiac fibroblasts called myofibroblasts (MyoFs) [1]. Moreover, cardiac fibrotic tissue is characterised by high variability in terms of composition, size, stiffness and structure, depending on location and time from heart attack. Currently, there is no effective treatment to reverse cardiac fibrosis, therefore heart transplantation remains the only available clinical approach. Following the 3Rs principle (Reduction, Replacement, Refinement), in vitro models of human cardiac post-infarct tissue could improve preclinical validation of new therapies aimed at heart regeneration.

The aim of this work was to engineer in vitro models of early-stage human cardiac fibrotic tissue, exploiting 2D and 3D “bioartificial” synthetic/natural polymer scaffolds.

Experimental Methods
Randomly oriented 2D nanofibrous polycaprolactone (PCL; Mw: 43.000 Da) scaffolds were fabricated by electrospinning (Linari Engineering), with small and interconnected porosities, closely mimicking the ECM morphological features. 3D square-meshed PCL scaffolds with different interconnected pore sizes (150 µm; 350 µm) were fabricated through melt-extrusion additive manufacturing (Rokit Invivo). The three scaffold types reproduce the structure of early stage cardiac fibrotic tissue with different severity.

To mimic cardiac ECM chemical composition, gelatin (G; Type A) was grafted on scaffold surfaces using mussel-inspired pre-coating [2]. Physicochemical characterisations were performed after each functionalization step. G grafting efficacy was confirmed by QCM-D, ATR-FTIR, and static contact angle analyses that was also used to assess coating stability upon 1 week incubation in phosphate buffered saline (PBS) at 37°C. Adult human cardiac fibroblasts from healthy human ventricle (HCFs) were cultured on 2D and 3D scaffolds for up to 3 weeks.

Results and Discussion
2D electrospun scaffolds showed homogeneous morphology with no process defects (Figure 1 a). 3D scaffolds, with both 150 µm and 350 µm pore sizes showed well defined and homogeneous porosity (Figure 1 b-c). Regarding the biomimetic coating, QCM-D and ATR-FTIR analyses confirmed G successful deposition. The static contact angle measurements showed higher wettability for G modified scaffolds, which was maintained upon 1 week incubation in phosphate buffered saline (PBS) demonstrating coating stability.

Biological validation showed bioartificial scaffolds capability to sustain HCFs adhesion and spreading. Phalloidin staining analysis highlighted cell coverage on all scaffolds and control samples after 3 weeks culture time (Figure 2). Interestingly, HCFs activation, triggered by intrinsic scaffold stiffness, was demonstrated by the increase (compared to control) in α-smooth muscle actinin (α-SMA) and Discoidin Domain-containing Receptor 2 (DDR2) expression. HCFs on control samples did not express α-SMA and DDR2, as evaluated by immunostaining, while HCFs cultured...
on 2D and 3D functionalized scaffolds expressed both fibrotic markers. The secretion of typical cardiac ECM proteins (Fibronectin, Laminin, Tenascin and Collagens) was confirmed by immunofluorescence analysis.

**Conclusion**

This work proposes such 2D and 3D engineered “bioartificial” tissues as platforms for *in vitro* modelling of early stage cardiac fibrotic tissue with different thickness and severity depending on scaffold architecture. Results will be beneficial for the preclinical investigation of new therapies and the study of different degrees of cardiac fibrosis.

Elastin-like Recombinamer and Collagen Bi-Layered Construct as a Model of the External Elastic Lamina and Tunica Adventitia of the Vascular Wall

Miguel González-Pérez, Dimitria B. Camasão, Diego Mantovani, Matilde Alonso, José C. Rodríguez-Cabello

Laval University, Laboratory for Biomaterials and Bioengineering, Quebec City, CA; University of Valladolid, BIOFORGE, Valladolid, ES

Introduction
The development of bioinspired models of the vascular wall presents a special interest in the biomedical field. Whether to serve as a model for studying common vascular diseases or for becoming the future solution for evaluating the activity of drugs and bioactive molecules in vitro [1]. Based on previous promising approaches employing collagen as scaffold for vessel walls [2] and the second main principal component present on these tissues, namely elastin, a bi-layered model of the external elastic lamina (EEL) and tunica adventitia of the vascular wall was designed. Collagen type I was isolated directly from rat tail tendon and embedded with fibroblasts (FBs) to reproduce the tunica adventitia, whereas the elastin replicating the EEL was recombinantly produced in Escherichia coli bacteria. This family of polypeptides, also known as elastin-like recombinamers (ELRs), were designed containing cell-adhesive, protease-sensitive sequences and click reactive groups to constitute the EEL matrix. Mechanical and histological analysis were performed to evaluate the cell-remodeling activity and the approximation of the designed model to the native EEL and tunica adventitia physiology under in vitro maturation for two weeks.

Experimental Methods
A biocasting technique comprising the use of a multiwell plate containing a cylindrical mandrel in the center was developed. Evolution in the mechanical response of the model, namely elastic modulus, tensile strength and strain at break, was investigated by circumferential tensile stress-relaxation test. Whereas histology allowed to evaluate the distribution of cells, collagen and ELR matrix morphology, and production of α-smooth muscle actin (α-SMA), focal adhesion kinase (FAK), and acid polysaccharides at 3, 7 and 14 days.

Results and Discussion
The obtained data identified the elastic and more viscous character conferred by the ELR and collagen matrix, respectively. Maturation in vitro revealed the ability of the RGD cell-adhesive epitopes to deviate the HDFn polarization from the surface of the model, in contact with the culture medium, towards the ELR/collagen interface instead. Histology showed the presence of α-SMA, FAK, and acid polysaccharides indicating the active cell remodeling activity and differentiation of the embedded FBs into myofibroblasts, thus suggesting their active participation in the acquisition of a physiological-like morphology and environment.

Conclusion
A biocasting technique for fabricating a bi-layered model of the EEL and tunica adventitia from FBs, collagen and bioactive click-crosslinkable ELRs was designed. The developed model positively resembled the native morphology and composition while confirmed the ability of the moldable collagen matrix and the encoded bioactive sequences in the ELR counterpart to direct the behavior of FBs cells.

A textile approach of tissue-engineered vascular graft: implantation, conservation and sterilization

Diane Potart, Maude Gluais, Nicolas Da Silva, Yoann Torres, Nicolas L'Heureux

Université de Bordeaux, Science de la Vie et de la Santé (SVS), Bordeaux, FR

Introduction
To meet the clinical need for small vascular graft, we propose a new “human textile” approach creating a completely biological Tissue-Engineered Vascular Graft (TEVG). Vessels were produced by weaving into a tube yarn of Cell-Assembled extracellular Matrix (CAM) synthetized in vitro by human skin fibroblasts. Our TEVG clinical use as an off-the-shelf product requires in vivo validation, flexible production, final product storage and sterility assurance. Therefore, the objectives of this study are to 1) assess the human TEBV functionality in an immunodeficient rat model, 2) find the best conservation method maintaining CAM mechanical properties and matrix structure, and 3) find the best terminal sterilization method to simplify TEBVs production while preserving its biomechanical and biological properties.

Experimental Methods
Well-organized human CAM sheets were produced in vitro after maintaining human skin fibroblasts in culture during two months with 20% bovine serum and 0.5 mM ascorbate. CAM sheets were cut into 2mm wide ribbons and woven into small tubes (8 mm long, 1.6 mm inner diameter). Collars were especially created at each end allowing TEVGs suture with native vessels. Those TEVGs were implanted in abdominal aortas of immunodeficient rats by a microvascular surgeon and their functionality and remodeling will be tested up to 12 months.

CAM sheet were cut into 5 mm wide ribbons that were conserved in conditions compatible with clinical use (-80°C, -20°C, 4°C (dry or wet) and Room Temperature (RT) (dry or wet)). After 1 year, ribbons were mechanically tested and compared to control (-80°C, 1 night of conservation).

Our CAM was sterilized using gamma irradiation (dry or wet, with high or low dose rates), electron beam irradiation, ethylene oxide (EtO), or supercritical carbon dioxide (scCO2). Sterilized 5 mm wide ribbons (16 cm long, n=8/condition/time) were implanted subcutaneously in immunodeficient rats (4 ribbons/rat, 54 rats) and tensile tests were performed before implantation and after 2, 4, 20, and 40 weeks.

Subcutaneous explants were fixed and embedded in paraffin, and will be stained (H&E, Masson’s Trichrome) or processed for immunofluorescence (including antibodies against collagen-I and M1/M2 immunostaining).

Sterilized sheets are currently tested using DSC (Differential Scanning Calorimetry) and FTIR (Fourier Transform InfraRed spectroscopy). Endothelial cells proliferation on sterilized CAM sheets is also evaluated.

Results and Discussion
Preliminary surgeries in 1 mm diameter abdominal aortas of nude rats demonstrated graft implantability and the absence of transmural leakage. To this day, we are following 12 successful grafts and we already reached 6 months of survival.

After 1 year of conservation, ribbons showed no loss of strength, and RT dry condition even lead to a force increase (+26% / control). This could be due to a sample rehydration incapacity. This hypothesis is supported by the decrease in section of these samples (-60% / control) and requires further evaluation. We also noticed that wet conditions (4°C and RT) showed lower max strain (-10% / control).

Before implantation, the ribbons strength of the gamma-wet group was significantly lower than control (sterile production group) by 34%, while the EtO group was stronger (+20% / control). After five months, the gamma-wet...
group remained the weakest, while scCO2 group seemed to be stronger than other conditions. 10 months results are under evaluation. Histological and physicochemical evaluation with DSC and FTIR are expected soon, as well as endothelialization results.

**Conclusion**

Our next step will be TEBV long-term implantations to assess its remodeling. We are expecting a graft spontaneous endothelialization by the host, avoiding its thrombosis.

We confirmed that our CAM can be easily conserved without losing mechanical properties up to 1 year, and that sterilization methods influence CAM mechanical properties. ScCO2 appears to be a promising solution. Histological and physicochemical analyses are expected to complete these results, highlighting the possibility of having a “off-the-shelf” product.

Functionalization of biodegradable Zn-based alloys with poly(ε-caprolactone) and bioactive peptides to control degradation and enhance endothelialization

Claudia García Mintegui, Victor Chausse, Cédric Labay, Carles Mas Moruno, José Luis Cortina, Marta Pegueroles

Technical University of Catalonia, Barcelona, ES

Introduction

Zinc alloys arise as potential candidates for bioresorbable stents due to their moderate degradation rate in comparison with Mg-based and Fe-based alloys [1]. However, the control of the degradation behavior and the optimization of endothelial cell response remains an unmet challenge. This study explores different strategies to coat Zn-based alloys with poly(ε-caprolactone) (PCL) to control degradation. Subsequently, PCL-coated surfaces will be functionalized with bioactive synthetic peptides in order to accelerate surface endothelialization.

Experimental Methods

Zn, Zn-0.5Mg, and Zn-2Ag discs (Goodfellow) were ground with SiC abrasive paper up to grit 4000. PCL coatings were prepared as follows: (a) PCL nanocoating was developed by ε-caprolactone polymerization via cold plasma-polymerization process; (b) PCL (Mw: 70,000-90,000 g/mol) was dissolved in chloroform in 5.0 wt.% and spin-coated at 5,000 rpm onto samples surfaces during 30 s. Later, coated surfaces were functionalized with RGD, REDV linear and RGD+REDV dual peptides, synthesized in solid-phase, and covalently attached to the samples surfaces using EDC/NHS activation and coupling. Surface physicochemical characterization was performed by X-ray photoelectron spectroscopy (XPS) and a dual beam focused ion beam/field emission scanning electron microscope (FIB/FESEM). Electrochemical behavior in DMEM solution (37 ± 1 °C) was evaluated by potentiodynamic tests (ASTM G5-14) and electrochemical impedance spectroscopy (EIS) at 1, 2, and 3 days of immersion. Peptides immobilization to the surface was characterized by fluorescence microscopy and XPS. In vitro biological response was evaluated after 6 h of adhesion of human umbilical vein endothelial cells (HUVECs) and posterior live/dead and DAPI/Alexa Fluor 546 phalloidin staining.

Results and Discussion

FIB/FESEM determined a uniform PCL nanolayer of ~ 20 nm after the plasma-polymerization process (Fig. 1). The spin-coated samples presented a homogeneous PCL microlayer of ~ 2 μm. Potentiodynamic tests of spin-coated samples exhibited a noteworthy decrease in current density values suggesting that PCL is acting as a corrosion barrier. EIS supported that the corrosion resistance was provided by the PCL coating. No significant differences in corrosion were noticed for PCL-nanocoated samples with respect to untreated samples, as expected due to the nanothickness of the coating. PCL-coated Zn alloy surfaces were successfully biofunctionalized as observed by fluorescent confocal microscopy and N 1s XPS spectra. HUVEC adhesion studies indicated a good cell attachment and aggregation for Zn and PCL-coated surfaces (Fig. 2 a, c). However, changes in HUVEC adhesion morphology were observed for PCL-coated surfaces, with higher cell spreading that can foster endothelialization (Fig 2 d). REDV, RGD and the mixture of both peptides have been shown to accelerate endothelial cell adhesion, proliferation and migration [2]. However, the adhesion of RGD and REDV mixture was not correctly controlled. The covalent immobilization of RGD+REDV platform onto PCL-coated surfaces was correctly achieved, and allows to control the conformation of the peptides and the disposal to the cells. Finally, the combination of antifouling PCL micro-coating with pro-endothelialization peptidic platform showed a better biological performance.
Conclusion

PCL coating onto Zn-Alloys was successfully achieved by two different techniques, controlling the degradation rate through the thickness of the PCL layer. The electrochemical results suggest that the degradation behavior strongly depend on the thickness of the layer. In this work, the combination of antifouling PCL-microcoating with pro-endothelialization multipetidic RGD+REDV platforms enhanced surface endothelialization being a possible solution to overcome the reported poor *in vitro* cell biocompatibility of Zn alloys.

Extrusion of nanocomposite poly-l-lactic acid for stent application

Lison Rocher, Gary Menary, Alex Lennon

Queen's university, School of Aerospace and Engineering, Belfast, GB

Introduction
Drug eluting stents are the current gold standard to treat coronary artery disease but they remain in the body and may cause late stage complications after a couple of years [1]. To overcome this issue, bioresorbable vascular stents (BVS) can fully degrade in the body within three years after the vessel healing. However current limitations of BVS (like their lower mechanical properties, microstructural heterogeneities and lack of radiopacity) have to be improved before their use in clinical practice [2,3]. To manufacture BVS, small tubes are extruded and then biaxially stretched before laser-cutting to a stent design and crimping onto a balloon.

To address the issues related to BVS, tungsten disulphide (WS₂) inorganic nanotubes (INT) were investigated to reinforce poly-l-lactic acid (PLLA) and increase its radiopacity. The aim of this study was to produce and characterise PLLA/WS₂ tubes loaded with 0.5wt% and 3wt% of nanoparticles to create a suitable preform for the stretch blow moulding process.

Experimental Methods
Medical grade PLLA (Corbion, Netherlands) was reinforced with INT-WS₂ (Holon Institute of Technology, Israel). Prior to extrusion, the polymer was ground into powder and mixed with the nanoparticles. The mix was dried for 4h at 120°C to avoid hydrolytic degradation. Neat PLLA tubes were produced following the same process. The tubular extrusion was performed at 230°C with a twin-screw extruder to ensure good mixing followed by quenching in a water bath.

The dispersion of the nanotubes was studied using scanning electron microscopy (SEM) and high-resolution x-ray micro-computed tomography (μCT). Gel permeation chromatography (GPC) was used to evaluate the effect of processing on the PLLA molecular weight (Mw). Thermal and morphological properties were determined using differential scanning calorimetry (DSC) at a rate of 10°C/min. Uniaxial tensile testing was performed to evaluate the tubes mechanical properties.

Results and Discussion
Extruded tubes produced have 1.90 ± 0.03 mm outside diameter and 0.59 ± 0.02 mm wall thickness along with good concentricity measured by optical microscopy.

GPC analysis indicated about 12% decrease of Mw for both the neat PLLA and 0.5wt% samples during drying and extrusion and about 34% for the sample loaded with 3wt% of nanotubes. This suggests that excessive loading of nanotubes can be detrimental to PLLA molecular chains during the extrusion process.

No agglomerate was observed from SEM images and the nanotubes looked well dispersed in PLLA (Figure 1a). Comparison of nanotubes length before and after processing showed a significant shortening due to the high shear induced in the extruder (from 4.05 ± 1.7μm to 2.2 ± 0.8μm). The nanotubes radiodensity and the high resolution of the instrument allow the evaluation of dispersion with μCT. The inclusion analysis indicated the presence of small agglomerates and a higher nanotube concentration toward the inner wall of the preform (Figure 1b), which was not detected with SEM due to highly localised scanning.

Mechanical properties results indicated similar ranges in term of Young’s modulus and elongation at break for all samples but the ultimate tensile strength for the 3wt% sample was decreased by ~8% compared to the neat PLLA tube (Figure 2a). These results can be due to the nanotubes shortening during extrusion, the decrease of Mw at 3wt%, or the state of dispersion, which could be improved during the expansion process.
The DSC results showed that the nanotubes have a strong nucleation effect on PLLA and impact its crystallization temperatures ($T_{cc}$ and $T_c$). No changes in glass transition and melting temperatures were observed (Figure 2b). Enthalpy measurements revealed a low level of crystallinity ($X_c < 13\%$) for all samples, indicating efficient quenching post-extrusion.

**Conclusion**

PLLA/WS$_2$ was investigated as a new material to improve BVS. Neat PLLA and PLLA/WS$_2$ tubes with appropriate dimensions were produced by extrusion. GPC measurements indicate that an excessive loading of nanotubes decreases PLLA $M_w$, which can explain the small drop of tensile strength observed. The SEM and μCT results present complementary information suggesting that dispersion should be improved during expansion process. DSC data reveal a strong nucleation effect from the nanotubes. While no mechanical improvement was found in extruded tube preforms, further work will explore the impact of the nanotubes on the biaxially stretched PLLA microstructure that can be expected in stretch-blow-moulded tubes.

The Influence of Sterilization on PLLA for Cardiovascular Stent Applications

Emily Morra, Alex Lennon, Fraser Buchanan

Queen's University Belfast, School of Mechanical and Aerospace Engineering, Belfast, GB

Introduction
Sterilization of any medical device is a critical prerequisite for successful clinical application and represents the final processing step prior to device use in vivo. Sterilization is the process by which a product is sterilized within its final barrier system, thus ensuring a device meets required sterility assurance levels. Biodegradable polymers such as poly (l-lactic acid) (PLLA), used as a key component of many biodegradable stent designs, present challenges for sterilization in that they are temperature sensitive and undergo hydrolytic degradation. The most common techniques used in sterilization of biodegradable polymers are ethylene oxide gas (EtO) or radiation-based techniques such as gamma or electron beam (e-beam) at a dose range of 15-25 kGy. In the sterilization industry alternative techniques such as vaporized hydrogen peroxide (VHP) are also being explored to broaden available sterilization modalities. The development of new techniques corresponds with a push from environmental agencies to decrease reliance on EtO, which is a flammable and carcinogenic gas [1]. Each of these techniques has aspects which can affect biodegradable stent properties, and characterizing response to sterilization is critical to determining a device’s ability to meet functional requirements throughout its lifetime.

Experimental Methods
Medical grade PLLA (Purasorb PL38, Corbion, Gorinchem) was processed using compression moulding into 1 mm thick sheets which were then annealed and laser cut into test specimens. Samples were treated with one of three sterilization techniques at a range of doses: e-beam (5, 15, 25, 40, or 60 kGy), VHP (2, 4, 6, or 8 pulses), or EtO (typical product cycle). These doses were chosen to reflect the range a device would be exposed to during sterilization as well as lower and more extreme values. Sterilization work was carried out by STERIS (Tullamore, Ireland). Sterilized samples were characterised using a variety of techniques to assess the influence of sterilization on initial material properties. This included uniaxial tensile testing and dynamic mechanical analysis (DMA) for mechanical properties, differential scanning calorimetry (DSC) for thermal properties and crystallinity, and gel permeation chromatography (GPC) for molecular weight.

Results and Discussion
E-beam sterilization was found to influence initial material properties and the magnitude of this effect corresponded to increasing dose. E-beam caused a decrease in ultimate tensile strength and percent strain at break, which was especially evident at the selected extreme doses of 40 and 60 kGy. Samples treated with VHP did not experience the same corresponding decrease in ultimate tensile strength and percent strain at break, across doses used for sterilization as well as the more extreme dose. Similar to VHP, the EtO cycle chosen did not cause a change in either property. Young's modulus determined by tensile testing remained relatively unaffected by sterilization across all doses and treatments and this finding corresponded to the storage moduli calculated using DMA. The observed mechanical behavior was supported by GPC results, where E-beam caused a decrease in molecular weight corresponding to dose received while VHP and EtO did not cause a significant decrease in molecular weight. The dominant effect of e-beam sterilization on biodegradable polymers is degradation through chain scission and this was evident in the experimental results. While the doses used for terminal sterilization do not reach the extremes purposely selected for this experiment, some level of degradation must be considered when determining device lifetime. The heat and humidity required for EtO sterilization can also induce degradation, but this can be mitigated...
by using an optimized EtO cycle design. Similar to an EtO cycle, VHP sterilization is performed under vacuum to maximise vapour penetration. Although not as stable as EtO in vapour form, VHP efficacy can be optimised by controlling concentration, exposure time, and delivery mechanisms. VHP sterilization does not generate toxic residuals, unlike with EtO gas. VHP also has a lower temperature processing window and largely reduced cycle time compared to EtO. This reduces device exposure time to temperature, humidity, and vacuum, which in turn reduces the likeliness of degradation occurring.

**Conclusion**

VHP represents a novel sterilization technique which has received industry and regulatory attention, however its suitability for bioresorbable polymers has not been extensively characterised. The stability observed in samples treated across the range of VHP doses indicate that it could be a viable alternative sterilization modality for use with PLLA.

From *in vivo* to *in vitro*: Perfusable multiscale vascularized tissues

Prasanna Padmanaban, Jiena Zhang, Jeroen Rouwkema

University of Twente, Biomechanical Engineering Department / Faculty of Engineering Technology / Technical Medical Centre, Enschede, NL

**Introduction**

Knowledge about the flow field of the blood in surrounding tissues and the red blood cells within capillaries is important for a physical understanding of vascular networks remodeling and organization [1-2]. Keeping this in mind, our aim is to study and tune the vascular organization within both artificial eggshell systems and engineered perfusable muscle tissues using external flows.

**Experimental Methods**

Both artificial eggshell systems and muscle tissue perfusion chambers were replica molded using PDMS. Red blood cells velocities and vascular network properties such as vessel diameter, length, sprouting etc. have been characterized using in-house assembled microscopy.

**Results and Discussion**

We conduct an experimental study on the flow field, both within the endothelialized perfusable microchannels in muscle tissues and the microchannel placed on the top of vascularized membrane within artificial eggshell systems (see the Figure Multiscale vascularized tissues) to understand the influence of fluid flow on vascular network organization. We achieved spatiotemporal control of fluid perfusion and vascular cells within both the systems. Our experimental data are complemented by numerical simulations.

**Conclusion**

Coupling fluid flow parameters to the organization of vascular networks leads to a deeper understanding regarding the structural information and mechanical environment of these developing vascular networks, which is an important component in controlling vascular organization in engineered tissues.

Vascularization and high-resolution imaging of 3D polysaccharide-based scaffolds as model of liver sinusoid

Alessandra Dellaquila1,2, Didier Letourneur1, Teresa Simon-Yarza1

1 Université de Paris, INSERM U1148, LVTS, Paris, FR; 2 University of Bielefeld, Biomolecular Photonics, Department of Physics, Bielefeld, DE; 3 Elvesys Microfluidics Innovation Center, Paris, FR

Introduction

Liver capillaries, known as sinusoids, play a fundamental role in hepatic pathophysiology, such as filtering of molecules from the blood, clearing of wastes and managing the vascular immune response [1]. Despite the recent advancements in tissue engineering, the development of 3D in vitro models of the hepatic sinusoid is still hampered by the following drawbacks: (i) fabricating scaffolds with physical properties that mimic the in vivo microenvironment, (ii) engineering a functional vascular network within the scaffold and (iii) in-depth imaging characterization of 3D vascularized constructs.

To address these limitations, we developed vascularized polysaccharide scaffolds: here, we present their fabrication and characterization for optimal vasculature formation. Imaging by conventional and high-resolution microscopy was performed for in-depth characterization of the constructs.

Experimental Methods

The scaffolds were fabricated by freeze-drying from a solution of pullulan and dextran, known to be biocompatible polysaccharides [2]. The tubular channels within the porous matrix were obtained by subtractive molding technique: briefly, the polymeric mixture was casted onto a custom-made mold containing suture monofilaments (50 µm in diameter), that were removed after the hydrogel cross-linking [3]. The empty channels were selectively coated with collagen type I for cellular adhesion prior to freeze-drying. To enhance the imaging of channels by confocal microscopy, the porous gels were engineered by optimizing the fabrication and freeze-drying process. The scaffolds physical properties were evaluated by porosity and swelling tests and mechanical characterization was performed by nanoindentation. Fourier-transform infrared spectroscopy (FT-IR), elemental analysis and second-harmonic generation (SHG) were used to assess the presence of the collagen coating.

The scaffolds were subsequently seeded in vitro with human umbilical vein endothelial cells (HUVECs) as a model of liver vasculature. Different cellular densities (ranging from 1 · 106 to 10 · 106 cells/mL) and seeding strategies were investigated and their impact on scaffold vascularization was evaluated. Endothelium formation over time (up to 21 days) was followed by combining confocal and multiphoton microscopy (MPM) imaging. Morphological and functional endothelium studies (staining for actin, CD31 and VE-Cadherin) were performed by either confocal, MPM or light sheet microscopy (Figure 1).

Results and Discussion

The results of physical and mechanical studies of the collagen coated scaffolds showed a porosity of about 40% and Young’s modulus below 12 kPa, indicating the capability of the constructs to mimic soft tissues [4]. FT-IR, elemental analysis and SHG imaging confirmed the successful selective coating of the channels with collagen (Figure 2a). Imaging by confocal microscopy was enhanced thanks to the optimized scaffold fabrication while the use of MPM and light sheet techniques enabled a faster and deeper imaging of the channels within the 3D matrices with reduced photodamage. Under optimal seeding conditions, a complete endothelium was obtained after 4 days of culture and the HUVECs started forming sprouts within the porous gel at day 7 (Figure 2b), showing preliminary vascular angiogenesis. The expression of adhesion molecules such as CD31/PECAM1 confirmed the formation of functional vessels (Figure 2c).

Page 745 of 2028
Conclusion
This study reports the fabrication and characterization of vascularized porous polysaccharide scaffolds and their in-depth imaging. Current studies are focusing on the integration of other hepatic cell types and on dynamic studies of the endothelium under flow to build a perfusable vascularized liver model.

University of Twente, Department of Biomechanical Engineering, Technical Medical Centre, Enschede, NL

Introduction
Achieving hierarchically organized vasculature within an artificially developed tissue analogue is critical for its successful implantation. In native ECM, spatiotemporally controlled multiple growth factor’s bioavailability guides the vascular morphogenesis. While previous strategies have shown to achieve stable release rates via protein immobilization or coupling within polymer matrices (via linker proteins or peptides), they often fail to recapitulate the dynamic, multifunctional behaviour of the ECM. Therefore, we harnessed the unique properties of DNA based aptamers that are affinity ligands designed to recognize proteins with high affinity and specificity, for controlling growth factor bioavailability within 3D polymer matrix that in-turn could guide the developing self-organizing microvascular networks. Herein, we aim to develop vascular endothelial growth factor (VEGF$_{165}$) specific aptamer-functionalized platform that could spatiotemporally control VEGF bioavailability (retention & release) and study its effect for guiding self-organizing microvascular networks by employing bio fabrication techniques such as 3D bioprinting & photo-patterning.

Experimental Methods
The aptamer-functionalized hydrogel was prepared via visible light induced photo-polymerization of gelatin methacryloyl (GelMA) and acrydite-functionalized aptamers having DNA sequence specific for VEGF$_{165}$. For bioprinting, two bio-inks were prepared (i) with aptamer-functionalized hydrogel & (ii) GelMA + fluorescent blue microbeads (control); followed by mixing with human umbilical vein endothelial cells (HUVECs) and mesenchymal stem cells (MSCs). The construct were 3D bioprinted as lines of aptamer-functionalized bio-ink next to control GelMA lines, making an interface. Subsequently, photo-crosslinked and loaded with VEGF$_{165}$ for 1 hr. It was expected that the aptamer regions would be able to sequester VEGF$_{165}$ from the culture medium, compared to plain GelMA. To understand this effect on complex shapes and designs, photo-patterning technique with similar hydrogel formulations were used. All of these samples were studied for triggered VEGF release efficiency via complementary sequences (CS) addition (using ELISA assay) and its effect on microvascular network formation in 3D (cell viability & immunostainings).

Results and Discussion
The results obtained from ELISA experiments confirmed triggered release of VEGF$_{165}$ from the aptamer-functionalized hydrogels in response to CS addition. Without CS addition, these hydrogels showed zero leakage of VEGF$_{165}$ for 10 days. Furthermore, the bioprinted and photo-patterned aptamer-functionalized regions revealed high cellular viability and ability to guide microvascular network formation (by HUVECs and MSCs) confined within these regions and minimal invasion to GelMA regions, even after 10 days of culture (see Figure). The differences in microvascular organization was observed in the samples with triggered VEGF release on day 5, compared to control. These observations altogether confirmed the ability of bioprinted and patterned aptamer functionalized hydrogels in controlling self-organizing microvascular networks within 3D microenvironment.

Conclusion
The present study confirms the potential of aptamer-functionalized platform for guiding self-organizing microvascular networks within 3D microenvironment by spatiotemporally controlling VEGF$_{165}$ bioavailability.

Guided self-organizing microvascular network formation by controlling VEGF bioavailability. Self-organizing microvascular network formation confined within the VEGF_{165}-loaded 3D bioprinted aptamer regions after culturing for 10 days. Even though same cell concentrations and culture conditions were used for both regions, the localized aptamer-bound-VEGF_{165} molecules showed enhanced network formation confined within aptamer regions. The presence of blue fluorescent beads marks GelMA region. The image is a maximum projection of confocal z-stack and scale bar is 100 microns.

Optimizing synergy between materials and cell microenvironments using functional polyesters

Milica Radisic

University of Toronto, IBME, Toronto, CA

Material based technologies play an integral role in many medical treatment strategies, including joint replacements, vascular stents, drug delivery methods, contact lenses and medical sutures. The application of successful technologies continues to grow, with an estimated market size of $130 billion USD by 2020. Although successes are notable, a number of biomaterial-based devices are limited in application by non-specific material properties to tissue type and undesired inflammation at the device interface. In application, polyester materials have traditionally been an effective polymer strategy, with successes in tissue engineering scaffolds and a variety of biomedical devices. Leveraging advantageous polyester degradability and well understood chemical synthesis, these materials serve as a strong functional platform to further optimize material-cell microenvironments. In this talk, I will describe the development of polyesters that (a) exhibit controllable mechanical properties to mimic the elastic properties of cardiac tissue extracellular matrix (ECM) and (b) incorporate a biomimetic moiety of mammalian immunity to recapitulate mechanistic inflammation regulation at the material surface.

Development of engineered cardiac tissue requires material scaffolds that match the elastic behavior of cardiac ECM. Using polycondensation techniques to incorporate unsaturated carbonyl groups into elastic polyester material gels, we generated materials that can be molded into intricate designs with secondary crosslinking to generate constructs with highly tunable elasticity. By adapting material synthesis conditions (i.e. monomer ratios, reaction time), elastic mechanical behavior was highly tunable across a range of soft biomaterial applications. Material applicability was highlighted in a number of micro-designed elastomeric scaffold supports for engineered tissue, both for in vitro organ-on-a-chip and in vivo cardiac patch technologies, wherein the two-step synthesis process allowed for micro molding into intricate shapes prior to gelation.

With biomaterial application in vivo, inflammation at the biomaterial surface limits device application. To tackle this, we looked to itaconate, a powerful small molecule metabolite of innate immunity that has recently emerged as a regulator of innate immune inflammation. This molecule has been previously limited therapeutically by short circulation times. To circumvent this, itaconate was incorporated directly into material backbones to impart biomimetic small molecule modulation, with quantified hydrolytic degradation release from polyester chains. Harnessing hydrolytic degradation release from polyester backbones, itaconate polymers resulted in the mechanism specific immunoregulatory properties on macrophage polarization in vitro. In a functional assay, the polymer-released itaconate inhibited bacterial growth on acetate. Translation to an in vivo model of biomaterial associated inflammation, intraperitoneal injection of ITA polymers demonstrated a rapid resolution of inflammation in comparison to a control polymer silicone, demonstrating the value of sustained biomimetic presentation of itaconate. Using scalable polyester synthesis techniques, we have demonstrated the power of instructive biomaterial technologies as functional modulators of the cell microenvironment.
Piezoelectric Patches Improve Cardiac Electrical Proficiency After Myocardial Ischemic Injury

**Introduction**

Ischemic heart diseases (e.g. myocardial infarction (MI)) are the leading cause of death worldwide. Novel approaches have been focusing on restoring cardiac function by targeting cardiac repair, however in vivo studies promoting both contractile and electrical functional recovery are scarce.

Piezoelectric materials acquire electric charges upon mechanical deformation. Since the heart exhibits cyclic movements, implantation of these materials on the myocardium holds great potential for designing biomaterials with self-sustained electrical stimulation, harnessing the contractile proficiency of healthy regions of the ventricle to stimulate damaged ones.

Although a therapeutic tissue engineering strategy with piezoelectric materials is yet to be tested in vivo, these materials have already been tested on hearts in the context of recharging the battery of electronic pacemakers [1]. Herein, the therapeutic potential of biomaterial-based films with piezoelectric properties, similar to scaffolds previously produced by us [2], was evaluated, as cell-free patches, on viable or MI heart tissue on both ex vivo and in vivo rodent models.

**Experimental Methods**

Flexible patches with piezoelectric properties (Piezo patches) were obtained by electrospinning polyvinylidene fluoride-trifluoroethylene aligned nanofibers on polycaprolactone (PCL) nanofilms, obtained by spin coating. As an inert control, PCL patches were produced, containing PCL nanofibers instead. The patches were characterized mechanically through tensile tests.

These materials were applied to ex vivo cardiac tissue on Langerdoff-perfused working healthy and MI rat hearts and on healthy rat cardiac slices. The effects of the patches on the former were assessed by electrocardiography (ECG) before and after patch application, on both healthy and MI hearts; while the effect on cardiac slices were characterized by contractility measurements.

To evaluate the effect of the patches on an in vivo disease model, they were implanted in the hearts of an in vivo murine model of MI. One month after the induction of the MI and subsequent patch implantation, mice were evaluated functionally by echocardiography and surface ECGs. Their hearts were harvested and processed for histology.

Histological sections were used to morphometric analysis (e.g. infarct region area, left ventricle (LV) dilation,
cardiomyocyte (CM) cross-sectional area) and to perform Laser Capture Microdissection of LV regions near or far from the implanted Patches, which were collected and their RNA extracted and sequenced by RNASeq for transcriptomic analysis.

**Results and Discussion**

Piezo and PCL patches exhibit an elastic modulus of 7.89 and 11.16 MPa respectively, in the same range as other cardiac patches (e.g. 6.7 MPa) [3].

None of the patches cause relevant changes in ECG parameters on Langendorff-perfused rat hearts (neither healthy nor MI). This shows that the Piezo patches have no negative effect on the electrophysiological and mechanical characteristics of Langendorff-perfused working hearts, in contrast with other studies [4].

When applied in healthy viable rat cardiac slices, Piezo patches cause an increased contractility force amplitude, when compared with the PCL patches, although without statistical significance. This suggests that the Piezo patch might be generating sufficient local electrical stimulation that induces an improvement on the contraction efficiency of the cardiac slices.

Echocardiographic evaluations performed on MI mice, one month after the implantation, showed a tendency for improvement in the Piezo group, suggesting an improved systolic function and decreased LV remodeling. Moreover, LV mass was increased in the PCL group, suggesting a compensatory hypertrophic response to the MI. Importantly, the Piezo group exhibited significantly improved electrical integrity, as observed by statistical significant differences on several ECG parameters.

Although no differences were observed in histological parameters (e.g. infarct size, LV dilation), transcriptomic analysis of LV tissue microdissected from regions near or far from either Piezo or PCL patches, showed that LV far from the PCL patch showed an upregulation of several genes associated with extracellular matrix remodeling, when compared with Piezo group, in the same tissue region. Curiously, the cross-sectional area of the CMs on that same region was statistically significantly increased in the PCL group, which aligns with the observed increase in LV mass.

**Conclusion**

*Ex vivo* experiments with perfused hearts and cardiac slices showed that the Piezo patch doesn’t negatively affect tissue function in a short time-frame and slightly improves contractility. In a longer time-frame (one month), the Piezo patch causes an improvement in an MI mouse model, mainly on electrical integrity. This study shows for the first time the possibility to harness the contractile motion of the heart tissue to further electrically stimulate the same tissue for improvement of function, viability and remodeling.

Introduction
Recent advancements in nanotechnology have the potential to revolutionize both preventive and therapeutic approaches for treating cardiovascular disease [1]. Nanoengineering approaches could be exploited to develop scaffolds recapitulating the complex signals necessary for cardiac regeneration. Recently, cardiac scaffolds were modified with nanoparticles (NPs) able to recognize a specific ECM metalloproteinase (MMP) with the aim to prevent left ventricular (LV) dysfunction after myocardial infarction (MI) [2]. It is known that an increased LV myocardial MMP activity and selective upregulation of MMPs in heart failure occur. The control of MMP activation and expression in the failing human LV myocardium represents a significant therapeutic target for heart disease. Our idea was to exploit the molecular imprinting polymers (MIP) in order to restore the correct MMPs/TIMPs balance. In this work, we have explored more in depth the potential of this technique through a wide scenario of evaluations from the computational study to the synthesis and physico-chemical, dimensional and biological characterization.

Experimental Methods
Methacrylic acid (MAA), poly(ethylene glycol) ethyl ether methacrylate ((PEG)EEMA) as monomers and trimethylolpropane methacrylate (TRIM) as cross-linker were used. Human MMP-9 was used as template. MD simulations were performed by using the AMBER16 software employing the General Amber Force Field (GAFF) for MAA and (PEG) EEMA species and the ff14SB Force Field for the MMP-9 protein. The structure of isolated MMP-9 protein was extracted from PDB database. MIP NPs were synthesized using precipitation radical polymerisation of MAA and (PEG)EEMA with monomer ratio 75/25 (selected from the computational analysis) with a low coverage of the protein. FT-IR Chemical Imaging was used to evaluate the chemical map of pure MMP-9 and NP aggregates before and after template extraction. DLS analysis was carried out on different NP aqueous dispersions. SEM analysis was performed on both MIP NPs and control NPs. HPLC analysis was performed to evaluate rebinding capacity and selectivity of MIP NPs towards MMP-9. Viability assay was carried out on H9c2 cardiomyoblasts incubated with increasing MIP NPs concentrations at 24, 48 and 72 hrs through Propidium Iodide Flow Cytometry analysis.

Results and Discussion
The evolution of the interaction between MMP-9 and MIP NPs as a function of monomer concentration was evaluated by a new and original computational protocol. A stronger water/protein interaction than the monomers/protein one was observed, although, in the case of low coverage, this effect was reduced especially for (PEG)EEMA monomers that resulted more strongly anchored to the protein surface. FT-IR Chemical Imaging allowed to identify a diagnostic band for MMP-9 and detect this band both before and after template extraction from MIP NPs. An interesting similarity between a partial coverage where the enzyme structure is exposed respect to monomer shell and chemical map showing a surface presence of enzyme on NPs was observed. An high percentage of MMP-9 entrapped into NPs was evaluated by HPLC confirming the strong interaction protein/NPs and an elevated enzyme extraction. SEM analysis showed an average value of sphere dimension only slightly higher for MIP NPs than control NPs. This result
was confirmed by DLS analysis indicating that surface sites can take place allowing the removal of MMP-9 after imprinting. HPLC analysis showed a rebinding capacity of MIP NPs towards the enzyme confirming the presence of highly-specific recognition zones in agreement with the computational study. MIP NPs exhibited also selectivity towards MMP-9 respect to an analogue enzyme (MMP-2). Finally, no cytotoxic activity of MIP NPs was observed on H9c2 cells: the viability values were close to 100% independently of dose and incubation time.

**Conclusion**

Molecular imprinting was proposed for the production of nanoparticles capable of modulating enzymes of the MMP family for restoring the correct MMPs regulation in the cardiac microenvironment. This study aims to underline the importance of a comprehensive study, using a large and synergetic set of analyses and methodologies, to better explore and imitate the complex interactions between engineered nanosystems and native tissue for progress in myocardial regeneration.

Extracellular vesicles as IncRNA-H19 carriers to the cardiovascular system

Andreia Vilaça¹,²,³, Marida Sansonetti⁵, Hugo Fernandes⁴,¹, Leon de Windt², Lino Ferreira⁴,¹

¹ University of Coimbra, Centro de Neurociências e Biologia Celular, Coimbra, PT; ² Maastricht University, Department of Molecular Genetics, Maastricht, NL; ³ Maastricht University, CARIM School for Cardiovascular Diseases - Faculty of Health, Medicine and Life Sciences, Maastricht, NL; ⁴ University of Coimbra, Faculty of Medicine, Coimbra, PT; ⁵ Hannover Medical School, Institute of Molecular and Translational Therapeutic Strategies (IMTTS), Hannover, DE

Introduction

Long non-coding RNAs (lncRNAs) have increasingly been reported as major epigenetic regulators of gene expression within the cardiovascular system, and are therefore very attractive as drug candidates or targets [1]. They are >200nt long and can fold into complex 3D structures, a feature usually required to exert their biological function. These characteristics complicate chemical RNA synthesis as well as intact and functional RNA delivery. Extracellular vesicles (EVs) have been shown to naturally contain lncRNAs [2] and to successfully deliver these to the cardiovascular system [3], mediating tissue regeneration [4]. Moreover, previous studies have shown that lncRNAs can be loaded in EVs following donor cell transfection and transferred to recipient cells [5]. However, whether different splice variants of a given lncRNA can be located within EVs and how recipient cells uptake them remains elusive. Thus, in this work, we aimed at identifying different splice variants of a given IncRNA inside EVs and their uptake by major cardiac cell types.

Experimental Methods

This work focused on the lncRNA-H19, known to participate in several biological processes involved in cardiac repair upon delivery by EVs. We overexpressed the mouse H19 gene in human mesenchymal stem cells (WJ-MSC) for 48h, after which we collected the EVs and parental cells. Expression of the IncRNA-H19 splice variants (variants 201, 202, 203, 204, 205 and 207, i.e. 6 out of 7 known splice variants) in the EVs or the parental cells was assessed by RT-qPCR. Subsequently, both PKH67-labeled native EVs or unlabeled H19-EVs were used to treat cultures of neonatal mouse cardiomyocytes or fibroblasts and mouse aortic endothelial cells (MAECs) for 4h to evaluate the uptake of EVs by each cell type through confocal microscopy and the expression of the different splice variants by RT-qPCR. To confirm the functional transfer of lncRNA-H19 from the EVs, we treated MAECs with H19-EVs or vector-EVs and assessed migration (via wound closure assay) and angiogenesis (via tube formation assay) profiles for 12h. Finally, we evaluated the EV tropism on rat cardiac slices by incubating them with PKH67-labeled EVs for 4h or 24h and evaluating the PKH67 internalization in cardiomyocytes and endothelial cells through immunohistochemistry.

Results and Discussion

Our results showed that H19-transfected WJ-MSCs express all analyzed splice variants of IncRNA-H19 and that a similar expression profile was seen in the EVs collected from these cells at the same timepoint. We further demonstrate that EVs are uptaken by the major three cardiac cell types and that all analyzed splice variants, with the exception of H19-207, increase following H19-EV treatment in all cell types. Moreover, we show that transfection of MAECs with H19-EVs significantly (p<0.05) accelerated the angiogenic response of these cells, resulting in a >10% increase in the total tube length and in a >20% increase total number of junctions, compared to control. In the wound closure assay, H19 did not seem to improve basal EV function, since both H19-EVs and vector-EVs elicited a strong enough response to match that of the positive control (bFGF). In this case, all conditions tested significantly (p<0.05)
decreased wound area, relative to untreated MAECs. Finally, analysis of EV tropism in cardiac slices indicates that the EVs are quickly internalized and processed by cardiomyocytes and endothelial cells. We further noted that EVs accumulate preferentially in the cells layering the surface of the cardiac slice but they are also found in deeper cell layers, albeit at lower amounts.

**Conclusion**

Collectively, our results indicate that different splice variants can be loaded into EVs. These are readily uptaken by different cardiac cell types inducing relevant biological functions. This study encourages the use of EVs for cardiac delivery of IncRNAs and paves the way for personalized splice variant delivery, particularly interesting in the context of disease.

Magneto-responsive Core-shell Microbeads for Engineering Peristalsis and Alveolar Breathing In-vitro

Ludovica Cacopardo, Nicole Guazzelli, Arti Ahluwalia

University of Pisa, Pisa, IT

Introduction
Physiologically relevant in-vitro models need to reproduce both structural and mechanical features of the in-vivo environment. 3D scaffolds and cell spheroids are emerging as powerful tools to replicate three-dimensional structures. While, bioreactors are employed to apply uniaxial or biaxial stretching to cell monolayers. However, despite the complexity of these systems, to date, the replication of multidirectional (radial) three-dimensional (out of plane) stretching is a challenge [1, 2].

Here, we present a new bioprinting strategy to obtain core-shell structures, able to replicate the structure and motility of the intestinal and alveolar barrier thanks to magneto-responsive materials (Figure 1). In the case of the alveoli the air-containing beads will be embedded in a magneto-responsive septum-like gel able to mimic the in-vivo deformation mechanism. The core-shell structures were characterised as a function of different extrusion velocities, while deformation was evaluated as on the base of different magnet combinations and magnetite nanoparticle (NP) concentrations.

Experimental Methods
A core-shell microbead (COSMIC) generator was designed and fabricated using commercial coaxial needles (16-26 and 19-26 Gauge) connected with two syringes, which are actuated with two stepper motors. The extrusion velocity is controlled via computer thanks to a graphical user interface. The core-shell structures were characterised using 1 and 2% w/v alginate in the shell and i) 1 - 2 % w/v FITC-alginate (1:100 w/w, Creative PEGWorks, USA), ii) air or iii) 0.1% and 1% w/v pluronic-127 solution in the core. FITC-alginate was used for imaging purposes only, i.e. it does not affect bead extrusion.

A 0.1 M calcium chloride (CaCl₂) solution was placed under the needle to allow alginate crosslinking. Spheres dimension was quantified in function of different relative core/shell extrusion velocities (10, 20, 40 µL/s) using brightfields and fluorescence images (Olympus, Japan) and the Image-j software.

Cell viability tests were performed using Caco-2 cells with an encapsulation density of 1M/mL. All reagents were purchased from Sigma-Aldrich (Milano, Italy), unless differently specified.

Results and Discussion
The obtained diameters range from about 700 to 1700 µm for the core with a shell thickness ranging from about 90 to 500 µm. In the beads with a solid FITC-alginate core, the best results in terms of distinction between core and shell were obtained for shell extrusion velocity higher than core velocity. For instance, Figure 2a show a bead obtained using the following velocities: core at 20 µL/s and shell at 40 µL/s (c20s40). Differently, for the air core, the best results were obtained at for core extrusion velocity higher than shell velocity (Figure 2b: c40s10). In the case of the liquid core, good results were obtained for all the velocities combinations. However, core-shell distition was more defined in the case of higher pluronic concentrations.
The best deformation performance was obtained with a combination of the 10 and 20 mm magnets with strain levels around 7%. No significant differences were observed as a function of the NP concentration. Indeed, despite the higher magnetic responsivity, increasing NP concentration may result in less compliant structures.

Finally, cell testing confirmed the cytocompatibility of the encapsulation procedure, showing that our strategy is suitable to obtain cell-laden core-shell structures.

**Conclusion**

In conclusion, the main advantage of our strategy is the combination of structure and 3D stretching, which, to the best of our knowledge, has not been implemented in-vitro. Thus, COSMIC represents a step further towards the definition of physiologically relevant in-vitro models, which improve the translation between research and clinical applications and also have the potential to reduce animal tests as required by EU directives.

The fabrication and characterisation of the septum-like gel and the design of an automated stimulation system based on electromagnets are on-going. Further developments foresee the evaluation of the 3D structure and of the stretching effects on cell morphology, organization and polarization.

Temporal changes in the secretome of microgel-entrapped vascular cells during in vitro priming improve their angiogenic potential

Ana L. Torres1,2, Sílvia J. Bidarra1,2, Daniela P. Vasconcelos1,2, Judite N. Barbosa1,2,3, Eduardo A. Silva4, Diana S. Nascimento1,2,3, Cristina C. Barrias1,2,3

Introduction
Strategies to promote tissue revascularization are central for tissue engineering and regenerative medicine. We previously reported the design of microgels that guided the assembly of entrapped outgrowth endothelial cells (OEC) and mesenchymal stem cells (MSC) into primitive vascular beds [1]. This system presented high angiogenic/vasculogenic potential upon transplantation in mice, standing out as an attractive strategy for minimally invasive therapeutic vascularization [2]. Along in vitro culture, cohesive vascularized microtissues were formed, with capillary-like networks enveloped in endogenous ECM. While dynamic cellular alterations associated with in vitro vascular morphogenesis are still elusive, they are known to include changes of the cells secretome that will affect their therapeutic potential. Notably, most clinical trials for cardiovascular cell therapies focused on the possible benefits of paracrine modulators, rather than on cells ability to directly participate in neo-tissue formation. While several studies have reported the paracrine effects of MSC and endothelial cells [3,4], the secretory activity of cocultured cells remains poorly studied. Herein, we evaluated how dynamic changes of the secretome of microgel-entrapped vascular cells during culture affect their in vitro/in vivo angiogenic and inflammatory potential.

Experimental Methods
OEC and MSC were entrapped in RGD-alginate microgels as described [1] and cultured for 14 days. Conditioned media (CM) from in vitro cultured microgels were collected at days 1 and 14 for analysis. The levels of matrix metalloproteinases (MMP) were quantified by gelatin zymography, and migration/invasive potential was probed by microgel entrapment in fibrin gel. Angiogenesis-related proteins were probed by multiplex analysis. The in vivo angiogenic potential of CM was analyzed using chick embryos chorioallantoic membranes (CAM) assay. Cytokine composition and in vivo inflammatory profile of primed-microgels CM were probed by multiplex-cytokine analysis and an air-pouch mouse model, respectively. To evaluate response to pro-inflammatory conditions, cell-laden microgels were pre-conditioned with CM from lipopolysaccharide (LPS)-activated macrophages. Then, microgels were incubated for 24h in basal medium and CM were collected for multiplex analysis.

Results and Discussion
During in vitro maturation (from day 0 to day 14), cells in microgels remodeled the original alginate hydrogel to create their own niche, forming ECM-rich microtissues permeated by endothelial capillary-like networks. Maturation enhanced MMP2 and MMP9 secretion, which may help implanted cells to proteolytically invade host tissues and undergo tubulogenesis in the external milieu, as suggested by the fibrin assay. The release of multiple pro-angiogenic factors with proven ability to promote EC survival/function and blood vessel formation was also enhanced, suggesting that in vitro maturation translated into a more pro-angiogenic secretome, which was confirmed in vivo by the CAM assay. Multiplex analysis of cytokines and the air-pouch model were used to investigate changes in the in vitro/in vivo inflammatory profile of cells secretome, but no significant differences were observed for non-primed (day 1) vs. primed cells (day 14). In a clinical setting, microgels should be locally delivered into injured tissues, where the pro-
inflammatory milieu may induce further alterations of entrapped cells secretome. Significantly, upon pre-conditioning with CM from LPS-activated macrophages, cells in matured microgels (day 14) were clearly more responsive than the control (day 1). Overall, they adopted a more pro-angiogenic profile, with increased or de novo expression of several angiogenesis-related proteins. Also, they showed de novo secretion or up-regulation of different cytokines, which may reflect on their immunomodulatory potential.

**Conclusion**
The secretome of microgel-entrapped vascular cells dynamically changes along in vitro culture, as cells undergo morphogenesis into primitive vascular beds. Globally, the secretome of matured microgels presented improved angiogenic potential and altered immunomodulatory properties, which may partially explain their better angiogenic/vasculogenic potential upon transplantation.

Introduction
Pluripotent stem cells-derived organoids hold great potential for tissue engineering and drug testing purposes. However, organoid production is characterized by batch-process techniques that associate with artisan, labor-intensive, and low throughput production processes.1–3 Microfluidic technology offers solutions for improved production of cellular aggregates in terms of quality and production rate, which can be achieved via microfluidic encapsulation of cells in hollow core-shell microgels.4 We therefore hypothesized that microfluidic droplet generation could also be leveraged to realize high throughput production of pluripotent stem cell-derived organoids. Advantageously, we recently invented In-Air microfluidics, which allows the ultra-high throughput microfluidic production of micromaterials in an off-chip manner without the use of oils and surfactants.5 We here report that hollow core-shell microgels generated with In-Air microfluidics allowed for the production of embryoid bodies, which autonomously transformed in cavitated organoids that committed subsequently to the mesodermal and myocardial lineage.

Experimental Methods
We developed a novel In-Air microfluidics setup for the production of hollow core-shell microgels, which consisted of a three nozzle design (Figure 1a). The first microjet was composed of a solution containing 10% dextran and 0.05 M CaCl2 and was actuated with a piezoelectric actuator (5 Vpp, 5 kHz) (figure 1b). The second microjet contained a solution of 0.2% alginate and 10% (v/v) ethanol (EtOH) which encapsulated the droplets of the first microjet. The third microjet contained a solution of 0.2 M CaCl2 and 55% (v/v) EtOH which encapsulated the droplet containing the solutions of the first and second microjet. The resulting layered droplets were subsequently captured in a 0.1 M CaCl2 collection bath. This process allowed for the inside-out and outside-in crosslinking of the alginate shell, resulting in the monodisperse production of shape-stable hollow core-shell microgels with ~200 µm diameter and ~10 µm shell thickness (Figure 2a) at flow rates of over 3 ml/min. Human embryonic stem cells genetically modified with a dual-fluorescent reporter (i.e., MESP1/NKX2.5 and NKX2.5/ α-Actinin) were encapsulated at 0.5–10×106 cells/ml (Figure 2b). Cell-laden microgels were collected in a surplus of collection medium, which guaranteed that the EtOH concentration within the core consistently remained <1%. Embryoid body formation cells was achieved by culturing in E8 stem cell medium, and functional myocardiac organoid formation was achieved using BPEL differentiation medium. Embryoid bodies and cardiac organoids were analyzed using bright field microscopy and various modes of fluorescent confocal microscopy.

Results and Discussion
To allow for shape-stable hollow core-shell microgel formation, material concentrations and flow rates were optimized. Using different nozzle sizes (50/100/150 µm), monodisperse hollow core-shell microgels of various sizes (i.e., 80-300 µm in diameter) could be produced. By adjusting the frequency of the piezoelectric actuator, the number of cores per particle could be controlled (i.e., 1, 2, or 3 cores per particle). Moreover, by using the alginate shell as a scaffold material, it was possible to produce photocrosslinkable PEGDA hollow core-shell microgels, as well as enzymatic crosslinkable tyramine-conjugated dextran hollow core-shell microgels. In-air microfluidic encapsulation
of various human pluripotent stem cells (i.e., embryonic stem cells) associated with viabilities of >95% immediately upon encapsulation. Within 24 hours, the microencapsulated cells aggregated into embryoid bodies, which continued to be metabolically active and proliferate for at least 14 days of culture. Remarkably, the microencapsulated embryoid bodies cavitated and formed organoids in a fully self-instructed and autonomous manner (Figure 2c-e) while remaining positive for Sox2 and Oct3/4 (Figure 2f-h). Upon differentiation, the human embryoid bodies initially underwent mesoderm transition within four days of culture (Figure 2i) and then committed to the myocardial lineage. After 7 days of culture, cardiomyocytes were positive for NKX2.5 (Figure 2j), and showed positive for α-Actinin markers after 14 days (Figure 2k), resulting in cardiac organoids that displayed self-induced synchronized cardiac contractions.

**Conclusion**

Hollow core-shell microgels generated with In-Air microfluidics allowed for the production of human embryoid bodies that autonomously transformed in cavitated organoids, which could be triggered to become functional cardiac organoids. We anticipate that the facile, high-throughput, and clean nature of our platform can facilitate upscaled investigations for developmental studies, cell therapies, and drug screens.

Extracellular matrix viscoelasticity and its impact on cells

Ovijit Chaudhuri

Stanford University, Department of Mechanical Engineering, Stanford, US

The extracellular matrix (ECM) is a complex assembly of structural proteins that provides physical support and biochemical signaling to cells in tissues. Over the last two decades, studies have revealed the important role that ECM elasticity plays in regulating a variety of biological processes in cells, including stem cell differentiation and cancer progression. However, tissues and ECM are often viscoelastic, displaying stress relaxation over time in response to a deformation, and viscoplastic, exhibiting irreversible deformations in response to mechanical stress. We have been investigating the impact of ECM viscoelasticity on cells. Our approach involves the use engineered biomaterials for 3D culture, in which the mechanical properties can be independently modulated. In this talk, I will discuss our recent findings on how matrix viscoelasticity regulates the migration stem cells and cancer cells, and breast cancer progression.

Introduction
The advancement of biofabrication techniques, including 3D bioprinting, has enabled the development of more representative and physiologically relevant disease models, such as in cancer research. In breast cancer, various stages of tumor development and progression are promoted by adipose tissue, an important part of the tumor microenvironment. Therefore, in this study, we employed human adipose-derived stromal cell (ASC) spheroids as building blocks for adipose microtissues to establish a 3D-printed breast cancer model in which crucial aspects of the interplay between adipocytes and breast cancer cells can be recapitulated.

Experimental Methods
Cell culture; 3D cell culture; preparation of hyaluronic acid-based hydrogels; analysis of spheroid sedimentation behavior; determination of shear viscosity; 3D bioprinting; adipogenic differentiation; quantification of intracellular triglyceride and DNA content; co-culture; qRT-PCR; viability assay; detection of secreted proteins; (immuno-)histochemistry

Results and Discussion
First, we focused on the generation of ASC spheroids on a large-scale for use in an extrusion-based bioprinting setup. A system based on agarose molds was applied to obtain 256 spheroids per well, i.e., a total of 3072 spheroids per 12-well plate within 48 h in a highly controlled manner with a regular round shape and reproducible size. Spheroids composed of 2500 cells (diameter of 228 µm ± 22 µm) were then used to optimize the printing process in terms of homogeneous spheroid distribution and spheroid viability. Spheroids were dispersed in a solution of thiol-modified hyaluronic acid (HA–SH), which was UV-crosslinked to stable hydrogels with allyl-modified poly(glycidol) (P(AGE-co-G)). The addition of 1 wt.% unmodified high molecular weight HA (hmHA) increased bioink viscosity improving printability and, at the same time, decreased spheroid sedimentation during printing and UV-crosslinking, resulting in a distinctly more homogeneous spheroid distribution in the final constructs. Analysis of the influence of different printing process parameters on the viability of ASC spheroids revealed nozzles with an inner diameter of at least 330 µm and a printing pressure of 1 bar to be most suitable for spheroid printing, as shown by viability assays. To assess whether the printing process impairs the adipogenic differentiation capacity of the spheroids, adipogenesis in printed and cast constructs was compared. Histological and quantitative detection of accumulated triglycerides after 21 days revealed substantial adipogenic differentiation, compared to non-induced controls. These findings were corroborated by strongly elevated expression levels of adipogenic marker genes such as PPARγ, C/EBPa and FABP4 in differentiated constructs. Furthermore, extracellular matrix (ECM) deposition of induced versus non-induced spheroids was immunohistochemically evaluated. The development of a tissue-specific ECM is considered an important feature in 3D tissue constructs, since, in addition to providing physical support, the ECM actively contributes to the behavior of the cells and the complex interaction with their environment. Characterization of adipogenically differentiated spheroids showed an ECM composition resembling adipose tissue, with highly elevated...
expression of laminin and collagen IV, two main components of the adipocyte basement membrane, as well as enhanced collagen I and collagen VI expression, along with a marked reduction of fibronectin, as compared to non-induced controls. In all experiments, no significant differences of the differentiation capacity between printed and cast constructs were observed. Subsequently, these established adipose microtissues were implemented in a printed 3D breast cancer model as a proof-of-concept study. A tumor compartment consisting of an invasive tumor cell line (MDA-MB-231) was printed on top of the adipose tissue construct using the same HA-based hydrogel as bioink. The resulting co-constructs were then cultured for a further nine days. Histological and quantitative assessment of lipid storage revealed a considerable reduction of lipid content in the adipose microtissues upon co-culture with MDA-MB-231 cells, as compared to the monoculture control. Immunohistochemical analysis of major ECM components and quantitative assessment of the respective staining demonstrated a distinct ECM remodeling with increased collagen I, VI and fibronectin expression in the co-cultured adipose microtissues.

**Conclusion**

Taken together, our printed co-culture model allowed us to investigate characteristic cancer cell-induced alterations in the adipocyte phenotype also observed in vivo, i.e., reduction of lipid content and remodeling of the adipose ECM. In future studies, the use of advanced bioinks that support tumor cell migration as well as the inclusion of other cell types may contribute to further improve the biofabricated 3D model and elucidate the complex cell-cell and cell–matrix crosstalk within the tumor microenvironment.

Introduction
The interaction between cells and materials is a determining factor for the efficacy of cell-based products and therapies. Cell-matrix interactions are essential to transduce biomechanical cues that control cellular functions including migration, proliferation, apoptosis, metabolism, and differentiation.[1] Engineered living tissues often emulate these interactions by endowing biomaterials with constitutively active bioligands such as RGD-type moieties, which challenges control over cell fate and associates with a strong inflammatory response upon implantation.[2] Here, we report on a method to tether intrinsically non-cell-adhesive biomaterials to cells via discrete inducible on-cell crosslinking (DOCKING). This method crosslinks tyramine-functionalized macromolecules to tyrosine residues that are naturally present in extracellular protein domains via an enzyme-mediated oxidative reaction. In short, DOCKING is a bio-inspired and cytocompatible cell-material tethering method that enables the formation of intrinsically non-cell-adhesive yet mechano-instructive biomaterials eliciting a minimal inflammatory response, which primes it as a promising new strategy to control interactions between cells and materials.

Experimental Methods
To visualize DOCKING, mesenchymal stem cells (MSCs) and 3T3 cells were labeled with tyramide-AF647 by incubation with 3 U/ml horseradish peroxidase (HRP) and 0.3 mg/ml H2O2 in PBS. MSCs were individually tethered within 3D Dex-TA microneches using a previously reported microfluidic encapsulation system.[3] Hydrogels' stiffness was determined by nano-indentation with an atomic force microscopy (JPK NanoWizard) combined with inverted optical microscopy (Zeiss Axio Observer Z1). Viability and metabolic activity of cells was analyzed by staining with 2 µM calcein AM (live), 4 µM EthD-1 (dead), and 0.5 mg/ml MTT (metabolically active) in PBS and visualization using brightfield and fluorescence microscopy (EVOS FL). Adipogenic differentiation was analyzed using Oil-Red-O staining. Osteogenic differentiation was analyzed using Alizarin Red S staining. For transcriptome analysis, MSCs from three different human bone marrow donors were tethered and cultured in soft and stiff Dex-TA microgels for sixteen hours, then cultured for eight hours in bipotential differentiation medium, and subsequently lysed and sequenced. To identify cellular protein targets of DOCKING, biotin-tyramide was tethered to MSCs, isolated from cell lysates using a pull-down assay, and analyzed using liquid chromatography combined with mass spectrometry (LC-MS). Dex-TA gel disks were formed by mixing 100 mg/ml Dex-TA, 3 U/ml HRP, and 0.3 mg/ml H2O2 in PBS. Dex-TA-RGD hydrogels were formed by adding 2.2 mM RGD-Tyr to the hydrogel premix. To compare host response, hydrogel disks were subcutaneously implanted in C57BL/6 mice for four weeks.

Results and Discussion
Here, we report on the discrete inducible on-cell crosslinking (DOCKING), of non-cell-adhesive biomaterials onto cells via oxidative crosslinking of phenolic moieties. Specifically, we demonstrated that tyramine-functionalized dextran (Dex-TA) could be enzymatically crosslinked with tyrosine-rich extracellular fibronectin, thereby forming
pericellularly tethered hydrogel microniches. The intrinsically bio-inert and non-cell-adhesive Dex-TA hydrogel elicited a reduced inflammatory response upon implantation in mice as compared to its RGD-modified cell-adhesive counterpart. Importantly, enzyme-mediated oxidative crosslinking enabled the controlled mechanotransduction from non-cell-adhesive Dex-TA hydrogel to encapsulated cells via cell tethering. As a proof-of-concept, we leveraged an advanced microfluidic system to tether individual mesenchymal stem cells (MSCs) within micrometer-sized hydrogel matrices (i.e., microgels) using DOCKING to control MSC function and fate at single cell resolution. Through timed modulation of microgel stiffness, we could program the lineage commitment of microencapsulated stem cells, thereby indicating DOCKING-mediated mechanotransduction in a bioligand-free material. Proteome and transcriptome analyses revealed that DOCKING predominantly targets proteins associated with the cellular meta-adhesome, and that 3D on-cell-tethered biomaterial mechanics can induce early onset cell-fate-programming mechanotransduction pathways independent of cell size changes.

Conclusion
In summary, DOCKING provides a unique method to discretely tether cells to molecules or materials, including those that are otherwise non-cell-adhesive. This novel method opens up numerous opportunities in the biomedical field that, for example, benefit from mitigating the chronic inflammation associated with conventional bioligand-functionalized materials as well as providing novel strategies to mechanically program and study (stem) cells in a 3D, temporally controlled, and single-cell-resolution manner.

A biomimetic alveolar in vitro model to study lung cancer

Chiara Tonda-Turo, Michela Licciardello, Gianluca Ciardelli

Politecnico di Torino, Department of Mechanical and Aerospace Engineering, POLITOBIOMED LAB, Torino, IT

Introduction
Lung cancer, also known as lung carcinoma, is a malignant tumour characterized by uncontrolled cell growth in the specific tissue of respiratory system [1]. The lack of new therapies to treat lung carcinoma requires experimental models that can reproduce the behaviour of healthy and pathological tissues [2] to be applied in the study of pathology development. Here, we describe the implementation of a novel technological biomimetic platform to mimic both the multicellular composition of the alveolus and its vascular network, as well as the composition and structure of extracellular matrix. Our aim is to design and fabricate new structures, composed by biomaterials, that resemble the alveolar wall structure.

Experimental Methods
The basement membrane layer morphology was reproduced through electrospinning of a gelatin/polycaprolactone (GL/PCL) solution. Nanofibrous GL/PCL membranes were obtained after optimizing the electrospinning process and solution parameters. HULEC-5a cells (human lung microvascular endothelium cells) and A549 cells (human alveolar basal epithelial cells) were cultured on one side of the GL/PCL membrane respectively, to recreate the alveolar barrier. On the other hand, the connective tissue layer was replicated through bioprinting (ROKIT InVivo, Rokit, Seul) of collagen type I hydrogel loading human lung fibroblasts (MRC-5 cell line). Bovine collagen powder was dispersed in 0.5 M acid acetic solution, then the acid pH of solution was neutralized by adding 1M NaOH to induce the sol-gel transition. Rheological characterization was carried out to evaluate the viscoelastic properties of the material. MRC-5 cells were loaded into the hydrogel prior to gelification and their viability was monitored. Cellularized hydrogels were then printed on the GL/PCL membranes and the printing parameters were optimized in order to obtain a stable gel structure. The cellularized 3D structure was cultured both in static and dynamic (Livebox2 bioreactor, IVtech srl) conditions.

Results and Discussion
Nanofibers morphology was characterized by scanning electron microscopy (SEM) and the GL/PCL mats obtained by electrospinning process appear to be characterized by randomly oriented defect-free nanofibers (fig. 1A). Cyclical traction tests were performed to evaluate the effect of the physiological breathing motion (10% of strain at 0.2 Hz) on membranes mechanical properties demonstrating good fatigue resistance during the 40 tested cycles. In vitro cells tests confirmed the adhesion and proliferation of HULEC-5a and A549 cells on the membranes and each cell density was optimized to achieve a complete coverage of the mats to recreate a biomimetic alveolar barrier. The printing of collagen hydrogels was achieved extruding the sol-phase material from the syringe (kept at 4°C to avoid the collagen gelation) onto the platform at 37°C. Cellularized collagen hydrogels were obtained showing a high survival of MRC-5 encapsulated (fig. 1B). Finally, a complex 3D model of the multilayered architecture of the physiological alveolar structure was obtained by adding the cellularized hydrogel between the endothelium and the epithelium layers. Obtained results suggest that the realized alveolar in vitro model can be applied as a biomimetic environment recapitulating the alveolar structure to study pathology progression and to test novel treatments for lung cancer. Furthermore, the developed structures were integrated into a microfluidic system in which the physiological microenvironment could be reproduced with higher fidelity thanks to dynamic and three-dimensional cell culture conditions.

Conclusion
A biomimetic in vitro alveolar unit model was implemented mimicking the alveolar wall structure, physiologically characterised by an epithelium layer and a connective layer rich in capillaries. The developed model can be upgraded by culturing cancer derived cells to study pathology progression and predict drug efficacy.

Tissue engineered hybrid scaffold with relevant stiffness and extracellular matrix (ECM) as long-term in vitro model for low-grade serous ovarian carcinoma (LGSOC)

Elly De Vlieghere\textsuperscript{1,2}, Eva Blondeel\textsuperscript{1,2}, Nathan Carpentier\textsuperscript{4}, Sebastian Riemann\textsuperscript{3}, Wim Ceelen\textsuperscript{3,2}, Sandra Van Vlierberghe\textsuperscript{4}, Olivier De Wever\textsuperscript{1,2}

\textsuperscript{1} Ghent University, Department of Human Structure and Repair - Laboratory of Experimental Cancer Research, Gent, BE; \textsuperscript{2} Ghent University, Cancer Research Institute Ghent (CRIG), Gent, BE; \textsuperscript{3} Ghent University, Department of Human Structure and Repair - Laboratory of Experimental Surgery, Gent, BE; \textsuperscript{4} Ghent University, Polymer Chemistry and Biomaterials Group, Centre of Macromolecular Chemistry, Gent, BE

Introduction
Low-grade serous ovarian carcinomas (LGSOC) are known as a silent killer as they have formed peritoneal metastasis before they are diagnosed. Currently, LGSOC patients receive the same treatment as high-grade (HG)SOC, despite poor treatment responsiveness. To provide LGSOC patients with an adequate therapy, clinically relevant models recapitulating the tumor environment are needed.

Experimental Methods
Hybrid scaffold: The scaffolds are produced by extrusion-based 3D-printing AUP\textsuperscript{[1]} with the 3D Bioplotter (SysEng Bioscaffolder, Hünxe, Germany) to have similar dimensions in swollen state as a peritoneal metastasis nodule. The scaffolds are cylinder-shaped with 5mm diameter, 4mm height, 500µm pore size and 300µm strut diameter. Plasma treatment improves interaction with a methacyrylamide-modified gelatin (2w/v% GelMA solution containing 2 mol% Irgacure 2959 relative to the amount of methacrylamide moieties.) coating and enables cell interaction. The scaffolds are seeded with a mixture of cancer cells and cancer associated fibroblasts (CAFs) and type I collagen gel (2mg/ml).\textsuperscript{[2]} In vitro cultures were monitored by phase-contrast microscopy and bio-luminescent imaging (BLI).

Results and Discussion
AUP scaffolds with 3 different PEG backbones (4, 8 and 10 kDa) were printed. Printing conditions were optimized so each scaffold has the same dimensions (Ø and h 5 mm, 125 mm\textsuperscript{3}, pores +/- 500 µm). Stiffness was measured by indentation, the lower linear modulus was used to compare animal and human tissue with the printed scaffolds. 8 and 10 kDa scaffolds have a similar stiffness as normal tissue while 4 kDa scaffolds mimic the tumor stiffness (fig 1A-B).

LGSOC scaffolds were evaluated as long term in vitro culture model for cancer combined with CAFs. With BLI (fig 2A) we evaluated the viability by bioluminescent imaging (BLI) of the cancer cells independent of the CAFs while being in co-culture. Long term (1 month) follow-up shows that LGSOC cells responded to trametinib, however low activity remains (fig 2B). These cells have the possibility to become resistant to treatment.

Conclusion
Hybrid scaffolds mimic the tumor and its environment on a cellular and biophysical level. The 3D co-cultures allows long-term therapy evaluation, on cancer cells and CAFs. In addition, this long-term evaluation allows to investigate the role of the tumor environment on therapy resistance.

**Introduction**

Cell migration and invasion are hallmarks of development and cancer. For the ability of cells to migrate, dynamic and spatially regulated changes of the cytoskeleton, cell-cell adhesion and cell-extracellular matrix (ECM) interaction must occur. Brain tumor cells sense ECM structures as migratory cues, where they become polarized by reorganizing the actin cytoskeleton to facilitate both a protrusive leading and a contractile trailing edge. They are attracted to white matter tracts, formed by axons organized into aligned bundles, but also within the perivascular spaces of blood vessels, where they migrate and metastasize to surrounding brain regions. One explanation for the brain tumor cell movement is the high mechanical rigidity of axons and blood vessels. Glioblastoma multiforme (GBM) arise from glial cells in the central nervous system and represent the most common and aggressive human brain tumors. Malignant progression results in an extensive invasion throughout the brain. GBM tumors show an impassive response to current therapeutic approaches predicting a poor survival for patients. Thus, it is crucial to increase our understanding of tumor behavior in the microenvironment to improve therapeutic strategies by establishing new tumor models. Synthetic biomaterials, which are commonly employed in tissue engineering, are a valuable tool for modeling 3D tumor growth, migration and invasion. Melt electrowriting (MEW) allows to directly write or print complex multi-scaled architectural structures made of biodegradable substrates, such as poly(ε)-caprolactone (PCL). Therefore, aligned MEW-fiber constructs are capable of recapitulating topographical aspects of the in vivo environment, providing important material cues for 3D tumor cell modelling. A key player involved in regulating migration and invasion is the Phosphatase and Tensin Homolog (PTEN) protein. PTEN is a tumor-suppressor antagonizing the oncogenic Phosphoinositide 3-kinase (PI3K) pathway. PTEN loss of function results in constitutively active PI3K signaling and induces cell proliferation, as well as migration. PTEN loss of function mutations, are one of the most common genetic alterations in GBM and are directly associated with a malignant transformation. Interestingly, PTEN was also frequently found mutated in brain metastases descending from breast cancers.

**Experimental Methods**

Various designs of PCL scaffolds were 3D printed using MEW. PCL-scaffolds were functionalized with laminin to mimic axons and blood vessels to study GBM and breast tumor cell migration. Using live cell imaging we investigated scaffold cell attraction, adhesion, migration speed and cell movement along PCL-scaffold tracts. Scanning electron microscopy (SEM) and immunocytochemistry were performed to visualize the 3D cellular morphology on scaffolds. Additionally, we identified the genes involved in the tumor cell migration using RNA-sequencing and quantitative real-time polymerase chain reaction (qRT-PCR).

**Results and Discussion**

In this investigation we employed different 3D MEW printed PCL-scaffolds to mimic in vivo-like migratory cues of the brain to study the migration of GBM and breast tumor cells. We found similar biological behaviors in terms of...
scaffold attraction, adhesion, 3D cell shape, migration speed, and cell movement along PCL- scaffold tracts. We determined PTEN as one of the main factors for cell adhesion and migration, which we verified with different cell lines and PTEN genotypes. In addition, using RNA-sequencing of 2D and 3D - PCL GBM cells, we uncovered RHOB GTPase up-regulated in 3D-PCL migration. Inhibitory studies confirmed the role of RHOB in cell migration. Furthermore, we describe a unique PTEN-dependent "alternating morphology" - mechanism shared by migrating GBM and breast cancer cells in live cell imaging, where cells change from a flat to a round appearance with a boosted acceleration rate.

**Conclusion**

Taken together, our data helps to understand, which physical attributes are required for how GBM and breast cancer cells migrate and disseminate within the brain. We present a MEW-based 3D model to study the migratory behavior of brain tumors as well as brain metastases. Furthermore, we unraveled that PTEN and RHOB play a central role in tumor cell migration, which could be of particular interest for the development of new therapeutic approaches to slow down brain tumor progression.

Introduction
Currently, osteosarcoma is the most common bone cancer which mainly affects young people. Surgical resection of tumor followed by chemotherapy for micro-metastasis inhibition constitutes the current standard procedure. However, chemotherapy treatment uses pharmacological agents with the effect of blocking cell proliferation, without any distinction between healthy and cancer cells. In recent years, several studies have focused the attention on Photodynamic Therapy (PDT) or Photothermal treatment (PTT) as minimally invasive therapeutic procedure that can apply a selective cytotoxic activity toward cancer cells [1]. In this context, we propose the use of 2D photothermal transducing agent based on few-layer black phosphorous (2D BP) as an alternative tool for osteosarcoma treatment and report how 2D BP can inhibit cancer cell proliferation and simultaneously to stimulate newly forming bone tissue generation after osteosarcoma resection without PTT. In particular, we have developed 2D and 3D in vitro models to evaluate the efficacy of 2D BP on healthy (HOb) and cancer (Saos-2) cells and we also propose an in vitro co-culture model to study the effect of 2D BP to prevent cancer development in an inflammatory microenvironment.

Experimental Methods
2D BP was obtained by liquid exfoliation process of BP microcrystals. The purity was ascertained by Inductively coupled plasma mass spectrometry (ICP-MS) analysis, the morphological characterization was carried out by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Biological studies were performed by using 2D BP as coating (in vitro 2D model) and solution (in vitro 3D model). In vitro 2D model was used to investigate the selective effect of 2D BP on human healthy (HOb) and cancer cells (Saos-2), with and without PTT, by analyzing cell proliferation, oxidative stress (i.e. Reactive oxygen species- ROS, nitrites levels) and osteogenic differentiation (ALP activity) at day 3 of cell culture. The cell morphology was evaluated by SEM, confocal microscopy (CLSM) and hematoxylin-eosin staining. The effect of 2D BP on inflammatory response through pro and anti-inflammatory cytokine investigations on co-culture model consisting of Saos-2 and HOb, was also investigated. In vitro 3D model was developed by using Matrigel® as support of cell growth. 2D BP solution was injected at different concentrations (5–25–75 µg/mL) in 3D structure. The cell proliferation was evaluated through Alamar blue assay and Ki-67 marker at day3.

Results and Discussion
Our data pointed out that 2D BP induces healthy cell proliferation and inhibit cancer cell proliferation with and without PTT treatment. This behavior was explained by the involvement of 2D BP in the oxidative stress process by different production of nitrites and ROS in both cell lines. Indeed, without PTT treatment, 2D BP coating reduces the ROS and nitrites production in HOb cells suggesting antioxidant properties, meanwhile an opposite effect for Saos-2 was observed (Fig.1A). Furthermore, morphological investigations demonstrated how 2D BP affected cell vitality and morphology. HOb cells showed a good morphology and spreading in the presence of 2D BP, while Saos-2 appeared to lose their characteristic morphology as suffering cells (Fig.1B). Furthermore, it was also demonstrated that 2D BP allows to induce cell proliferation and osteogenic differentiation in basal medium without external growth factors in
HOb by the expression of ALP, an early marker of osteogenesis. Meanwhile, completely metabolic inhibition was observed for Saos-2 cells. The experiments performed on in vitro co-culture model of cancer-related inflammation demonstrated that the anti-proliferative effect of 2D BP is associated to its anti-inflammatory activity. In vitro 3D model demonstrated that 2D BP solution is able to inhibit in higher percentage the tumor cell proliferation (Saos-2) already at 25 µg/mL (Fig.2). This data was confirmed by the inhibition of Ki-67 expression in 3D structures treated by 2D BP 25 µg/mL.

Conclusion
The overall results demonstrated the selective effect of 2D BP on healthy (HOb) and cancer (Saos-2) cells and its property to induce osteogenic differentiation in healthy cells. For the first time, it was demonstrated that 2D BP is able to inhibit in selectively way the proliferation of cancer cells without the use of any chemotherapeutic agents and PTT therapy. These selective effects prompt the application of 2D BP as a highly promising candidate for bone biomedical applications.

S12 | Biocompatibility Testing According to ISO 10993: What are the Changes and What can the Biomaterials Community Learn from it?

Chairs
Marc Bohner
RMS Foundation, CH
Nicola Döbelin
RMS Foundation, Bettlach, CH
James Quinn (YSF)
Queen’s University Belfast, School of Pharmacy, Belfast, GB

Learning Objectives:
Learn the basics of ISO 10993
Understand the importance of literature studies
Learn the basics of a tox assessment (occurring prior to any cell culture test)
Learn from practical examples how to approach biocompatibility testing

The main document used commercially for biocompatibility testing is the ISO 10993 standard.

The recent changes of this standard have introduced what could be called a „pharma touch“ since biocompatibility assessment starts with a thorough analysis of potential leachables and their related toxicity. Systematic literature studies are also highly involved.
ISO 10993 is a series of international standards that provides an extensive framework for biocompatibility assessment of medical devices. Currently the series comprises 22 standards, technical specifications and reports, and guidances addressing all aspects of biocompatibility testing including risk assessment, selection of tests and materials, performance of chemical characterizations, in-vitro and in-vivo tests, as well as evaluation and reporting of test results. While cell culture and animal tests constitute an important pillar in biocompatibility testing, it is a common misconception that the standard series requires such tests to be performed under all circumstances. In fact, it puts a strong emphasis on minimizing the costs and the use of animals for biocompatibility testing. Instead, it advocates the use of existing data whenever possible. For example, instead of conducting a cell culture experiment to assess the cytotoxicity of a product, it may be more efficient and economic to determine the leachable and extractable components of the device, and to assess the cytotoxicity of these components based on data available in literature and databases. Many of the materials used in medical devices today have been extensively tested and a wide range of toxicological data is already publicly available. Hence for many products the cost of in vitro and in vivo testing can be drastically reduced without compromising the safety of the product. This presentation gives an overview of the approaches for biocompatibility assessment of medical devices put forward by the ISO 10993 series.

A comparative study of the hemocompatibility of polymeric and lipidic nanobiomaterials by linked cytokine flow cytometry analysis and cytotoxicity

Valeria Perugini¹, Cheryl Collins¹, Ruth Schmid², Yrr Morch², Isabelle Texier-Nogues³, Martin Brodde⁴, Matteo Santin¹

¹ University of Brighton, Centre for Regenerative Medicine and Devices, Brighton, GB; ² SINTEF, Biotechnology and Nanomedicine, Trondheim, NO; ³ CEA, Leti, Paris, FR; ⁴ OxProtect, Munster, DE

Introduction
Clinically-efficacious drug delivery systems can be obtained by the combination of nanobiomaterials (NBMs) carriers of different composition with specific drugs. Current regulatory guidelines advise the use of methods optimised for the testing of either biomaterials for medical devices or medicines, but they do not ensure the reliable assessment of the safety of more complex NBMs. Therefore, there is a need to develop a Regulatory Science Framework able to establish in a reliable manner the risk/benefit profile of NBMs by the evaluation of their biological responses. In particular, the systemic administration of NBMs requires an accurate study of their hemocompatibility including the overall haemotoxicity and the activation of inflammatory cells (i.e. monocytes/macrophages and granulocytes) and thrombogenicity (i.e. platelet activation). Biomarkers of inflammation include the secretion of cytokines that can be caused either by the activation of the monocytes/macrophages or as an indirect effect of the NBM's toxicity that disrupt cell integrity. LipImage™ 815 (CEA-Leti, France) are lipid nanoparticles containing a fluorescent dye. They have been tested in pre-clinical studies to target tumour cells and could therefore be used for cancer diagnosis. Poly(2-ethyl-butyl cyanoacrylate) (PEBCA) nanoparticles (SINTEF, Norway) have been loaded with the cytotoxic drug cabazitaxel (CBZ) and used in pre-clinical studies to target tumours as a promising treatment for breast cancer.

In this work, the effect of PEBCA and LipImage™ 815 on whole human blood samples is studied by a combination of protein assay, LDH released activities and flow cytometry analysis of released cytokines as a rapid hemocompatibility test for NBMs.

Experimental Methods
Whole heparinised blood was collected from 6 healthy human donors and spiked with NBMs. NBMs were tested for their cytotoxicity (LDH assay) and total protein concentration (Bredford's method) at different concentrations; LipImage™ 815 at 9, 18, 47, 94, and 940 μg/ml. PEBCA ± CBZ at 1, 2, 5, 10, 100 and 1000 μg/ml, 37°C, static conditions, 24h. Human Th1/Th2 cytokine standards (BD™ Cytometric Bead Array, CBA) were reconstituted in assay diluent and incubated for 15 minutes at room temperature (0 – 2500 pg/mL). After incubation, 6 human Th1/Th2 cytokine capture beads were treated with 50 μL PE-conjugated detection antibodies before being mixed with 10 μL plasma/standards diluted in 40 μL of serum enhancement. Two NMB concentrations were considered below and at the ascertained hemocytotoxicity threshold, 25 and 100 μg/ml. Both samples and standards were then incubated for 3 hours. After 3 wash steps with 1 mL of wash buffer, samples and standards were assessed by BD Accuri C6 flow cytometer and results analysed using a specific BD analysis software. Lysing Solution (Beckman Coulter) was added to the LDH positive controls by incubation for 10 min. All cytokine release data were analysed in relation to the cytotoxicity threshold as determined by LDH assay and total protein concentration and statistically analysed by t-test.

Results and Discussion
The results show that neither PEBCA nor Lipimage were toxic below 100 μg/ml. A significant release of LDH was detected from concentrations of 100 μg/ml and above. This corresponded to a significant reduction of the protein...
concentration in the blood supernatant. Protein concentration was gradually reduced by contact with both types of NBMs to 50% upon incubation with NBMs' concentrations of 100 μg/ml and above suggesting the occurrence of protein adsorption of onto their surfaces that may trigger the activation of inflammatory cells. The release of pro-inflammatory cytokines was detected at similar levels at concentration both below (25 μg/ml) and above (100 μg/ml) the ascertained haemotoxicity threshold showing that the combined assay could discriminate between an inflammation caused by cell activation from that originating from a burst release of the cells due to their loss of integrity. Expected individual variations were observed across donors, while the presence of a cytotoxic drug payload appeared to reduce the release of cytokines supporting the interpretation of the data that the release was not caused by a damage of the cell membrane.

**Conclusion**

The present work demonstrates that the combined protein, LDH and cytokine assay of whole human blood incubated with polymeric and lipidic drug nanocarrier has the potential to be a rapid and very informative method to assess the haemocompatibility of NBMs with/without drug payload which can be adopted by regulatory frameworks aiming to assess the risk/benefit profile of NBMs.

Introduction

The incidence of chronic wounds (CW) is growing at an accelerated rate every year. CW are generally characterized by a poor healing. However, wound dressings functionalized with active biomolecules may encourage and instigate healing in CW, playing an active role in wound closure \cite{1}. The introduction of antimicrobial peptides (AMPs) has been considered very promising as an alternative to antibiotics, mainly for their broad spectrum of antimicrobial activity, quick action, and low tendency to induce resistance. Tiger 17 has demonstrated important effects on different phases of wound healing and recruiting macrophages, promoting the proliferation/migration of keratinocytes/fibroblasts to the wound bed \cite{2}. Pexiganan is recognized for its wide spectrum of antimicrobial activity, acting directly on the anionic phospholipids of the bacterial cell membrane, turning the development of resistance less likely. Also, this AMP has reached phase III of clinical trials aiming at evaluating its wound healing properties towards diabetic foot infections \cite{3}. Electrospinning allows the production of polymeric nanomeshes with an intricate and complex network that can be functionalized with these active biomolecules to address specific CW demands via simple, reproducible and cost-effective approaches \cite{4}. Various synthetic and natural polymers have been used in the production of polymeric nanofibrous mats via electrospinning. Poly(vinyl alcohol) (PVA) and cellulose acetate (CA) are polymers well established for their biocompatibility and biodegradability. In blends, PVA provides excellent electrospinability and mechanical stability, while CA confers cellular viability \cite{5}. The present work reports the antimicrobial effect and hemocompatibility of Tiger17 and pexiganan peptides when immobilized onto PVA/CA crosslinked mats.

Experimental Methods

PVA and CA based meshes were prepared through electrospinning at the ratios 100/0, 90/10 and 80/20 %v/v (at 10 wt\% in a solvent system of 75/25 %v/v of acetic acid/distilled water. Optimal conditions for PVA/CA processing were established at 25 kV, feeding rate of 0.8 mL/h and distance between needle and collector of 18 cm. Crosslinking was performed using vapor of glutaraldehyde (GA) at 60°C during 7h. The blending homogeneity of the polymers and the efficiency of the crosslinking process were examined, together with the mats morphology, mechanical stability, permeability and thermal properties using Fourier-transformed infrared spectroscopy (FTIR), scanning electron microscopy, air and water vapor permeability testing equipment, thermogravimetry and a dynamometer. Tiger 17 and pexiganan were anchored to the mats by physisorption and using poly(ethylene glycol)-spacers as a binding agent, respectively. Their presence on the mats was confirmed using sulfosuccinimidyl-4-o-(4,4- dimethoxytrityl) butyrate. The antimicrobial action was followed against Staphylococcus aureus (\textit{S. aureus}) and Pseudomonas aeruginosa (\textit{P. aeruginosa}), the most prevalent bacteria found in CW. Clotting time was established visually by the loss of movement of re-calcified plasma, following the Lee-White method. Platelets’ adhesion and activation were mapped using brightfield microscopy.

Results and Discussion

Page 788 of 2028
PVA/CA nanofibrous mats were successfully produced via electrospinning, with a porous structure made of continuous nanofibers. Electrospun mats were crosslinked with GA vapor at 60°C by promoting the formation of intermolecular acetal bridges between the -OH in PVA and CA and the difunctional aldehyde molecule of GA, as confirmed by the presence of a FTIR peak at 1143 cm\(^{-1}\), attributed to the -O-C-O vibration of the acetal group. After crosslinking, the average diameters of 100/0, 90/10 and 80/20 PVA/CA nanofibers increased from 223, 217 and 194 nm to 200, 238 and 278 nm, respectively. The permeability index values, even on crosslinked mats, registered values above of 82%, being considered quite appropriated for wound dressing applications. With the introduction of CA in the mats, a slight increase in the ultimate tensile strength and on the thermal stability of electrospun mats was detected, being most important after crosslinking. Mats were successfully modified with Tiger 17 and pexiganan. They were found effective against the two bacteria, particularly pexiganan. Tiger 17 was seen to effect more significantly on the clotting time and platelets activation, enhancing them and, therefore, contributing to a potentially quicker wound closure.

**Conclusion**

Overall, preliminary data revealed the potential of the PVA/CA mats modified with the peptides Tiger 17 and pexiganan for applications in CW healing.

Self-assembled fibrinogen nanofibers promote fibroblast adhesion and prevent *E. coli* infiltration

Arundhati Joshi¹, Naiana Suter¹, Stephani Stamboroski¹², Dorothea Brueggemann¹

¹ University of Bremen, Institute for Biophysics, Bremen, DE; ² Fraunhofer Institute for Manufacturing Technology and Advanced Materials, Bremen, DE

Introduction

Fibrinogen has gained enormous attention in tissue engineering since it plays a central role in blood coagulation and is thought to contribute to the early stages of antimicrobial host defense. Specifically, nanofibrous fibrinogen scaffolds hold great promise for applications in personalized regenerative medicine as they mimic the nanoarchitecture of native blood clots and the extracellular matrix. Although manifold factors, such as hydrophobic surfaces, organic solvents or acidic pH, are already known to induce fibrillogenesis of fibrinogen, the fundamental mechanisms of fibrinogen fiber assembly still remain to be elucidated [1]. In contrast to the aforementioned factors, we recently introduced salt-induced self-assembly as a new approach to prepare nanofibrous fibrinogen scaffolds under physiological conditions [2,3]. Here, we present our findings on the interaction of these scaffolds with fibroblasts and *E. coli* bacteria.

Experimental Methods

The self-assembled fibrinogen nanofiber scaffold morphology was characterized with scanning electron microscopy (SEM) and atomic force microscopy (AFM). To evaluate the potential of self-assembled fibrinogen nanofibers for future wound healing applications, we used NIH 3T3 fibroblasts and *E. coli* bacterial cultures as model systems [4]. Adhesion, growth, morphology as well as migration of fibroblasts on the fibrinogen nanofiber scaffolds was analysed using confocal microscopy, SEM and live cell tracking. Interaction of *E. coli* bacteria with fibrinogen nanofibers was studied with image intensity analysis of light microscopy images and spectrophotometric measurements of bacterial cell lysates.

Results and Discussion

Self-assembly with phosphate buffered saline (PBS) solution yielded very dense nanofiber networks that resembled the structure of native fibrin clots, whereas potassium-based buffers yielded sparse and less defined fiber assemblies [2]. Nanofibrous fibrinogen scaffolds assembled in PBS displayed an average thickness of 3 µm and fiber diameters between 100 and 300 nm (see Fig. 1A). Crosslinking with formaldehyde vapour was found to preserve the fiber topography in an aqueous environment (see Fig. 1B) [3].

The nanofibrous scaffolds promoted the adhesion and growth of 3T3 fibroblasts for up to 72 h [4]. Smaller fibroblasts with many short filopodia, less pronounced actin cytoskeleton and elevated cell bodies were observed on nanofibrous fibrinogen (see Fig. 1C), which was in contrast to planar fibrinogen scaffolds produced in the absence of salt. Higher migration velocities of fibroblasts were observed on the nanofibers in comparison to planar fibrinogen. *E. coli* bacteria failed to migrate through the interconnected pores of fibrinogen nanofibers. In particular, the barrier formed by the fibrinogen nanofiber scaffolds significantly reduced bacterial growth in comparison to controls in the absence of fibrinogen scaffolds, mainly due to lack of access to the nutrient-rich agar underneath. Furthermore, SEM analysis revealed that the cell walls of *E. coli* bacteria on fibrinogen nanofibers were considerably damaged (see Fig. 1D).

Conclusion

In conclusion, self-assembled fibrinogen nanofibers formed interconnected porous networks that exhibited very good biocompatibility by supporting cell adhesion and preventing bacterial infiltration. These findings highlight their great
potential as future protein scaffolds for regenerative medicine and provide a good basis for further cell culture studies with other cell types involved in wound repair, such as keratinocytes and blood platelets.

From *in vitro* evolution of new bioactive amorphous calcium ortho/pyrophosphate materials in various acellular/cellular media to *in vivo* animal study

Maximilien Desbord¹, Jérémy Soulié¹, Robin Siadous², Rebecca Landon³, Alice Leroux², Christian Rey¹, Joelle Amedée², Fani Anagnostou³, Christèle Combes¹

¹ Université de Toulouse, Toulouse INP, CIRIMAT - ENSIACET, Toulouse, FR; ² Université de Bordeaux, BioTis Inserm 1026, Bordeaux, FR; ³ Université Paris Diderot, B3OA, Faculté de Médecine Paris Diderot Site Villemin, Paris, FR

Introduction

Amorphous calcium phosphate materials have attracted attention for bone substitution due to their metastability that improves their (bio)chemical reactivity and the subsequent release of active ions and/or dissolution/reprecipitation reactions leading to apatite formation at their surface. Two families of phosphate-based amorphous materials are mainly developed: the phosphate-based glasses that are generally melt-derived and low temperature amorphous calcium phosphates [1, 2]. Recently, we obtained by soft chemistry a new family of mixed calcium orthophosphate/pyrophosphate amorphous materials with structural properties close to those of materials mentioned above [3,4]. It is known that pyrophosphate ions can be hydrolyzed into orthophosphate ones at acidic pHs, at moderate temperature and/or by specific enzymes, alkaline phosphatase (ALP), naturally present *in vivo*, thus contributing to bone neoformation [5]. We aimed at studying for the first time: i) the physico-chemical evolution *in vitro* of such materials including different proportions of pyrophosphate in acellular aqueous media with or without enzymes in a view to control their resorption and biological properties; ii) their *in vitro* cytocompatibility and *in vivo* tissue response in small animal.

Experimental Methods

Mixed calcium ortho- and pyrophosphate amorphous materials of three different compositions (different ortho/(ortho+pyro) ratios, i.e. high, medium and low orthophosphate content) were synthesized by soft chemistry [4]. The evolution tests were carried out at 37°C for 15 days in different aqueous media (simulated body fluid (SBF) solution, Tris buffer with or without ALP) with a solid/ liquid ratio of 1.5 g/L. Materials and media recovered after different evolution times were fully characterized separately by XRD, Raman spectroscopy, SEM and chemical titrations. *In vitro* cytotoxicity and cytocompatibility testings were performed on hBMSCs. Then the most promising material composition was implanted as granules *in vivo* in a critical defect model (rat calvaria) and compared with Activioss™, a 45S5 commercial bioglass.

Results and Discussion

The three amorphous material compositions tested have shown great stability but have all evolved differently in correlation with their initial composition (initial ortho/(ortho+pyro) ratio). The material including the higher pyrophosphate content was the more stable and tended to remain amorphous, while the composition comprising the highest level of orthophosphate evolved into a nanocrystalline apatite analogous to the bone mineral in almost each medium tested. The evolution in the presence of ALP enzymes demonstrated their major role in the evolution of these materials *in vitro*: at day 6 material mass loss and the ortho/(ortho+pyro) ratio in the material were enhanced and directly correlated to the initial proportion of pyrophosphate in the material. The cell study showed that the materials are not cytotoxic and that they are able to activate differentiation of hMSCs and mineralization. Preliminary *in vivo* study testified for higher new bone tissue formed around the material granules than for the commercial bioglass.

Page 792 of 2028
Conclusion
All together these results demonstrated for the first time the *in vitro* and *in vivo* behavior of this new family of amorphous calcium phosphates which thus appeared as promising tunable bioactive bone substitute materials with a resorption and osseo-integration that could be directly controlled by their composition.

Resveratrol-Loaded Nanostructured Lipid Carriers: Evaluation of Antioxidant Properties on ARSACS Patient Fibroblasts

Ozlem Sen¹, Melis Emanet¹,², Stefano Doccini³, Filippo M. Santorelli³, Gianni Ciofani¹

¹ Istituto Italiano di Tecnologia, Smart Bio-Interfaces, Pisa, IT; ² Sabanci University, Sabanci University Nanotechnology Research and Application Center (SUNUM), Istanbul, TR; ³ IRCCS Fondazione Stella Maris, Molecular Medicine for Neurodegenerative and Neuro-Muscular Diseases Unit, Pisa, IT

Introduction
Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is a rare early-onset neurodegenerative disease, which is caused by mutations in SACS gene that encodes the sacsin protein. The sacsin protein localizes to mitochondria, and it is crucial in neurons for normal mitochondrial localization and morphology [1,2]. Although the exact role of this protein is unknown, it has been suggested that it plays roles in mitochondrial function [3]; on the other side, the decrement of the mitochondrial function is well-known to be related to increased reactive oxygen species (ROS) production [4]. Within this context, we hypothesized the use of resveratrol-loaded nanostructured lipid carriers (Res-NLCs) might decrease the ROS level and inflammation in ARSACS patient cells, owing to the antioxidant activity of resveratrol.

Experimental Methods
NLCs are designed by modification of solid lipid nanoparticles, including solid and liquid lipid phases and prepared by hot homogenization. The colloidal stability of NLCs was monitored using dynamic light scattering and zeta potential measurements. The Res release was assessed in PBS at three different time points (4, 24 and 72 h) and different pH values (pH 4.5, 7.4 and 9.0) and analyzed using a high-performance liquid chromatography (HPLC). The antioxidant capacity of Res-NLCs was measured using a Total Antioxidant Capacity Assay Kit. The cell proliferation of Res-NLCs was assessed on healthy and ARSACS patient fibroblasts using PicoGreen assay. The ROS production was tested via CellROX™ Green Reagent. To analyze the cytokine (interleukin 6, IL-6, and interleukin-8, IL-8) release, ELISA kits were used, and data were normalized according to the total proteins of each sample. Transcription of oxidative stress and mitochondria genes was investigated with quantitative real-time PCR (qRT-PCR). Proteomic analysis was carried out to show regulation of genes on patient fibroblasts upon Res-NLCs treatment.

Results and Discussion
In our study, glyceryl dibehenate and oleic acid were used as solid and liquid lipids, respectively, and resveratrol was added to the formulation to obtain Res-NLCs. Schematic representation and TEM image of Res-NLCs are shown in Figure 1. The stability studies show that the formulations remain stable at 4 °C in long-term storage (up to 2 months). Resveratrol release at pH 7.4 was found 25.2 ± 0.4% and 31.6 ± 3.3% after 24 and 72 h, respectively. The antioxidant ability of Res-NLCs was confirmed using a total antioxidant capacity kit, and it was shown to be concentration-dependent. According to the cell proliferation results, Res-NLCs did not show any toxicity in healthy and patient cells after 24 and 72 h of incubation, demonstrating their biocompatibility. The concentration used for further studies was determined as 140 µg/mL of Res-NLCs (corresponding to 5 µM of resveratrol). Effects on ROS production in tert-butyl-hydroperoxide (TBH)-treated healthy and patient cells, and on inflammatory cytokine release by lipopolysaccharide (LPS)-stimulated cultures were assessed with promising results. The human oxidative stress and mitochondria genes were further evaluated using qRT-PCR array and proteomic analysis in patient fibroblasts upon Res-NLCs treatment.

Conclusion
Taken together, obtained results show that Res-NLCs are a suitable tool in decreasing ROS production and inflammation in ARSACS patient cells.

Impact of silicone exposure after leakage or rupture of breast implants: histology and molecular analyses

Isabelle Brigaud¹, Tatiana Petithory¹, Carole Arnold¹, Franck Monnien², Isabelle Pluvy², Florelle Gindraux², Marie-Paule Algros², Karine Anselme¹

¹ Institute of Materials Science of Mulhouse, Mulhouse, FR; ² University Hospital of Besançon, Besançon, FR

Introduction
Rupture of the shell of breast implant exposes host tissue to silicone. The more often silicone leakage is confined to the capsular space (intracapsular rupture) and is clinically asymptomatic, indirectly supporting the concept of innocuity of this material. However, accumulating evidences cast doubt on this consensus (1,2). In this study, we addressed the question of breast implant silicone toxicity in vivo. We compared the tissue reaction and gene expression in capsular tissues facing ruptured or intact implants presenting 2 types of topography: OC (open cavity) and SOC (semi-opened cavity).

Experimental Methods
Immune response triggered by silicone exposure was evaluated both at the tissue and at molecular levels. Silicone-driven tissue modifications were observed from hematoxilin-eosin or hematoxilin-eosin-safran stained capsule sections. In parallel, we collected 37 capsular tissues facing textured implants, either intact (n=21) or associated to silent intra-capsular rupture (n=16) and established the molecular profile of key genes representative of immune response (Il8, Il16, Il17, Tgfβ, Mmp9, Timp1) and linked to pathological conditions including BIA-ALCL (Il13)(3). For that, collected tissues were immediately stored in RNAlater solution (Invitrogen, Carlsbad, Calif.) and preserved at -20 °C until further use. Tissue-containing tubes were then placed in a tissue homogenizer (Precellys Evolution, Bertin Instruments Tustin, USA) where tissues were mechanically crushed 30” to liquid at 8500 rpm. Lysates were then centrifuged 2’ at full speed at 4 °C. Recovered clear supernatants were used for subsequent RNA extraction. RNA extraction, RNA quality and integrity check-points together with RT-qPCR steps were carried out as described in (4). Pectoral muscle from breast reduction served as an outgroup calibration sample to calculate relative gene quantifications for all the capsule samples.

Results and Discussion
The contact with silicone led to chronic inflammation characterized by foreign body reaction, granuloma formation, and different forms of tissues metaplasia (synovial, palisade tissue), which were 1) found isolated or mixed in the same tissue and 2) modulated in terms of severity based on amount and duration to silicone exposure. At the molecular level, despite being mute clinically, the exposure to silicone triggered latent inflammation (Il8, Il13, Il16, Il17, Tgfβ) and extracellular matrix remodeling (Mmp9, Timp1). IL16, IL17 and TGFβ gene expressions were found significantly up-regulated in capsules facing ruptured OC-patterned implants compared to intact OC-patterned implants (p < 0.05). Only IL13 gene expression was found similar in tissues located in the vicinity of OC implants, regardless whether implants are intact or ruptured. For any of the 5 inflammatory genes, related gene expression was found similar in tissues facing SOC-patterned implants independently of the implant integrity (intact or ruptured). When we compared the OC- versus SOC-patterned implants, IL8, IL13, IL16, IL17 and TGFβ gene expressions were all found significantly up-regulated. IL13 and IL16 gene expressions were found significantly higher in capsules facing SOC-ruptured implants compared to those facing OC-ruptured implants while gene expression levels for IL8, IL17 and TGFβ were comparable. Both MMP9 and Timp1 gene expressions were found significantly up-regulated in capsules facing ruptured OC-patterned implants compared to intact OC-patterned implants. Up-regulation for MMP9 in tissues facing OC-ruptured implants compared to intact OC-patterned implants.
implants compared to those facing OC-intact implants was noticeably dramatic (~15 folds more in average). If MMP9 gene expression levels were found similar in tissues facing SOC-patterned implants independently of the implant integrity (intact or ruptured), we found that Timp1 was in average ~3 folds more expressed in tissues located in the vicinity of SOC-ruptured implants compared to those in the vicinity of intact SOC implants. Finally, MMP9 gene expression was found significantly higher in capsules facing OC-ruptured implants compared to those facing SOC-ruptured implants while gene expression levels for Timp1 was comparable in those conditions. In general, ECM-related gene expression levels and related variation mirrored expression pattern of the inflammatory genes in view of the different conditions.

Independently, implant topography and silicone exposure were confirmed as pro-inflammatory factors. Combination of these two parameters resulted in a maximal immune response.

Conclusion

Altogether, this study clearly ascertained that host body confronted to silicone develops latent immune response which might predispose to the development of various medical conditions.

We thus encourage surgeons to redefine ruptures, even silent, as urgent condition requiring immediate implant resection.

Universitat Internacional de Catalunya, Faculty of Medicine and Health Sciences, Barcelona, ES
Maria-Pau Ginebra
Technical University of Catalonia, ES
Hongyi Chen (YSF)
University College London, Mechanical Engineering Department, London, GB

The aims of this symposium are three folds:

1. To share recent progress in biomaterials big-data curation, sharing, analysis and exploitation
2. To highlight urgent needs of the domain in terms of data organization, open tools and repositories
3. To initiate and foster a community of biomaterials scientists committed to advancing data-driven biomaterials research
Biomaterial surface topography induces cell signaling events that control cell phenotype: how does it work and how can we use it?

Jan de Boer

Eindhoven University of Technology, Eindhoven, NL

Abstract
I will present our latest work on investigating and controlling the interaction between cells and biomaterials through design of surface topography. For instance, we looked into how tenocytes, the cells that build tendon and ligament tissues, interact with their extracellular matrix and how this impacts the formation focal adhesion complexes and F-actin. Transcriptomics analysis of topography exposed tenocytes and molecular biological research shows an interesting relay of the topographical information from the extracellular matrix into the tenocyte phenotype. Inspired by this, we used our high throughput screening platform, the TopoChip, to investigate the relationship between the topographical design parameters and tenocyte phenotype. We use quantitative high content imaging and machine learning algorithms to characterize the response of the cells to the thousands of different surfaces. Using machine learning algorithms, we can describe the relation between surface topography and cell response. If time allows, I will also talk about other cell types and how their phenotype depends on the surface topography, such as macrophages and hepatocytes. The focus of my seminar will be on our effort to digitize life at the interface of biomaterials and cells through parameterization of biomaterial properties, –omics based approaches to analyse cell response and computational science to understand and design bio-active biomaterials.

Biography
Jan de Boer is chair of the BioInterface Science lab at the Institute for Complex Molecular Systems and the department of Biomedical Engineering at Eindhoven University of Technology. His research is focused on understanding and implementing molecular biology in the field of tissue engineering, regenerative medicine and medical devices interface biology. His research is characterized by a holistic approach to both discovery and application, aiming at combining high throughput technologies such as the TopoChip platform, computational modeling and experimental cell biology to streamline the wealth of biological knowledge to clinical applications.
DEBBIE1.0: Biocompatibility data mining from MEDLINE into an open access database

Osnat Hakimi1, Javier Corvi2, Austin McKitrick3, Jose M. Fernandez2, Carla Fuenteslopez4, Clarence Lepine5, Salvador Capella-Gutierrez2, Josep-Lluis Gelpi6, Maria-Pau Ginebra7

Introduction

The majority of biocompatibility data gathered during biomaterials and medical implants research is published in the form of scientific articles. As a result, most biocompatibility information is presented in free text or graphic figures, and is therefore ‘unstructured’, making it a challenging input for computational processing. In the absence of structured biocompatibility data, tasks such as comparing the performance of similar polymers or selecting a biomaterial for a specific medical application relies on manual review of research articles - a daunting manual task, given the volume of work in the field [1].

Emerging computational tools, such as machine-learning-based systems, are becoming essential for coping with this information overload. Among these, text mining systems present an attractive option for automated extraction of information from text documents into structured data sets [2].

Here, we present the first automated system for biocompatibility information extraction from MEDLINE research abstracts. The system is a text mining pipeline, which periodically retrieves abstracts from PubMed and identifies studies where scaffolds or implants have been tested in a biological environment, such as cell culture, tissues, and animal models or human clinical studies. Thereafter, the pipeline identifies concepts of interest in the abstract text using the Biomaterials Annotator, a tool for biomaterials text annotation. These concepts of interest, along with the abstract text and some meta-data are then deposited in DEBBIE, the Database of Experimental Biomaterials and their Biological Effect.

Experimental Methods

The DEBBIE pipeline has four main components (see Figure 1):

1. Data retrieval from Medline using the python Entrez module.
2. Relevance classification using a machine learning algorithm
3. Concept recognition using the Biomaterials Annotator, our semantic annotation tool (github.com/ProjectDebbie/Biomaterials_annotator)
4. Database deposition in a MongoDB database. The database data model is based on the previously published DEB ontology[4].

DEBBIE pipeline has been specified in Nextflow language[3], and its workflow manager was used for orchestration and automated execution of the pipeline. To facilitate the workflow maintainability, extension, adaptation and installation, the DEBBIE sub-components were deployed using software containers (docker). The database and REST API are hosted at the Barcelona Supercomputing Canter’s StarLife server.

So far, the database contents and user interface were tested by 16 scientists, who provided feedback through a questionnaire and a focus group.

Results and Discussion

An experimental version of the DEBBIE database (DEBBIE1.0) is already running, alive, and open for users to test. Users can access the database search page (debbie.bsc.es/search/) and submit an open, single query (for example:
Thereafter, users receive a quick summary (see Figure 2), including the total number of abstracts mentioning the term of interest in the collection, and a line chart showing the number of abstracts per year. Also in the quick summary, there is a bar chart of the top associated terms, namely the concepts most frequently associated with the term of interest. Because the system relies on the Biomaterials Annotator, all identified terms belong to pre-designated relevant categories.

Below the quick summary, users can select and explore categories, providing different aspects related to biomaterials and their biocompatibility. For example, users can select categories such as ‘Associated Biological Process’ (eg. osteogenic differentiation, angiogenesis), ‘Adverse Effects’ (eg. cytotoxicity, inflammation) and ‘Medical Application, Disease or condition’ (example concepts: wound healing, implantation). Each term is an interactive link to the relevant abstracts containing concepts of interest within the search term collection.

The content of DEBBIE can also be accessed programmatically through the RESTful API located at debbie.bsc.es/search/rest. The documentation page for the database provides instructions on how it can be used under the section ‘quickstart’.

While DEBBIE is already open for exploration, the annotation pipeline, the database and web components are still evolving. Ongoing work includes improving the accuracy of the annotations, implementing a multinomial classifier for better relevance filtration and adjusting the user interface and search results display in accordance with users feedback.

Conclusion

We present the first automatically curated biomaterials database, specifically developed for the organization of biocompatibility data. Whilst we are improving the accuracy and performance of the database, feedback and visibility in the biomaterials community is fundamental to the usefulness of this resource.

In addition to the database, all the components, linguistic resources and code developed in the project are openly available through the project’s GitHub page (github.com/ProjectDebbie).

Dissolution and biocompatibility of combinatorially sputtered SiCrNbN coatings

Estefanía Echeverri¹, Charlotte Skjöldebrand¹, Gry Hulsart Billström², Cecilia Persson¹

¹ Uppsala University, Materials Science and Engineering, Uppsala, SE; ² Uppsala University, Medicinal Chemistry, Uppsala, SE

Introduction
Hip and knee joint replacements have been some of the most successful surgeries for the treatment of patients with chronic pain due to arthritis. A current challenge is however the younger and more active patients, which demands longer-lasting devices that will withstand several decades of cyclic loading. Corrosion and wear products are herein a concern since they can cause localized inflammation leading to periprosthetic bone loss and potentially implant loosening, necessitating revision surgery [1]. One approach to overcome the long-term issues is to develop materials more resistant to wear and corrosion, as well as materials giving less of an inflammatory response, e.g. by depositing a ceramic coating which acts as a barrier to the release of metal ions from the substrate as well as improving the wear resistance. Silicon nitride is a promising candidate because of its low wear rates and the possibility to limit the adverse effects of wear debris due to its slow dissolution in aqueous solutions [2]. This study aimed to investigate the dissolution and biocompatibility of SiCrNbN coatings deposited on cobalt chromium (CoCr) substrates. We hypothesized that the ceramic coating will reduce metal ion release compared to uncoated CoCr without affecting its biocompatibility.

Experimental Methods
The SiCrNbN coatings were deposited on CoCr disc substrates by reactive sputtering in an in-house built equipment, allowing for combinatorial processes, using Si, Cr and Nb solid targets. Nitrogen was supplied as a reactive gas. To improve the adhesion of the coating a CrN interlayer was deposited. The coatings were characterized in 9 points using x-ray photoelectron spectroscopy (XPS), vertical scanning interferometry (VSI) and scanning electron microscopy (SEM). The points were placed in a 3x3 grid with 22.5 mm between each point. The dissolution was evaluated by exposing the coated samples to cell media for 7 days. The obtained extracts were diluted (neat extracts (1:1), and 3 two-fold dilutions (1:2, 1:4 and 1:8)) and used to measure ion levels with inductively coupled plasma (ICP-OES) and to assess indirect biocompatibility in vitro using the tetrazolium dye MTT and L929 fibroblast cells.

Results and Discussion
The XPS results revealed compositional gradients with Si ranging between 27.4-32.8 at.%, Cr 4.1-10.9 at.%, Nb 3.5-8.4 at.%, N 41.8-46.8 at.% and O 10.9-14.6 at.%. SEM revealed coating thicknesses between 320-590 nm, and interlayers approx. 50 nm thick. Images displayed an overall smooth surface with an average roughness, Ra, of 5.6 to 9.3 nm, similar for all points. Grooves from polishing and occasional features at the microscale were observed, likely formed during deposition. The ICP results showed a reduction in Co ions from the substrate in the coated samples compared to uncoated. The cell viability results suggest that fibroblasts tolerated the neat extracts and its dilutions (1:1, 1:2, 1:4) obtained from the coated samples in a dose dependent manner.

Conclusion
The findings from this study suggest that the differences in composition did not affect the surface properties. The material characteristics indicate that silicon nitride has a promising potential to be used as a coating in metallic implants to improve corrosion resistance and reduce ion release, warranting further biological evaluation.

Biomaterials-on-chip: an alternative method to screen the biological properties of biomaterials

Sarah-Sophia D. Carter¹, Abdul-Raouf Atif¹, Michael Pujari-Palmer², Laurent Barbe¹, Maria Tenje¹, Gemma Mestres¹

¹ Uppsala University, Materials Science and Engineering, Science for Life Laboratory, Uppsala, SE; ² Swedish University of Agricultural Sciences, Clinical Sciences, Uppsala, SE

Introduction
In order to reach the clinic, biomaterials need to be thoroughly evaluated, which requires reliable in vitro methods. However, current in vitro methods, which have provided significant insights into the biological response to biomaterials, have shown to be inadequate for accurately predicting in vivo outcomes [1]. For this reason, the development of alternative in vitro approaches with increased physiological relevance is rapidly advancing. One such approach is the use of microfluidic technology, which allows cells to be cultured while confined in micrometric channels and, simultaneously, be perfused with cell culture medium, thereby enabling an environment closer to the in vivo bone niche.

In this work, two microfluidic systems were developed and used to evaluate the biological properties of different biomaterials for bone repair. A medical grade titanium alloy (Ti₆Al₄V) and calcium-deficient hydroxyapatite (CDHA) were integrated on the respective systems and characterized for a period of 10 days using, among others, imaging and biochemical assays. In subsequent sections, these microfluidic systems are referred to as titanium-on-chip and CDHA-on-chip.

Experimental Methods
The titanium-on-chip consisted of a double-sided tape channel, sandwiched between a conventional microscopic glass slide and cover glass, the latter comprising a laser cut hole to which the titanium disc was docked (Figure 1A). For the CDHA-on-chip, a calcium phosphate cement (CPC) was prepared by mixing α-tricalcium phosphate with 2.5% w/v Na₂HPO₄(aq) at a liquid-to-powder ratio of 0.65 ml/g. The CPC was poured into a polydimethylsiloxane (PDMS) channel and subsequently set for 10 days in a 0.9% w/v NaCl(aq) solution, thus transforming into CDHA. Afterwards, the PDMS was bonded to glass, leaving a 0.5 mm channel gap through which the cell culture medium could flow (Figure 1B).

On the titanium-on-chip, MC3T3-E1 pre-osteoblast cells were seeded at 45,000 cells/cm² and incubated under static conditions for 4 hours, prior to starting flow (2 µl/min). As a control, MC3T3-E1 cells were seeded on titanium discs kept in a well plate (titanium off-chip). A similar approach was used for the CDHA-on-chip, however, in this case an initial cell seeding density of 50,000 cells/cm² was used and the static incubation was set to 2 hours. The CDHA-on-chip was initially used to characterize the ionic exchange on-chip, using flow rates between 2-14 µl/min. Based on the results from this preliminary study, cell studies on the CDHA-on-chip were performed using a flow rate of 8 µl/min.

For both systems, cell viability, proliferation and differentiation were monitored over a period of 10 days using calcein/propidium iodide, lactate dehydrogenase assay and alkaline phosphatase (ALP) assay, respectively. For cell proliferation and cell differentiation studies, the analysis was performed using cell lysates.

Results and Discussion
MC3T3-E1 cells were successfully maintained (viable) on both titanium-on-chip and CDHA-on-chip, as was shown by a vast majority of living cells after 10 days of culture (Figure 1C, D). Interestingly, regardless of the biomaterial or microfluidic system, the general trend observed was that cell proliferation dominated on-chip experiments, to the detriment of cell differentiation when compared to the static condition (data shown for titanium-on-chip, Figure 2) [2].
A possible explanation for this finding is a depletion in cell-secreted factors when maintaining the cells under continuous dynamic culture conditions. However, in order to make conclusive statements, further work is needed.

**Conclusion**

Overall, this work demonstrates the importance of optimizing *in vitro* cell culture conditions, particularly for novel miniaturized and microfluidic applications, and raises awareness of how these conditions may affect biomaterial testing outcomes, thus illustrating the potential of alternative methods that can more closely approach physiological conditions.

Biosynthetic Hydrogels for Islet Engraftment and Immune Acceptance

Andrés J. García

Parker H. Petit Institute for Bioengineering and Bioscience, George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, US

Hydrogels, highly hydrated cross-linked polymer networks, have emerged as powerful synthetic analogs of extracellular matrices for basic cell studies as well as promising biomaterials for regenerative medicine applications. A critical advantage of these synthetic matrices over natural networks is that the biophysical and biochemical properties of the material can be tuned with high control and precision. For example, bioactive functionalities, such as cell adhesive sequences and growth factors, can be incorporated in precise densities. We have engineered poly(ethylene glycol) [PEG]-maleimide hydrogels that support improved pancreatic islet engraftment, vascularization and function in diabetic models. Two biomaterial strategies will be discussed. We have developed proteolytically degradable synthetic hydrogels, functionalized with vasculogenic factors, engineered to deliver islet grafts to extrahepatic transplant sites via in situ gelation. These hydrogels induce differences in vascularization and innate immune responses among subcutaneous, small bowel mesentery, and epididymal fat pad transplant sites with improved vascularization and reduced inflammation at the epididymal fat pad site. This biomaterial-based strategy improves the survival, engraftment, and function of a single pancreatic donor islet mass graft compared to the current clinical intraportal delivery technique. In a second application, we have developed a localized immunomodulation strategy using hydrogels presenting an apoptotic form of Fas ligand (SA-FasL) that results in prolonged survival of allogeneic islet grafts in diabetic mice. A short course of rapamycin treatment boosts the immunomodulatory efficacy of SA-FasL-hydrogels, resulting in acceptance and function of allografts over 200 days. Survivors generate normal systemic responses to donor antigens, implying immune privilege of the graft, and have increased T-regulatory cells in the graft. Current studies focus on evaluating this immunomodulatory strategy in a large animal model of type 1 diabetes. This localized immunomodulatory biomaterial-enabled approach may provide an alternative to chronic immunosuppression for clinical islet transplantation.

Taking control of innate immunity with nanobiologic therapeutics

**Willem J.M. Mulder**¹,²

¹ Radboud University Nijmegen Medical Center, Department of Internal Medicine, Radboud Institute of Molecular Life Sciences (RIMLS) and Radboud Center for Infectious Diseases (RCI), Nijmegen, NL; ² Eindhoven University of Technology, Laboratory of Chemical Biology, Department of Biomedical Engineering and Institute for Complex Molecular Systems, Eindhoven, NL

Immunotherapy is revolutionizing the treatment of diseases. Most immunotherapy strategies engage the adaptive immune system. In recent years, emerging evidence has shown that the innate immune reprogramming induces long-term changes through metabolic and epigenetic programming of myeloid cells, including monocytes, neutrophils and macrophages. This de facto innate immune memory is also referred to as trained immunity. Therefore, targeting myeloid cells and their progenitors is a powerful ‘trained immunity-regulating framework’ to govern the delicate balance of immune homeostasis, priming/training and tolerance. This Presentation will showcase how nanobiologic-based immunotherapies can be applied to achieve long-term therapeutic benefits in detrimental immune-driven diseases, including cancer, cardiovascular and infectious diseases, as well as to prevent organ rejection after transplantation.
Immunomodulatory IL-23R antagonist peptide coatings to prevent infection of percutaneous devices

John A. Pizarek¹², Nicholas G. Fischer¹, Conrado Aparicio¹

¹ University of Minnesota, Minnesota Dental Research Center for Biomaterials and Biomechanics, Minneapolis, US; ² Naval Medical Leader and Professional Development Command, Lieutenant Commander, United States Navy Dental Corps, Bethesda, US

Introduction
Percutaneous devices are some of the most common medical devices in use, yet device infection remains ubiquitous. Left untreated, infection may lead to device failure, costly additional surgical interventions, and possible mortality. The concomitant exploding use of antibiotics has led to rising antimicrobial resistance and formation of dysbiotic biofilms. Thus, percutaneous device infection remains a foreboding healthcare burden in critical need of alternative solutions [1].

Bacterial invasion of peri-implant surface leads to a keratinocyte innate inflammatory response. This results in production of pro-inflammatory cytokines, secretory immune molecules, that modulate an immune response by recruitment, activation and proliferation of specialized immune cells, such as macrophages. Specifically, the IL-17/IL-23 cytokine inflammatory axis is highly active in infected percutaneous dental implants compared to healthy implant sites [2]. Peptide nanocoatings offer highly tailorable presentation of immunomodulatory motifs to regulate such inflammatory axes [3]. We evaluated the keratinocyte response to an IL-23 receptor antagonist (IL-23Ra) peptide [4] coating for proliferation, production of IL-17/23, and cytokine secretome regulation. Conditioned media was collected to analyze macrophage polarization to M1 vs. M2 macrophages. Regulating the IL-17/23 pathway may reduce the induction and recruitment of aforementioned inflammatory cells and promote integrity of the soft tissue interface of percutaneous devices at sites of bacterial infection [5].

Experimental Methods
Model percutaneous device titanium surfaces were covalently functionalized with IL-23Ra. Randomized sequence IL-23Ra peptides (Random) and non-coated nanorough titanium disks (etched titanium; eTi) served as controls. Coatings were physicochemically analyzed by X-ray photoelectron spectroscopy (XPS), water contact angle, and peptide fluorescent labeling and visualization. Peptide surface density was quantified using a NanoOrange peptide quantification kit.

Keratinocyte proliferation was measured colorimetrically and with phallolidin/DAPI staining. Keratinocyte-conditioned media and cell lysates were collected and analyzed using a 36-target cytokine array for functional protein association network analysis (STRING). ELISAs were used to analyze levels of IL-23 and IL-17 in the presence and absence of pro-inflammatory Porphyromonas gingivalis lipopolysaccharide (LPS).

Human monocytes were isolated and cultured with keratinocyte-conditioned media at different ratios in macrophage differentiation media. Control monocytes were differentiated to M1 and M2 macrophages as controls. Macrophages were analyzed by immunofluorescence for CD68 and iNOS (M1 markers) and CD163 and CD206 (M2 markers). ANOVA and Tukey post-hoc tests assessed statistical significance (p<.05).

Results and Discussion
Physicochemical analysis demonstrated the successful immobilization of the peptide nanocoatings on titanium (XPS results in Figure 1a).
The IL-23Ra-coated titanium significantly increased proliferation of the keratinocytes (phalloidin/DAPI immunofluorescence at 1 day in Figure 1b) and significantly decreased IL-17 and IL-23 levels, both without (IL-17A results in Figure 1c) and with LPS stimulation (IL-17A results in Figure 1d), compared to controls. STRING analysis revealed a significant shift toward pro-reparative cytokine production on IL-23Ra peptide coated disks compared to controls.

Keratinocyte-conditioned media collected from IL-23Ra polarized macrophages toward M2 more than controls.

**Conclusion**

Our results supported the use of IL-23Ra-coatings to reduce the pro-inflammatory IL17/23 pathway, along with a reduction of keratinocyte pro-inflammatory cytokines production and polarization of macrophages toward M2. Immunomodulatory peptide nanocoatings may promote soft tissue healing around percutaneous devices and thereby reduce the burden of care of percutaneous devices.

Human Cell-Assembled extracellular Matrix (CAM) does not trigger the innate immune system and shows long-term in vivo stability

Laure Magnan1, Fabien Kawecki1, Gaëlle Labrunie1, Julien Izotte2, Sébastien Marais3, Marie-Pierre Foulc4, Michaël Lafourcade4, Nicolas L’Heureux1

1 University of Bordeaux / Inserm, BioTis - Laboratory for the Bioengineering of Tissues, Bordeaux, FR; 2 University of Bordeaux, Animal facility A2, Bordeaux, FR; 3 University of Bordeaux / CNRS / Inserm, Bordeaux Imaging Center (UMS 3420 / US4), Bordeaux, FR; 4 Société de Recherche Rescoll, Bordeaux, FR

Introduction

Cell-assembled extracellular matrix (CAM) has been used to produce vascular grafts without exogenous materials.1-2 These grafts were produced by rolling sheets of CAM that were fused in a bioreactor over many months of culture. We have now developed a textile-inspired approach that uses yarn of CAM that are assembled in vascular grafts by weaving.3 This approach avoids the need for fusion/bioreactors, offers directional and local control over mechanical properties, is automatable, and allows the production of graft 3X faster. While CAM-based grafts performed well in clinical trials, the in vivo remodeling and inflammatory response of this truly “bio” material has not yet been investigated. In this study, human CAM yarns were implanted subcutaneously in nude rats to investigate the innate immune response to this extracellular matrix processed into yarn.

Experimental Methods

Normal human skin fibroblasts were isolated from surgical waste (abdominoplasty). The epithelium was removed (500 mg/ml thermolysin) and the dermis was digested with collagenase (0.40 U/ml). After centrifugation, fibroblasts were plated into tissue culture flasks (10^4 cells/cm^2) in DMEM:HamF12 (1:1) with 20% fetal bovine serum (FBS – FetalClone III, Hyclone). Cells were passaged 3 times and tested for mycoplasma infection by PCR before storage in liquid nitrogen. To produce sheets (10x18 cm), cells were cultured in media containing 500 µM sodium ascorbate for 8 weeks in a T-225. MATURE sheets were rinsed in distilled water and frozen (-80°C). To produce yarn, sheets were thawed and cut into ribbons (typically 5-mm-wide) using a multi-blade system. In To produce twisted yarn (threads), one extremity of the rehydrated ribbon was attached to the rotating rod of a custom twisting device, while a manipulator pinched the other extremity. The calibrated motor was turned on for a calculated duration to twist the ribbons at the desired number of revolutions per cm of length (here 7.5). Yarn was then air-dried under the hood, spooled, and stored at -80°C. Upon thawing, this material is termed “devitalized”.4 Decellularized materials was obtained by incubating thawed sheets in decellularized (8 mM CHAPS, 1 M NaCl, 25 mM EDTA, 0.12 M NaOH) for 6 hours followed by extensive rinsing. Gamma-sterilization was performed on spooled dry yarn (25 kGy, Steris (Marcoule, France)). Tensile testing (Criterion® 43; MTS; Berlin, Germany) was performed with a 250 N force sensor, pre-stretched at 0.1 N and pulled until rupture at 20 mm/min.

Results and Discussion

The impact of processing steps relevant to yarn manufacturing (devitalization, decellularization, gamma sterilization, and twisting) was evaluated in vitro and in vivo. Both histological and mechanical effects were observed. Histology revealed that decellularization was successful and that gamma sterilization affected the matrix. Mechanically, both gamma sterilization and twisting reduced the force at failure of the yarn by 25% to 30% (p < 0.001 and 0.0001). The ultimate tensile stress (UTS) was significantly increased by decellularization and even more by twisting (p < 0.0001). After subcutaneous implantation in nude rats, all yarns were still present after six months, and were integrated into a non-inflamed loose connective tissue with a CAM tissue repopulated by fibroblastic cells and blood vessels. Two weeks after implantation, yarns caused minor peripheral inflammation except for gamma sterilized yarn that triggered
a more intense host response dominated by M1 macrophages. However, strips of a membrane of processed bovine collagen clinically available (BioMend®; 0107; Zimmer Biomet Dental, Rungis, France) was aggressively degraded showing that the nude rats had a functional innate immune system that recognized and attacked “damaged” ECM. Yarn mechanical strength was decreased two weeks after implantation except for the more compact “twisted” yarn. While the strength of other yarns were stable after initial remodeling, the gamma-sterilized yarn continued to lose mechanical strength over time and was significantly weaker than devitalized (control) yarns at six months.

**Conclusion**

This is the first study to formally demonstrate that devitalized human CAM is very long-lived in vivo and does not trigger a sustained degradative response but, rather, is very slowly remodeled. This data supports a strategy to produce human textiles from CAM yarn for regenerative medicine applications where a scaffold with low inflammation and long-term mechanical properties are critical.

Introduction

Interferon-γ (IFN-γ) has been identified as a key factor for antitumor immunity and response to immunotherapy [1]. However, most of the clinical trials reported a limited potential of IFN-γ as single therapy, highlighting the importance of evaluating its potential when combined with immunotherapies.

We described chitosan (Ch)/poly(γ-glutamic acid) (γ-PGA) nanoparticles (NPs) able to modulate immature and immunosuppressive antigen-presenting cells (APCs) to an immunostimulatory profile, leading to T cell activation and impairing APCs-mediated cancer cell invasion [2]. Further, we recently showed that Ch/γ-PGA NPs synergize with conventional radiotherapy, decreasing breast tumor growth and lung metastasis in an orthotopic breast tumor mice model, by decreasing local and systemic immunosuppression [3]. These immunomodulatory abilities of Ch/γ-PGA NPs point them as appealing adjuvants to IFN-γ-based therapies. We have previously shown that Ch/γ-PGA NPs incorporating IFN-γ were able to induce an immunostimulatory profile on APCs, hampering cancer cell invasion in vitro. This effect was mainly mediated by Ch/γ-PGA NPs, but the incorporation of IFN-γ potentiated the effect observed [4]. Therefore, the current study addressed the potential synergistic effects of Ch/γ-PGA NPs combined with IFN-γ using an immunocompetent 4T1 orthotopic breast tumor mouse model.

Experimental Methods

NPs were prepared by co-acervation method and characterized by dynamic light scattering (DLS) and transmission electron microscopy (TEM). 1x10⁶ 4T1-luciferase cells, a mouse breast tumor cell line, were injected orthotopically in the mammary fat pad of BALB/cByJ. Animals were divided in four groups: non-treated (control), treated with Ch/γ-PGA NPs, with IFN-γ or with the combination of both treatments (NPs+IFN-γ). After 7 days, when the tumors reached 94.1±32.1 mm³, animals were subcutaneously injected, adjacent to the tumor, 6 times for 2 weeks with Ch/γ-PGA NPs, IFN-γ or with both (NPs + IFN-γ). Tumor volume was measured using a caliper and calculated as (length × width × width)/2 (mm³) and tumor progression was followed by bioluminescence imaging every week. Animals were sacrificed at day 28. Tumor burden, lung metastasis formation and immune cell profile were explored. Tumor size was normalized, considering the initial size, prior any treatment.

Results and Discussion

The DLS and TEM results indicated that Ch/γ-PGA NPs presented a constant size (206.8 ± 3.2 nm) with a reduced polydispersion index (0.18 ± 0.09), a positive zeta potential (18.4 ± 0.5 mV) and a spherical shape. Regarding in vivo studies, treatments had no significant impact on mice weight nor liver or kidney structure, confirming their safety. While non-treated animals had progressive tumor growth (514.7 ± 61.2 %) and developed lung metastasis, NPs- and IFN-γ-treated animals significantly decreased primary tumor burden (286.5 ± 41.6 % and 262.0 ± 43.4 %,
respectively). Remarkably, when both treatments were combined, breast tumor growth was blocked (107.8 ± 25.5 %). This impairment was associated with a reduction in splenomegaly, a decrease in the percentage of splenic myeloid-derived suppressor cells and an increase in antitumoral CD4+IFN-γ+ population. Notably, animals from the combinatorial treatment (NPs+IFN-γ) presented lower bioluminescence in the lungs than other groups, which indicate lower metastatic burden. Additionally, NPs+IFN-γ-treated animals had lower levels of the systemic pro-tumoral cytokines (IL-3, IL-4, IL-10) in comparison to non-treated animals.

**Conclusion**

Overall, these results suggest that Ch/γ-PGA NPs potentiate and synergize with IFN-γ to reduce tumor progression, opening new perspectives to be used in anticancer strategies.

Introduction

The new revolution of 3D printing technologies has led to the development of bioprinting processes capable of fabricating scaffolds for regenerative medicine applications. This technology integrates living cells and biomaterials within a precisely controlled system to create complex structures that cannot be achieved using existing scaffold fabrication processes. The ultimate goal of bioprinting is to be able to produce tissues and organs in the laboratory for use in surgical therapies and transplants [1]. The application of Artificial Intelligence (AI) methodologies for the optimisation of the bioprinting process has the potential to bring about rapid advancements towards the achievement of this goal. Within this study, a computer vision method will be developed to explore scaffold degradation rate. This approach will be compared to standard scaffold degradation quantification methods i.e. calculation of changes in scaffold weight and dimensions. These methods will be applied to assess the influence of tannic acid (TA) concentration and crosslinking time on the degradation rate of bioprinted collagen scaffolds.

Experimental Methods

Collagen bioinks were prepared by combining Porcine tendon type I collagen (SYMATESE, France) with 0.5 M acetic acid (Merck, Ireland) at concentrations of 4\% and 6\% (w/v). The collagen solution was homogenised for 30 min at 4\(^\circ\)C. Collagen scaffolds were then printed using the Inkredible\textsuperscript{+} bioprinter (Cellink, Sweden) with a 22G cannulated needle. The scaffolds were crosslinked with tannic acid (TA, Merck, Ireland) at concentrations of 4\% and 6\% (w/v) for 15 or 37.5 min at 37\(^\circ\)C. Scaffolds (dimensions of 10\(\times\)10\(\times\)3 mm, infill density of 15\%) were printed using the following parameters: printhead and printing stage temperature -20\(^\circ\)C, air pressure -235\(\pm\)10 kPa and printhead speed - 10mm/s.

Degradation rate of the scaffolds was studied by immersing them into 3 mL PBS solution (pH 7 at 37\(^\circ\)C) for up to 14 days. The degradation rate was determined by quantifying changing in scaffold weight (D_Weights) and dimensions (D_Dime) daily. In addition, images of the scaffolds were taken daily using a microscope camera and scaffold degradation was assessed by segmenting the object and calculating the change in area (D_Comp). Fig.1 illustrates the methodology used to capture the images and analyse the scaffold degradation rate. The code used image segmentation to determine the scaffold area in the image (pixels) and convert it to SI units (m\(^2\)). The area degradation rate was computed by calculating a daily percentage change in scaffold area. The relative error between the D_Weights, D_Dime and D_Comp methods was then determined.

Results and Discussion

Fig.2(A-D) demonstrates the average degradation rate of the scaffolds (n=4) measured using the three different methods for the different bioink formulations. The results show that degradation can be observed as a uniform change in the scaffold dimensions. In terms of average rate of change in degradation, similar levels were recorded for the experimental and computational methods (D_Weights=6.6\%, D_Dime=7.3\% and D_Comp=6.8\%). This shows that there is a similarity between these methods in terms of measuring the degradation rate. Calculation of the relative error for each group showed a small difference between D_Dime and D_Comp results (7.4\% for Group 1). However, there was a greater difference in relative error between D_Weights and D_Comp.
results (22.7% for Group 1). This is due to the lack of information recorded for changes in scaffold internal architecture using the D_Dime method. This indicates there is higher precision when using the D_Comp method to measure scaffold degradation.

These results show that the use of computer vision provides a fast and efficient method for quantifying the degradation rate of bioprinted scaffolds, while removing the need to handle the scaffolds required for other methods for assessing degradation. Furthermore, the results show that increasing the crosslinking time from 15 to 37.5 min results in a reduction in the degradation rate of collagen scaffolds.

**Conclusion**

Image segmentation has been successfully applied to measure the degradation rate of 3D printed scaffolds and demonstrates that it is a potentially reliable method to use in determining the degradation rate of bioprinted scaffold. However, it is clear from the results, that internal feature changes of a scaffold, such as pore size, were difficult to obtain due to limitations with the 2D imaging technique. The study shows that increasing the crosslinking time reduces the degradation rate of collagen scaffolds. Further work will explore the ability of a more complex computer vision model to relate external changes in the shape to internal degradation. Specifically, the next stage is to develop the study to use machine learning methods to derive computer vision models that can convert the observed values into predicted weights.

Biocompatible DLP resins based on poly(ester/carbonate) urethane acrylates

Rong Wang, Tobias Kuhnt, Ramiro Marroquin-Garcia, Agustina Aldana, Lorenzo Moroni, Matthew Baker

Maastricht University, MERLN Institute; Complex Tissue Regeneration Department, Maastricht, NL

Introduction
Among the additive manufacturing techniques, light-based fabrication like Digital Light Processing (DLP) results in high-resolution and fast printing times. DLP has been recently explored in regenerative medicine owing to high accuracy to print complex scaffolds like vascular branches [1, 2]. However, the development of customizable biodegradable and biocompatible resins remains a bottleneck. Scalable resins with proven biocompatibility and biodegradability are necessary in order to further develop custom tissue engineered implants. Of particular concern, there exist few resin platforms with tailorable cell adhesion, tailorable degradation rates, or with intermediate and elastomeric mechanical properties. We recently reported a series of customizable resins based on poly(caprolactone-co-trimethylene carbonate) (PCT) and poly(caprolactone-co-lactide) (PEU), end-capped with lysine isocyanate and acrylate to address these aims [3,4].

Experimental Methods
PCT and PEU copolymers were synthesized and end-capped using acrylated l-lysine isocyanate (LDI-HEA) as previously reported [3,4]. In the PCT series, the copolymers compositions were varied from 80:20, 75:25 and 70:30 caprolactone (CL) to trimethylene carbonate (TMC) at a constant molecular weight (4k g/mol); in the PEU series, the copolymer molecular weights were varied (1k–10k g/mol) at a constant composition 75/25. All copolymers were characterized by nuclear magnetic resonance (1H-NMR and 13C-NMR), gel permeation chromatography (GPC) and differential scanning calorimetry (DSC). For DLP printing, resins were prepared by adding 2-(2-ethoxyethoxy)ethyl acrylate (EOEOEA) (30 wt%) and TPO (1 wt%). Mechanical properties were determined via a combination of rheology and tensile testing. Cell viability and morphology was determined using human dermal fibroblast (HDF) adhesion assays and the PCT copolymers were tested in vivo in a pig model for subcutaneous inflammation.

Results and Discussion
The copolymer composition, degree of polymerization and molecular weight were determined by 1H-NMR and GPC. All co-polymers showed good dispersities (D) in the range of 1.1 to 1.6, and reflected both the targeted composition and molecular weight. The polymers were able to be formulated into resins with their performance as a resin dictated by the melting temperature of the polymer. In addition, we were able to utilizing a heating bath to overcome limitations of printing at room temperature. The scaffolds all showed mechanical properties in the intermediate regime (MPa). The 3D printed scaffolds showed variation in HDF adhesion as a function of the molecular weight and polymer composition. The PCT scaffolds showed a lack of significant inflammatory response in a short-time-frame subcutaneous implantation in a pig model, and the polymers showed controllable degradation based on polymer composition.

Conclusion
The synthesis of the PCT and PEU copolymers has allowed us to explore these DLP polymerizable resins with controllable properties and cell adhesion. Currently, we are exploring adding in stimuli responsive elements and controllable bioactivity into the scaffolds. This platform provides a tailorable starting point for future studies in the translation of biodegradable and tailor-made scaffolds for tissue regeneration. The cytocompatibility and
biodegradability, as it was reported, together the current results lend these polymers well to further in vitro and in vivo testing of DLP printed scaffold for soft and medium-soft tissue regeneration.

An Ideal Photoresin for Fast Volumetric Bioprinting Based on Thiol-Norbornene Photoclick Crosslinking

Riccardo Rizzo, Dominic Ruetsche, Hao Liu, Marcy Zenobi-Wong

ETH, Department of Health Sciences and Technology, Zurich, CH

Introduction

In last two decades, light-mediated biofabrication techniques have increasingly gained interest thanks to the development of novel photochemical strategies and hardware solutions. Recently, volumetric printing (VP) (also known as volumetric additive manufacturing or computed axial lithography) has emerged as a powerful tool to overcome major limitations of printing methods based on layer-by-layer processes (i.e. digital light processing (DLP), stereolithography (SL), extrusion). This light-based technique enables the generation of low-defects centimeter-sized complex 3D objects within seconds, thus significantly reducing the printing time and light exposure. To date, common (meth)acrylate photoresins (i.e. Gel-MA) represent the standard materials for VP. In this work we introduce an optimized photoresin based on gelatin-norbornene (Gel-NB) for VP and volumetric bioprinting (VBP) as well as an efficient and scalable method to produce such material which overcome the current limitations resulting from the use of chain-growth based photoresins.

Experimental Methods

Gel-NB was synthesized in a pH-controlled alkaline buffer with the sequential addition of carbic anhydride (CA). Various Gel:CA w/w were used in order to target different degree of substitution (DS), which were estimated by $^1$H-NMR in the presence of an internal standard (DSS). Gel-NB synthesis scalability was assessed for batches of 2, 10 and 50 g. Gel-NB based photoresins were prepared by mixing with thiolated crosslinkers and 0.05% LAP photoinitiator. Oscillatory photorheological analysis was performed to assess the influence on rheological properties of DS, polymer content, thiol:ene ratio and type of thiolated crosslinker. Printing was performed with a commercially available volumetric printer (Readily3D). Muscle cells (C2C12) and fibroblast (NHDF) were used for VBP. Cell viability was assessed with Live/Dead staining, while immunofluorescence of sarcomere myosin heavy chain was performed to study tissue maturation of bioprinted skeletal muscle constructs.

Results and Discussion

The use of highly reactive thiol-ene step-growth chemistry poses several benefits over the chain-growth polymerization mechanism, starting from the more rapid crosslinking kinetics which resulted in the fastest VP reported to date (~10 s). On the other hand, highly efficient thiol-norbornene crosslinking enables the use of lower polymer concentration, which is crucial to generate a more cell-permissive environment and of lower polymer degree of substitution (DS), which is beneficial for the retention of native polymer bioactive and biophysical properties. The use of Gel-NB in combination with 4-arm-PEG-thiol (PEG4SH) and other thiolated linkers have also shown remarkable tunability over rheological properties, with photocrosslinked hydrogel stiffness varying from ~40 Pa to 15 kPa. In addition, we developed a simple, fast and accessible to non-expert synthesis method to produce Gel-NB with notable scalability (2-50 g) and broad, tailorable degree of substitution (3-50%). We demonstrated the high versatility of Gel-NB/PEG4SH photoresin formulation to print various complex 3D objects with high throughput by using Gel-NB concentration down to 2.5% (Figure 1a-d). Finally, we demonstrated the potential of Gel-NB based resins for VBP (Figure 1e-g). Thanks to the soft matrix obtained with low polymer concentration and the fact that the extremely efficient thiol-norbornene crosslinking drastically reduces light-exposure and radical formation compared to chain-growth systems, we obtained excellent cell viability (~100%) upon printing. In addition, we showed VBP of cell-laden perfusable models as tissue-on-a-chip proof of concept. Free-form complex skeletal muscle models were also...
bioprinted showing cell proliferation, spreading and differentiation towards contractile myotubes on the soft gelatin-based matrix.

**Conclusion**

In this work, we presented a simple, inexpensive, and scalable method to produce Gel-NB which can contribute to a widespread use of such efficient material for light-based bioprinting techniques. In particular, here we demonstrated that Gel-NB based photoresins exhibit ideal biophysical and photochemical properties for VBP. With potential application ranging from tissue engineering and regenerative medicine to soft robotics, the use thiol-norbornene photo-click crosslinking hold great promise for VBP future advances.

Micro-extrusion induced orientation of collagen fibrils embedded in hyaluronan and bioinks chondrogenic property

Matteo D'Este¹, Andrea Schwab¹, David O. Eglin¹², Flurina Staubli¹

¹ AO Research Institute Davos, Regenerative Orthopedics, Davos Platz, CH; ² Ecoles des Mines Saint Etienne, IMT, Campus Santé Innovations, Saint-Priest en Jarez, FR

Introduction

3D Bioprinting is providing the possibility to produce engineered tissues based on 3D computer models with desired shapes and with gradients in composition and cell type. This is mostly achieved at macroscopic level and up to the ~10⁻¹ mm scale. However, methods to control microscopic architecture with extrusion-based printing are seldomly reported. Still, tissues physical and biological properties critically depend to this architecture. In this study, we introduce a technique to control distribution and orientation of type 1 collagen (col) in fibrillar form embedded within a hyaluronan (HA) bioink matrix via extrusion-based 3D printing. Cell-free and cell laden constructs were prepared and characterized, analyzing the influence of this controlled microscopic anisotropy on cell behavior and chondrogenic differentiation.

Experimental Methods

Tyramine modified HA (THA) was combined with acidic col at two polymer ratios (THA:col at 12.5:2.5 mg/ml and 16.7:1.7 mg/ml). THA was enzymatically crosslinked with horseradish peroxidase and 18 to 24 ppm hydrogen peroxide [1] and col fibrillogenesis was induced via pH shift to neutrality at 37°C. shear thinning and viscoelastic properties of THA, col and composites were characterized via rheometry. THA-col was extruded with a RegenHU 3D Discovery™ controlling col fibrils alignment. Col orientation was visualized via Second Harmonic Generation (SHG) and immunostaining/confocal microscopy. Images were processed with image J (NIH) to quantify fibrils orientation. Human bone marrow derived mesenchymal stromal cell (hMSC) aggregates were embedded within the bioink to evaluate cell migration and orientation, assessed by F-actin and DAPI staining (Fig 1 C). In vitro chondrogenic behavior of hMSC embedded in casted THA-col (chondrogenic media containing 10 ng/ml Transforming Growth Factor β1) was evaluated via histology, gene expression (COL1A1, COL2A1, COL10A1, RunX2, SOX9, Aggrecan ACAN) and proteoglycan quantification. Chondrogenic differentiation was compared to hMSC pellet as a gold standard.

Results and Discussion

A workflow starting from liquid precursors with simultaneous col fibrillation and HA crosslinking was developed to achieve uniform distribution of col fibrils within the HA-based viscoelastic matrix [2]. Shear-induced fibrils alignment along the printing direction was shown by immunohistochemistry, immunofluorescence and SHG (Figure 1 A, B). As expected, alignment increased for reducing nozzle diameter (Fig 1 C, D). The shear thinning of THA was preserved in the THA-col composite at the investigated mixing ratios. THA-col showed 2-fold increase in storage modulus compared to THA. Cell migration was stimulated by the presence of col. Actin filament staining showed cytoskeleton alignment along the fibrils orientation, determined by the printing direction (Fig 1C). Production of proteoglycan rich extracellular matrix during hMSC chondrogenesis was observed after 21 days in vitro culture of hMSC embedded in THA-col (figure 2B). Chondrogenic associated genes COL2A1 (>100-fold), ACAN (>100-fold) and SOX9 were upregulated in all samples 21 days of culture (Fig 2). Compared to hMSC pellets, hypertrophic markers COL1A1, COL10A1 and RunX2 were less upregulated in the THA-col hydrogels with higher ratio of SOX9/RunX2 in both THA-col samples (~10-fold) compared to no upregulation in the pellet group (~1-fold).
The field of biofabrication has achieved significant advances in controlling constructs shape and composition. However, mechanical and biological properties of tissues depend also on the specific spatial arrangement of fibrillar components, structural molecules and biological factors. Introducing control over the microscopic architecture of these components is key to recapitulate complex tissue structure and morphology.

**Conclusion**

In this work, we have introduced a method to obtain THA-col composite with macroscopic homogeneity and microscopic heterogeneity mimicking the matrix architecture of animal tissues. Ongoing studies are assessing the effect of the fibrils orientation on chondrogenesis and new matrix deposition. The possibility of printing matrix components with control over microscopic alignment brings biofabrication one step closer to capturing the complexity in tissues.

Composite biomaterial-ink based on hyaluronan and nano hydroxyapatite for biofabrication of bone graft substitutes delivering chemically modified RNAs

Daphne van der Heide¹,², Elena Della Bella¹, Huipin Yuan³, Florence De Groot-Barrère³, Martin J. Stoddart¹, Matteo D’Este¹

¹ AO Research Institute Davos, Davos, CH; ² Institute for Biomechanics, Department of Health Sciences and Technology, ETH Zürich, Zürich, CH; ³ Kuros Biosciences Bv, Bilthoven, NL

Introduction

Normally, most bone injuries heal without complications, however, there are an increasing number of cases where bone lesions result in delayed healing or non-union. The gold standard treatment, autografting, has severe drawbacks, due to donor site morbidity and limited availability [1]. Furthermore, bone graft substitutes containing growth factors have been associated with dose-related safety concerns. Additionally, the current clinically available bone graft substitutes lack control of spatial architecture to anatomically match defect sites after complex fractures. Therefore, the aim in this study was to engineer a biomaterial-ink as a bone regenerative therapeutic approach combining osteoinductive calcium phosphate and matrix biopolymers for delivery of chemically modified RNAs (cmRNAs) inducing nerve, vessel and bone formation using 3D-printing (Figure 1). To this end, a biomaterial ink based on hyaluronan derivatized with tyramine (HA-Tyr), combined with a range of nano hydroxyapatite (nanoHA) particles, was developed.

Experimental Methods

NanoHA was produced by Kuros Biosciences Bv and characterized via SEM and TEM imaging [2]. The optimized biomaterial-ink consisted of 3.5% w/v HA-Tyr (degree of functionalization = 6%, prepared according to a previous described method [3]) with 0.1 U/mL horseradish peroxidase (HRP), 0.17 mM (5.78 ppm) H₂O₂, and 0.02% w/v Eosin Y. Rheological measurements were performed, starting from the biomaterial-ink pre-polymer solution in the absence of nanoHA to avoid measurement artefacts. All tests were carried out with a cone-plate geometry of 25 mm diameter, gap of 0.049 mm, at 20°C. The gelation time (n = 4) was measured triggering the enzymatic crosslinking with H₂O₂, and continuously monitoring the storage (G’) and loss modulus (G’’). After 30 minutes, the same samples were illuminated for additional 30 minutes from the bottom by means of a light source with a wavelength of 505 nm. The oscillatory strain sweep (n = 3) was performed between 0.001% and 100% strain, with frequency 1 Hz. The biomaterial ink was then combined with nanoHA. A parametric study was carried out to characterize the biomaterial ink’s printability and cohesion for increasing nanoHA content. Biomaterial-inks with nanoHA content between 0 and 30% w/v were tested for swelling (n = 4). Each sample was casted in cylindrical shape with a ø 8 mm and a thickness of 3 mm, incubated in PBS at 37°C to allow swelling and then weighed after 0, 4, 6, 24, 48, 72 and 168 hours. The swelling ratio was calculated using the following formula: swelling ratio = ((weight after swelling – weight at 0 hours) / weight at 0 hours) x 100%. The range of compositions identified will be further assessed for cytotoxicity and in vitro osteogenesis (gene expression, protein production and mineralization) using human Mesenchymal Stem Cells (hMSCs).

Results and Discussion

HA-Tyr biomaterial-ink has two independent crosslinking mechanisms. The enzymatic crosslinking was used for obtaining a soft extrudable gel with a 2.5-fold increase in G’ compared to the prepolymer (Figure 2A). The photocrosslinking achieved a 11.4-fold increase in G’ and was used for final shape fixation. The damping factor (tan δ) was 0.58 at 1% strain, indicating good printability (Figure 2B) [4]. SEM and TEM showed that nanoHA particles have a...
needle-shaped morphology and a size of 10-50 x 50-400 nm. Extrusion of HA-Tyr with a range of nanoHA particles, resulted in the formation of a continuous strut, with good shape retention and without waviness up to 30% w/v nanoHA. Swelling was dependent on nanoHA concentration, with highest swelling ratio of the formulation containing 10% w/v nanoHA (Figure 2C). The extruded filaments stayed intact and with no nanoHA leaching over a time period of 3 weeks, indicating that visible light crosslinking occurs also in presence of non-transparent nanoHA (Figure 2D).

**Conclusion**

With this study we have identified a 3D-printable composite HA-Tyr/nanoHA biomaterial-ink suitable for combination with cmRNAs that has significant potential for biofabrication of bone graft substitutes.

Coaxial bioprinting as a strategy to apply differentiation factors in a spatially defined manner inside osteochondral tissue substitutes

David Kilian¹, Silvia Cometta¹, Anne Bernhardt¹, Rania Taymour¹, Julia Emmermacher¹², Tilman Ahlfeld¹, Michael Gelinsky¹, Anja Lode¹

¹ TU Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Faculty of Medicine, Dresden, DE; ² TU Dresden, Institute of Natural Materials Technology, Faculty of Mechanical Engineering, Dresden, DE

Introduction
A challenge for biofabrication of osteochondral tissue substitutes is to spatially define the differentiation pattern of encapsulated stem cells or pre-differentiated cell types towards osteogenic/chondrogenic lineage in one construct. We developed a system based on coaxial (core-shell) bioprinting to combine a bioink carrying human chondrocytes (hCC) or pre-osteoblasts (hOB) with a biomaterial ink and specific factors in defined compartments of one strand. This allowed independent and spatial adjustment of ink compositions for cell support (shell) and release kinetics of bioactive molecules.

Material selection was based on the potential of an alginate-methylcellulose blend for in vitro chondrogenesis in mineralized tissue substitutes [1] and a human plasma-supported bioink for in vitro osteogenesis [2]. The release kinetics of factors were controlled via Laponite, disc-shaped nanoclay particles with a high binding affinity for various molecules applied in skeletal bioprinting applications before [3].

Experimental Methods
3D plotting was performed using the multichannel-3D bioprinter BioScaffolder 3.1 (GeSiM mbH, Germany) equipped with a module for coaxial printing (Fig.1A). Inks applied for bioprinting were based on 3 % alginate with 9 % methylcellulose (3-9-0) [4], and 3 % alginate with 3 % methylcellulose (3-3-X) with varying Laponite content (X=0-12%).

In preliminary experiments a model cell line of human mesenchymal stem cells (hTERT-MSC) was applied. Cell viability in non-coaxial, monophasic scaffolds of varying Laponite content and in core-shell scaffolds with Laponite-supported inks in a cell-free core, and cells embedded in a 3-9-0-shell was compared after Calcein staining of DiD-prelabelled cells via confocal fluorescence microscopy. Indirect cytotoxicity of monophasic Laponite scaffolds was studied with hTERT-MSC cultivated in 2D. Rheological data (shear stress, mass flow etc.) were used to analytically determine a model for flow parameters inside the printing nozzle for the applied bioinks [5].

For differentiation and co-cultivation experiments in core-shell scaffolds, primary hCC and hOB were extracted from human femoral head after informed consent of patients undergoing hip replacement surgery. Cells were applied in the shell material (3-9-0 for hCC, 3-9-0+plasma for hOB) while the respective factors (TGF-β3, BMP-2) were delivered via the core of coaxial strands (Fig.1B). Specific medium compositions for hOB and hCC differentiation in monoculture, as well as for bi-zonal hCC-hOB co-culture (Fig.1C) were defined. Viability of the cells was studied over 3 weeks of differentiation in mono- and co-cultures. In monocultures, chondrogenesis and osteogenesis were examined on mRNA expression levels of respective markers and on biochemical level investigating the secretion of collagen type II and sulphated glycosaminoglycans, and ALP respectively.

Results and Discussion
The developed inks allowed the control over release kinetics in a Laponite-dependent pattern, demonstrated in cell-free, monophasic conditions for albumin, lysozyme, dexamethasone and BMP-2. However, a lower cell viability of encapsulated hTERT-MSC in monophasic scaffolds with increasing Laponite concentration was found compared to Laponite-free bioinks while this drop was prevented by applying the cells in a 3-9-0 shell compartment surrounding...
the Laponite pastes in the core. No intrinsic cytotoxicity of scaffolds with Laponite concentrations of 0-9 % was identified. Modeling and evaluating flow parameters during monophasic extrusion through a 410 µm-needle with higher Laponite content revealed that the shear stress was not increased in these conditions. Since high viscosity led to a lower mass flow in concentrations above 3% (3-3-6; 3-3-9), the analytically determined maximum flow and shear stress were even lower in these inks compared to 3-3-0 and 3-3-3.

During differentiation of hCC in core-shell scaffolds, the majority of the cells survived the fabrication process and treatment, which led to increased mRNA levels of collagen type II in response to TGF-β3 supplied via core ink 3-3-3, while for 3-3-3 only and for 3-9-0 with TGF-β3, no effect was observed. Investigating the osteogenesis of hOB in the shell of monoculture scaffolds showed that the cells reacted to BMP-2 in the 3-3-3 core reservoir by ALP production. In co-culture conditions, both cell types survived with a viability rate that was not affected compared to the monoculture conditions (mean viability at day 7, hOB: 70 %, hCC: 60 %, n>3) while by day 21, the hOB had formed a cellular network in the respective zone and at the zonal interface (Fig.1D).

**Conclusion**

Coaxially separating the compartments for cells and factors allowed the free adjustment and balancing of respective ink requirements – a concept that can be easily transferred to other co-cultivation systems. This study provides a basis for fabricating and understanding 3D bioprinted, multi-cellular tissue substitutes and for co-cultivation of hCC and hOB.

Influence of Hot Isostatic Pressing on the corrosion resistance of Mg-4wt%Y-3wt%Nd processed by Laser - Powder Bed Fusion

Hanna Nilsson-Åhman¹,², Pelle Mellin¹, Cecilia Persson²

¹ Swerim AB, Kista, SE; ² Uppsala University, Department of Material Science and Engineering, Uppsala, SE

Introduction
Magnesium (Mg) alloys have recently gained increased attention as a biodegradable metal implant. They can be biocompatible and have superior mechanical properties compared to the biodegradable polymeric implants used today. However, poor formability and excessive corrosion rates have limited the clinical implementation of Mg alloys to an extruded Mg-Y-Nd alloy[1]. Additive manufacturing through Laser - Powder Bed Fusion (L-PBF) allows for the production of patient specific implant designs. Hot Isostatic Pressing (HIP) is a common method applied after printing to obtain fully dense materials for improved mechanical and corrosion properties. However, the amount of work done on L-PBF of Mg alloys remains limited. Esmaily et al [2] found an improved corrosion resistance after HIP of a Mg-Y-Nd alloy processed by L-PBF, as evidenced by surface activity and H₂ evolution over 24h. However, the influence of HIP on the long term corrosion properties and the part morphology after corrosion have not been evaluated. Herein we show that HIP can be highly detrimental to the long-term corrosion properties of a Mg alloy processed by L-PBF.

Experimental Methods
Spherical powder of alloy Mg-4wt%Y-3wt%Nd, particle size 24µm - 67µm (NMD GMbH) was processed by L-PBF (EOS M290). Samples measuring 10*10*30mm were produced with laser power of 200W, scanning speed of 1111 mm/s, layer thickness of 30µm, and hatch distance of 0.1 mm. Some samples were subsequently HIPed (QIH9, Quintus), at T= 520 °C, P=105 MPa and t=3h. The porosity was evaluated before and after HIP, using Archimedes density testing, and image analysis (ImageJ). The microstructure was characterized by light optical microscopy (LOM, Leica DM IRM, Leica microsystems), scanning electron microscopy (SEM, Sigma 300VP, Zeiss) and electron backscatter diffraction (EBSD, Aztec crystal). Secondary phases were characterized using X-ray diffraction (XRD, D8 Discover, Bruker) and electron diffraction spectroscopy (EDS, Aztec 5.0).

The corrosion media used was Dulbecco’s Phosphate Buffered Solution (Sigma Aldrich). Samples with sizes of 10*10*3mm were prepared from the as-built (AB), HIPed and extruded material. The surfaces were subsequently grinded down to 2500 grit. The electrochemical activity of the samples was characterized by potentiodynamic testing (Versa studio). The corrosion rate in immersion for 28 days was measured by H₂ evolution and weight loss. The chemical composition of the corrosion products and morphology of the corroded surfaces was evaluated after 28 days using LOM, SEM, XRD and EDS.

Results and Discussion
The density of the AB samples was 99.5%, and a density of above 99.9% was achieved after HIP. Secondary phases in the form of Mg-RE (RE=Y and/or Nd) intermetallics were present in all materials, but in varying size and amount. Flakes of Y₂O₃, and Zr precipitates were present in the AB and HIPed material. The Mg-RE intermetallic particles grew during HIP, and the neighboring areas were depleted from alloying elements. In the extruded material, a higher amount of the alloying elements is dissolved in the matrix, and no Y₂O₃ or Zr particles are present. The average grain size of the AB material was 3.5µm, 12.4µm for the HIPed, and 10µm for the extruded material. The potentiodynamic testing showed a lower corrosion current for the HIPed material compared with the AB material, but higher than the extruded material. The AB samples also had the highest H₂ evolution, followed by the HIPed, and
lastly the extruded samples. However, the mass loss for the AB material was 5± 1%, for the HIPed material 15±4%. The extruded material showed no significant mass loss.

LOM images after 28 days of immersion (Fig. 1 a-c) exhibited a rough surface with a white layer of corrosion products for the HIPed samples, consisting mainly in hydroxides and phosphates, and having a thickness of several microns. The surfaces of the AB and extruded samples remained smoother, largely consisting in a cracked oxide/hydroxide layer of a couple of microns.

For the HIPed samples there was an accumulation of detached pieces and corrosion products at the bottom of the test tube, which explains the discrepancy between the weight loss and the H₂ evolution. The poor corrosion properties of the HIPed material can be related to the zones depleted in alloying elements, making them more susceptible for localized attack [3], and the growth in grain size [4]. The superior corrosion properties of the extruded material can be related to the absence Y₂O₃ and Zr, and a larger amount of alloying elements dissolved in the matrix [5].

Conclusion

HIP improved the electrochemical properties of the surface but was highly detrimental to the long term corrosion properties. The change in microstructure played a more important role than the increase in density. Further optimization of the L-PBF process or subsequent heat treatments is needed for making the implementation of Mg-4wt%Y-3wt%Nd as a biodegradable metal implant possible.

The stiffness of biomaterials is increasingly appreciated as a key variable in the response of adherent cells and interacting tissues. However, most current work ignores that tissues are viscoelastic, with time-dependent mechanical behavior. We have demonstrated that the rate of biomaterial stress relaxation has dramatic effects on stem cell fate, and recently found it impacts multiple cell types in the tumor microenvironment, including cancer cells, monocytes, and T cells. Inspired by the importance of viscoelasticity to native extracellular matrix, new medical adhesives and medical devices are being synthesized from energy dissipative hydrogel networks.

University of Porto “Tuna”

Performance by a University of Porto “Tuna” from Abel Salazar Institute of Biomedical Sciences, University of Porto, Porto, Portugal

Tuna Académica de Biomédicas was created in September 2003 by a group of students and former students of the Abel Salazar Institute of Biomedical Sciences, University of Porto, Portugal. The ambition was to unite a group of friends around a tradition as unique as the Portuguese concept of “Tuna Universitária” and create an ideal of fraternity that would last for generations, always prioritizing music in order to adequately represent the concept of tuna, ICBAS and the Porto city.

Thus, in these 16 years of existence, the group has been growing, in number and in quality, currently surpassing 100 members, all students or professionals already working in Medicine, Veterinary Medicine and Aquatic Sciences. Among numerous awards won in Tuna Festivals across the country and in Spain, we also organize our own festival - TABernal - which has 9 successful editions, in addition to having already held 6 European Tours, passing through countries like Spain, France, Switzerland, Germany, Luxembourg and Italy, and 2 National Tours. In 2005 we launched our 1st CD - Memórias de um Tuno - which has already been published in 4 editions and thousands of copies have been sold. In 2017 we released our 2nd CD - Um Porto para o Mundo.

Molecular and colloidal building blocks to assemble structured biomaterial scaffolds in situ

Laura De Laporte\textsuperscript{1,2,3}

\textsuperscript{1} RWTH University Aachen, ITMC, Aachen, DE; \textsuperscript{2} DWI - Leibniz Institute for Interactive Materials e.V., aachen, DE; \textsuperscript{3} University Hospital RWTH Aachen, AME/AMB, aachen, DE

We apply polymeric molecular and nano- to micron-scale building blocks to assemble soft 3D biomaterials with anisotropic and dynamic properties. Microgels and fibers are produced by technologies based on fiber spinning, microfluidics, and in-mold polymerization. To arrange the building blocks in a spatially controlled manner, self-assembly mechanisms and alignment by external magnetic fields are employed. Reactive rod-shaped microgels interlink and form macroporous constructs supporting 3D cell growth. On the other hand, the Anisogel technology offers a solution to regenerate sensitive tissues with an oriented architecture, which requires a low invasive therapy. It can be injected as a liquid and structured \textit{in situ} in a controlled manner with defined biochemical, mechanical, and structural parameters. Magnetoceptive, anisometric microgels or short fibers are incorporated to create a unidirectional structure. Cells and nerves grow in a linear manner and the fibronectin produced by fibroblasts is aligned. Regenerated nerves are functional with spontaneous activity and electrical signals propagating along the anisotropy axis of the material. Another developed platform is a thermoresponsive hydrogel system, encapsulated with plasmonic gold-nanorods, which actuates by oscillating light. This system elucidates how rapid hydrogel beating leads to a reduction in cell migration, while enhancing focal adhesions, native production of extracellular matrix, and nuclear translocation of mechanosensitive proteins, depending on the amplitude and frequency of actuation.
Aligned nerve growth in Anisogel

Aligned growth of primary neurons from chick embryonic dorsal root ganglion inside a PEG-based Anisogel (purple). The Anisogel provides orientation cues by its magnetically aligned rod-shaped microgels in green. The microgels are fixed by a surrounding biofunctionalized PEG hydrogel.

Organs-On-a-Chip: A New Tool for the Study of Human Physiology

Ben M. Maoz¹²

¹ Tel Aviv University, Biomedical Engineering, Tel Aviv, IL; ² Tel Aviv University, Sagol School of Neuroscience, Tel Aviv, IL

Micro-engineered cell culture models, termed Organs-on-Chips, have emerged as a new tool to recapitulate human physiology and drug responses. Multiple studies and research programs have shown that Organs-on-Chips can capture the multicellular architectures, vascular-parenchymal tissue interfaces, chemical gradients, mechanical cues, and vascular perfusion of the body. Accordingly, these models can reproduce tissue and organ functionality and mimic human disease states to an extent thus far unattainable with conventional 2D or 3D culture systems. In this talk, we will present two approaches of using this technology. The first, will demonstrate how drug can be tested by linking of 8 human-Organ-on-a-Chip and showing results that are comparable to clinical data. Furthermore, we demonstrate how to exploit the micro-engineering technology in a novel system-level approach to decompose the integrated functions of the neurovascular unit into individual cellular compartments, while retaining their paracellular metabolic coupling. Using individual, fluidically-connected chip units, we have created a system that models influx and efflux functions of the brain vasculature and the metabolic interaction with the brain parenchyma. This model reveals a previously unknown role of the brain endothelium in neural cell metabolism: In addition to its well-established functions in metabolic transport, the brain endothelium secretes metabolites that are directly utilized by neurons. This discovery would have been impossible to achieve using conventional in vitro or in vivo measurements.

Biomimetic advanced *in vitro* models of glioblastoma multiforme

Daniele De Pasquale, Gianni Ciofani

*Italian Institute of Technology, Center for Materials and Interfaces, Pontedera, IT*

Introduction

Glioblastoma multiforme (GBM) is one of the most lethal cancers. Currently, GBM treatment consists of invasive techniques with strong side effects and poor outcome. Thus, there is an urgent need to find effective anticancer approaches and to improve *in vitro* research towards reliable tests for a better prediction of therapeutic efficacy and possible side effects *in vivo*.

Conventional 2D *in vitro* models poorly represent the tumor microenvironment and the complex interactions occurring when a drug has to be targeted. Thus, they fail at being a reliable model to describe anticancer treatments *in vivo*. Recently, *in vitro* research has focused on developing biomimetic models able to recapitulate some peculiar aspects of cancer microenvironment.

In this work, we present alternative approaches to study GBM, based on biomimetic models for advanced *in vitro* studies. In particular, we propose an innovative GBM spheroid model that can be controlled remotely with a simple magnet. Magnetically-driven cage-spheroids (MDCSs) offer the possibility to easily manipulate cancer cell spheroids, to control their size to standardize large-scale *in vitro* studies in order to better describe treatments efficacy, and to place GBM spheroids in complex *in vitro* constructs.

Experimental Methods

GBM primary cells derived from patients’ biopsies were cultured, amplified, and later seeded in MDCSs. MDCSs are hexagonal prisms of 120 µm in diameter realized by two-photon polymerization technique (Nanoscribe) with a photoresist (IP-L 780) doped with iron oxide nanoparticles to impart magnetic features. Viability tests (WST-1) were performed to compare MDCSs with conventional cultures derived from the same patient’s cells. Immunohistochemistry investigations for proliferative and stemness-related markers (Ki-67, SOX2, CD133) were carried out. The movement of MDCSs in desired positions driven by an external magnet was also characterized.

Results and Discussion

MDCSs present good magnetic responsiveness, as they faithfully follow the direction imposed by an external permanent magnet; moreover, cultures in MDCSs show the typical spheroids stratification, with an external proliferation layer and a semi-quiescent core. Cells in MDCSs also showed the expression of stemness-related markers. No differences were detected between conventional spheroids and MDCSs in terms of cell viability.

Conclusion

We can conclude that constructs obtained with MDCSs show identical biological features compared to conventional spheroids, yet allowing for a remote and easy control of their movement in complex systems, a feature not offered by conventional 3D cultures.

Modular hydrogels reveal impact of type I innate lymphoid cells on intestinal organoids

Geraldine Jowett1,2, Michael Norman1, Tracy Yu1, Suzette Lust1, Christian Lorenz2, Ricardo da Silva1, Joana Neves2, Eileen Gentleman1

1 King’s College London, Centre for Craniofacial and Regenerative Biology, London, GB; 2 King’s College London, Centre for Host-Microbiome Interactions, London, GB; 3 King’s College London, Department of Physics, London, GB

Introduction
Pathological matrix remodelling plays a central role in many human diseases, but is challenging to study as in vitro models often cannot replicate the complex 3D cell-matrix interactions that drive pathologies. Here, we describe a 3D model of the gut that allowed us to uncover an unexpected role for a rare immune cell type called Type-1 innate lymphoid cells (ILC1) in driving epithelial proliferation and gut fibrosis in patients with inflammatory bowel diseases. ILC1 are enriched in patient mucosa with active inflammatory bowel disease (IBD), but the impact of this accumulation remains elusive, and α-IFNγ therapeutics against their signature cytokine lack clinical efficacy. We hypothesise that ILC1 accumulation in IBD is not simply a driver of inflammation, but rather that ILC1 play a role in driving disease pathology itself. Therefore, the aim of this work was to use reductionist models based on intestinal organoid-ILC1 co-cultures to uncover how ILC1 impact the intestinal epithelium and matrix.

We used molecular dynamics simulations to design PEG hydrogels that cross-link quickly, but can still mimic the stiffness of normal intestinal tissue. We then co-cultured encapsulated human intestinal organoids with ILC1, and using a combination of atomic force microscopy force spectroscopy and multiple particle tracking microrheology, found that ILC1 drive intestinal matrix remodelling through a balance of MMP9-mediated matrix degradation and TGFβ1-driven fibronectin deposition. Our findings demonstrate the potential of using hydrogels in disease modelling, and open the possibility of unravelling how pathological matrix remodelling contributes to disease.

Experimental Methods
We established co-cultures of murine small intestinal organoids (SIO) with ILC1, and human induced pluripotent stem cell (iPSC)-derived intestinal organoids (HIO) with patient ILC1. We also developed a functionalized, PEG-based synthetic hydrogel system designed to form efficient networks at low polymer concentrations (Fig. 1).

Results and Discussion
Pico-SMARTSeq2 transcriptomics on SIO co-cultures revealed that IFNγ sensitises epithelial cells to Fas-mediated apoptosis. However, ILC1 also drive expansion of the epithelial stem cell crypt through p38γ phosphorylation and aberrant Cd44v6 expression, which is unexpectedly regulated by ILC1-derived TGFβ1, not IFNγ. We next established that human ILC1 also secrete TGFβ1, and drive CD44v6 expression in both HIO epithelium and the surrounding mesenchyme, though notably this phenotype is only recapitulated by ILC1 from patient biopsies with active inflammation. As TGFβ1 is a master regulator of fibrosis, the leading indicator for surgery in IBD, we next characterised the ability of ILC1 to regulate matrix remodelling. We created modifiable PEG hydrogels that cross-link quickly but at low stiffnesses and harnessed this platform to perform microrheology and atomic force microscopy on encapsulated HIO. We show that ILC1 drive matrix stiffening and degradation, which we posit occurs through a balance of MMP9 degradation and TGFβ1 induced fibronectin deposition.

Conclusion
Our synthetic organoid co-culture system enabled us to tease apart an important role for intestinal ILC1 in epithelial and matrix remodelling, which may drive either wound healing or fibrotic pathologies in IBD (Fig. 2). Moreover, this...
controlled 3D microenvironment provides a broader platform for dissecting interactions between complex human iPSC-derived tissues and rare cell subtypes in development and disease.

**Figure 1: PEG hydrogel design**

PEG-based hydrogels are formed using two sequential and orthogonal click reactions. PEG-4NPC is first conjugated with degradable, adhesive, or non-adhesive/non-degradable peptides, and then reacted 1:1 with PEG-4VS. Stiffness is altered by changing polymer concentration. Ligand density/degradability are controlled by varying the percent of their respective conjugates.

**Figure 2: ILC1-human intestinal organoid co-cultures**

Schematic showing how patient-derived ILC1 co-cultured with human iPSC-derived intestinal organoids impact the epithelium by driving intestinal crypt expansion through CD44v6. ILC1 also drive both extracellular matrix secretion (matrix stiffening) and MMP-mediated degradation of the hydrogel (matrix softening).

Designing a new targeted dendritic nanosystem for nucleic acid delivery to neuronal cells: the combination of fully biodegradable dendrimers and proteins

Ana P. Spencer¹,², Pedro Mota¹, Sara Silva-Reis¹, Ana Jesus¹, Victoria Leiro¹, Ana P. Pêgo¹,²,³

¹ i3S/INEB- Instituto de Investigação e Inovação em Saúde/Instituto de Engenharia Biomédica, Universidade do Porto, Porto, PT; ² Faculdade de Engenharia da Universidade do Porto (FEUP), Universidade do Porto, Porto, PT; ³ Instituto de Ciências Biomédicas Abel Salazar (ICBAS), Universidade do Porto, Porto, PT

Introduction

With 500,000 new cases worldwide per year, spinal cord injury (SCI) is one of the most serious medical conditions with substantial consequences to the patient, with the total loss of functionality in the most severe cases. Recently, gene therapy has been proposed as a powerful treatment of SCI. However, it requires the development of effective and clinically suitable delivery vectors with the ability to compact and protect nucleic acids. Cationic dendrimers are especially attractive nanobiomaterials due to their unique and tunable features: globular, nanosized, and very branched architecture, with the presence of several functional groups in the periphery, which allow their functionalization with different ligands simulating the multivalency of many biological systems [1]. Despite these remarkable properties, the non-biodegradability of the most commonly used dendrimers can lead to cytotoxicity due to the bioaccumulation of synthetic materials [1]. Thus, a new family of fully biodegradable (fb) PEG-dendrimers has been recently proposed and patented by us to act as nucleic acid delivery vectors [2-4]. Our PEG-dendrimers showed a great ability to complex and protect siRNA in compact nanoparticles (dendriplexes) that showed physicochemical properties very suitable for cellular uptake without causing any toxic effect in neuronal cells [4]. Here, we describe the preparation and characterization of a new targeted dendritic nanosystem, based on our amine-terminated fb PEG-dendrimers complexing siRNA, and functionalized with the non-toxic receptor-binding domain (HC) of tetanus neurotoxin as targeting molecule, which confers neurospecificity to the system [5]. This was designed to carry nucleic acids to neuronal cells, ultimately seeking their application in the development of new therapeutics to treat SCI patients.

Experimental Methods

The fb amine-terminated PEG-dendrimers were successfully synthesized and characterized by NMR and FTIR. Dendriplexes were prepared at different N/P ratios (N=number of primary amines in the dendritic structure; P=number of phosphate groups in the RNA backbone) ranging from 5 to 80 by adding siRNA to different volumes of dendrimer solution and characterized regarding siRNA retention capacity (SYBR®Gold accessibility assay and polyacrylamide gel electrophoresis), size and polydispersion index (PdI) by dynamic light scattering and surface charge by laser Doppler electrophoresis. Subsequently, dendriplexes were functionalized with the selected targeting moiety – HC protein. Briefly, the purified HC was functionalized with a heterofunctional PEG spacer (PEG:HC ratio of 1) and tethered to the reactive functional group at the PEG end of dendrimers/dendriplexes. The targeted dendriplexes were characterized as previously mentioned. The capacity of non-targeted dendriplexes to bind and be internalized by cells was assessed by flow cytometry and confocal fluorescence microscopy. Neuronal cells (ND7/23 and HT22 cells) and embryonic dorsal root ganglion (DRG) explants were incubated with dendriplexes carrying Cy5-tagged siRNA and then analyzed by the mentioned techniques.

Results and Discussion

A new fb PEG-dendrimer has been successfully synthesized until the 3rd generation [3]. The assembled siRNA dendriplexes were characterized in terms of their physicochemical properties, showing low nanosizes (<60 nm) and...
PDI (<0.3). These non-targeted dendriplexes demonstrated a great capacity to deliver siRNA in neuronal cell lines through clathrin-mediated endocytic mechanism beginning to appear inside cells after 6h of incubation. In addition, siRNA delivery capacity has been demonstrated in more complex and hard-to-transfect biological models, such as DRG (Figure 1). After incubation, the dendriplexes’ distribution is identified mainly within the cell body of neurons (center of DRG). Dendriplexes’ uptake by neurons was confirmed in the cross-section image showing the Cy5 fluorescence within βIII-tubulin (neuronal marker)-stained cells. Targeted dendriplexes were formed using different HC concentrations and showed good physicochemical properties (low nanosizes and PDI). Currently, the cell specificity of the HC functionalized nanosystems is under investigation.

Conclusion

Based on our PEG-dendrimers, a new targeted fb PEG-dendritic nanosystem was developed to deliver nucleic acids to neuronal cells. The encouraging physicochemical properties of dendriplexes make them a great candidate for neuronal cellular uptake. The new fully biodegradable dendritic nanosystem proposed shows great promise to contribute to a long-awaited therapeutic strategy for SCI patients.

Collagen/nano-apatite scaffolds as osteosarcoma 3D culture models to investigate the resistance mechanism to cold plasma therapy

Miguel Mateu-Sanz, Juan Tornin, Maria Pau Ginebra, Cristina Canal

Technical University of Catalonia (UPC), Biomaterials, Biomechanics and Tissue Engineering Group (BBT), Dpt. Materials Science and Engineering, Escola d'Enginyeria Barcelona Est (EEBE), Barcelona, ES

Introduction

Osteosarcoma (OS) is the main primary bone cancer, and most current therapies are not completely efficient [1]. Recently, Cold Atmospheric Plasmas, which consist in ionized gases composed by UV–visible radiation, electromagnetic fields and a wide variety of reactive species, have been validated as anti-cancer agents against OS [2]. This type of plasmas can be directly applied over OS cells or can be used to produce reactive species in aqueous solutions, which are believed to be the main cause of the anti-cancer effects [3]. Despite showing promising results, these studies have been obtained in 2D cultures that do not suitably represent tumor complexity. It is known that the bone environment plays a crucial role in the maintenance of drug-resistant Cancer Stem Cells (CSC) and in the progression of OS. CSC are subpopulations of tumor cells resistant to traditional therapies and they are responsible for tumor relapses. The aim of this work is to develop a suitable 3D culture system to produce distinct OS tissue-engineered models which allows to record the effects of cold plasma therapy on a relevant tumor microenvironment, considering their ability to eliminate CSC populations.

Experimental Methods

Composite scaffolds were prepared by freeze-drying of Collagen Type 1 (Col1) with hydroxyapatite nanoparticles (nHA) prepared by biomimetic routes. The Col1/nHA scaffolds were characterized in terms of porosity, nanoparticle distribution, mechanical properties, swelling and stability. Different human OS cell lines (MG-63 [4], G-292, SaOS-2 and U-2 OS) were seeded in the scaffold and their adhesion, proliferation and osteomimicry were characterized by DNA quantification (PicoGreen assay), fluorescence confocal microscopy and qPCR of osteogenic markers. Plasma-activated Ringer’s saline (PAR) was obtained by treating Ringer’s saline with a plasma jet (kINPen® IND) for times up to 240 seconds (s) and used to treat the tumors generated. The resulting cell viability was evaluated (DNA quantification and LIVE/DEAD assay) and compared to 2D cultures. Gene expression of OS progression and stemness-related markers were evaluated by qPCR in the 3D models exposed to PAR.

Results and Discussion

The macroporous scaffolds presented high porosity close to 86% (with most pores of 60 μm diameter) and high specific surface area of 22.38 m²/g. nHA were uniformly distributed in the scaffold (Figure 1A) which displayed high swelling ratio and good stability during two weeks with a weight loss of 10.82% ± 2.86% [4]. The Col1/nHA scaffolds allowed OS cells to proliferate, interact with the 3D matrix (Figure 1A) and increase osteomimicry. Following treatment with PAR, cell viability was reduced below 14.09 ± 2.61% with 120 s PAR of treatment in 2D, while in 3D models cell viability was above 44.73 ± 2.45% in 240 s PAR (Figure 1B). This was related to the reactive oxygen and nitrogen species generated in PAR in a time-dependent manner. Plasma treatment decreased the expression of osteogenic markers OPN and ALP under 0.5 ± 0.13 and 0.45 ± 0.1-fold change for the longest PAR treatment, while strongly enhancing (more than 5-fold change) the expression of stem-like related genes SOX-2, OCT3/4 or NANOG in a dose-dependent manner. Moreover, PAR treatment promoted in MG-63 an increase (2-fold change) of the sarcospheres (spherical, clonal expanding colony of CSC) formed from 3D-OS cultures [4]. Combination of PAR treatment with a specific inhibitor abrogated these negative effects in OS stemness, increasing the sensibility of OS
cells to plasma-derived reactive species, suppressing the remnant cell viability and giving hints on the possible mechanism implicated in the resistance to PAR described above.

**Conclusion**

The Col1/nHA scaffold developed provides a suitable substrate to generate a wide range of 3D OS tumor models *in vitro*, allowing to investigate the effects of reactive species generated by cold plasma therapies in a relevant context of the disease. The tumor microenvironment and presence of stem cell-like subpopulations allowed to propose an undescribed mechanism employed by OS cells to resist PAR induced-lethality in 3D cultures by the induction of stem properties. This study provides new insights to develop an effective treatment based in cold plasmas for OS therapy.

An endochondral ossification strategy using dynamically cultured liquefied and multilayered microcapsules

Inês J. Fernandes, Sara Nadine, Sónia G. Patrício, Clara R. Correia, João F. Mano

University of Aveiro, Chemistry, Aveiro, PT

Introduction
Bone tissue presents an incredible intrinsic self-repair ability. However, large bone defects may result in cessation of the regenerative process. Therefore, bone tissue engineering (TE) strategies have been explored to obtain the successful repair of large bone defects by recapitulating two distinct mechanisms of bone formation/healing, namely endochondral (ECO) or intramembranous ossification (IMO). Although IMO has been the standard bone TE strategy, the ECO process is being increasingly explored because of the well vascularized bone tissue that is obtained. ECO begins with the chondrogenic differentiation of recruited mesenchymal stem/stromal cells (MSCs) forming an initial cartilaginous template, followed by hypertrophic differentiation that will result in the release of osteogenic and angiogenic factors. Such biomolecules give rise to newly deposited bone tissue but also helps tissue vascularization.

Inspired by this mechanism, we propose a co-culture system composed by cartilaginous 3D microtemplates (MT), umbilical cord MSCs (UCMSCs), and human umbilical vein endothelial cells (HUVECs), bioencapsulated in liquefied and multilayered microcapsules (MC). These MC are composed by (i) a multilayered membrane obtained through the layer-by-layer assembly of poly(L-lysine), alginate, and chitosan, (ii) a liquefied alginate core, and (iii) cells.

The cartilaginous 3D MT are previously cultured in vitro for 21 days, as well as the non-primed 3D MT, used as control. Then, such MT are co-cultured with UCMSCs and HUVECs within the MC in dynamic conditions for another 21 days. MC with cartilaginous 3D MT are cultured with (ECO) and without (ECO control) osteogenic differentiation factors. Also, MC with non-primed 3D MT are cultured with (IMO) and without (negative control) osteogenic differentiation factors. Our hypothesis is that the engineered and privileged microenvironment of such ECO MC would mimic the native bone creation and healing processes, leading to the in vitro production of close-to-native vascularized bone-like microtissues (Fig. 1VI).

Experimental Methods
The MSCs-derived cartilaginous 3D MT are produced at high-rates and cultured in vitro for 21 days in chondrogenic differentiation medium (Fig 1I). Non-primed 3D MT, cultured in basal medium, are used as control. Then, the MT are co-cultured with MSCs and HUVECs in an alginate solution (6x10^5 templates/mL and 5x10^6 cells/mL). Alginate microgels are generated by electrohydrodynamic atomization technique. For that, under influence of electrical forces (10kV), the alginate solution breaks up into droplets. After crosslinking in calcium chloride, microgels encapsulating cells are obtained (Fig. 1II). Then, layer-by-layer is performed using poly(L-lysine), alginate, and chitosan as polyelectrolytes to produce a 10-multilayered membrane surrounding the obtained microgels (Fig. 1III). Ultimately, the core is liquefied by chelation with EDTA for 5 min (Fig. 1IV). Afterwards, liquefied MC with non-primed and cartilaginous MT are cultured up to 21 days in basal or osteogenic differentiation media. The proposed MC are tested under dynamic culture conditions, using a rotary cell culture system (Fig. 1V).

Results and Discussion
Cell viability was maintained during all the experiments. The cartilaginous nature of the 3D MT cultured in chondrogenic medium was confirmed by collagen II immunofluorescence assay and glycosaminoglycans quantification. After 21 days of encapsulation, the ECO MC presented osteopontin (OPN) and hydroxyapatite (HA) staining, indicating the production of bone extracellular matrix (Fig. 2A and 2B). Furthermore, both ECO (Fig. 2A) and ECO control conditions showed an increased endothelial cell recruitment compared to IMO. The elemental...
analysis by scanning electron microscopy and energy-dispersive X-ray spectroscopy (SEM-EDS) showed a higher matrix mineralization in the ECO MC, being the only condition to present a calcium/phosphorous (Ca/P) ratio (1.71) close to the native HA ratio (1.67) (Fig. 2D-F). HA was widely dispersed and formed large nodule-like structures in the surface of the ECO microtissues (Fig. 2C). Although IMO MC presented OPN and HA staining, the nanocrystals of HA presented a lower Ca/P ratio (1.11).

**Conclusion**

In conclusion, ECO MC proved to be an effective strategy for the *in vitro* osteogenic differentiation. Furthermore, results show the relevance of using the cartilaginous 3D MT in bone repair, highlighting the advantage of ECO over IMO strategy. In the future, we intend to use the proposed system as an injectable and non-invasive TE strategy for bone regeneration applications.

Uptake and transport of milk-derived extracellular vesicles across the Caco-2 intestinal barrier model

**Josepha Roerig**¹, Laura Schiller², Cica Vissiennon², Michael C. Hacker¹,³, Christian Wölk¹, Michaela Schulz-Siegmund¹

¹ Leipzig University, Pharmaceutical Technology, Institute of Pharmacy, Medical Faculty, Leipzig, DE; ² Leipzig University, Institute of Medical Physics and Biophysics, Medical Faculty, Leipzig, DE; ³ Heinrich Heine University Duesseldorf, Institute of Pharmaceutics and Biopharmaceutics, Duesseldorf, DE

**Introduction**

Extracellular Vesicles (EVs) are membrane-enclosed nanostructures which gain increasing interest for their role in intercellular communication as natural nucleic acid carriers (e.g. miRNA). We have chosen bovine raw milk as a source for EVs as these milk EVs withstand the harsh conditions of the gastrointestinal system making them interesting for oral drug delivery purposes¹. Moreover, bovine milk is cost-efficient and largely available to shed light in EV characteristics and their uptake mechanisms. This work aims to critically study uptake and transport properties of milk EVs in vitro. Therefore, uptake is compared to liposomes (DPPC/Chol) in intestinal cells. For transport experiments a standardized protocol considering the distinct EV requirements was established and apparent permeability coefficients (P_{app}) reflecting the transport rate were calculated.

**Experimental Methods**

**EV Isolation:** A differential centrifugation protocol was applied to bovine raw milk. The supernatant was loaded onto a Sephacryl S-500 (GE Healthcare, USA) column as described by Blans et al.² The presence of EVs was evaluated by dot blot analysis with antibodies against the EV-marker CD63, CD9, Tsg101, and the milk whey contaminant casein. EV-containing fractions were pooled and investigated for morphology and absence of aggregates using transmission electron microscopy (TEM).

**Total Protein and Lipid Concentration:** The total protein content was determined using a Bradford assay with absorbance measured at 610 nm. The lipid content was estimated using a sulfo-phospho-vanillin (SPV) assay as described by Visnovitz et al.³. Absorbance was measured at 540 nm.

**Nanoparticle Tracking Analysis:** To determine the EV size distribution and particle concentration, nanoparticle tracking analysis (NTA) with a Nanosight LM10 (Malvern Instruments) was used. Three videos of 60 seconds were recorded for analysis.

**EV Fluorescence Labelling:** EVs were labelled with 5 µM Vybrant DiO (membranes), 20 µM CellTrace CFSE (intravesicular proteins), or 10 µM SYTO® (RNA). Excess dye was removed with ultrafiltration columns. Dye controls were prepared with buffer instead.

**V and Liposome Uptake into Caco-2 Cells:** Enterocyte-like Caco-2 cells differentiated over 21 days on PET inserts (0.4 µm). Cells were incubated with stained EVs for 15 min to 6 h. For comparison with liposome uptake, cells were incubated with the same particle number of DPPC-Chol (70/30 mol/mol) liposomes. Cell uptake was evaluated with a confocal laser scanning microscope (Leica, Germany). To account for different labelling efficiencies of EVs and liposomes, a fluorescence correction factor was calculated.

**EV Transport across the Caco-2 Monolayer:** Caco-2 cells grown on 3 µm PET inserts were used for transport studies. Stained EVs were added to the donor compartment and fluorescence measured in the acceptor compartment to calculate the P_{app} transport rate.

**Results and Discussion**
Bovine milk was subjected to a SEC resulting in reproducible elution profiles (Figure 1A). EVs eluted in the first peak well separated from the main whey contaminant casein as confirmed by dot blot. TEM confirmed the presence of vesicular structures with a characteristic cup-shaped appearance after uranylacetate treatment (Figure 1B). The mean size was measured as 190.8 (±3.3) nm by NTA.

To characterize the EV isolation yield, protein content, lipid content and particle concentration were measured (Table 1) as recommended by guidelines from the International Society for EVs.

Table 1. EV yield after SEC isolation.

Three different labelling approaches showed comparable results by microscopic evaluation after 15 min to 6 hours indicating a fast EV internalization into Caco-2 cells. Dye controls exhibited no signal, so excess dye removal seemed to be successful. A novel fluorescence correction factor was implemented to compensate for differences in membrane labelling of EVs and liposomes. EVs outperformed liposomes regarding uptake efficiencies. Z-stacks revealed internalization of EVs whereas liposomes (DPPC/Chol) rather remained attached to the cell surface (Figure 2).

The transport rate was quantified for the first time as $P_{app} = 2.4 – 6.5 \cdot 10^{-6}$ cm/s.

**Conclusion**

Size-exclusion chromatography offers a reproducible method to isolate bovine milk-derived EVs of a good purity. The fast uptake of EVs in intestinal Caco-2 cells makes them promising for oral drug delivery purposes. Additionally, the variety of analytical methods applied creates a basis to further investigate the beneficial properties associated with EVs compared to liposomes to set a basis for rationally designed EV therapeutics. $P_{app}$ values reflecting the transport rate obtained with this model will add to the comparability of EV bioavailability testings.

Supramolecular peptide assemblies as a platform for antifouling, antimicrobial and antiviral materials

Meital Reches\textsuperscript{1,2}

\textsuperscript{1} The Hebrew University, Chemistry, Jerusalem, IL; \textsuperscript{2} The Hebrew University | Center for Nanoscience and Nanotechnology, Jerusalem, IL

The lecture will present bio-inspired functional coatings that are spontaneously formed by short peptides. These peptide-based coatings self-assemble on metals, oxides and polymers under mild conditions without any need for a curing step. The coating can serve in many applications. One application is preventing biofouling - the undesirable adhesion of biomolecules and organisms to surfaces. This process leads to numerous adverse phenomena including hospital-acquired infection, blockage of water desalination facilities and food contamination. We showed that this coating prevents the first step of biofouling, which involves the adsorption of bioorganic molecules to the substrate. Moreover, the coating significantly reduces the attachment of various organisms such as bacteria and fungi to surfaces. Another function that these peptide-based coatings can mediate is the adhesion of mammalian cells to implants. This function is important for the integrating of implants into the human body. Finally, we showed that these peptides self-assemble in solution into particles that adsorb and release active compounds that synergistically reduce the number of bacteria and viruses on the surface.

Silicon Nitride, A Bioceramic for Bone Tissue Engineering: A Reinforced Cryogel System with Antibacterial and Osteogenic Effects

Seunghun S. Lee¹, Leanid Laganenka², Xiaoyu Du¹, Wolf-Dietrich Hardt², Stephen J. Ferguson¹

¹ ETH Zurich, Institute for Biomechanics, Department of Health Sciences and Technology, Zurich, CH; ² ETH Zurich, Institute of Microbiology, Department of Biology, Zurich, CH

Introduction
Silicon nitride (SiN, [Si₃N₄]) is a promising bioceramic for use in a wide variety of orthopedic applications. Over the past decades, it has been mainly used in industrial applications such as the space shuttle engines, but not in the medical field due to scarce data on the biological effect of SiN. More recently it has been increasingly identified as an emerging material for dental and orthopaedic implant applications. Although a few reports about antibacterial property and osteoconductivity of SiN have been published, to date, there have been limited studies of SiN-based scaffolds for bone tissue engineering. Here, we developed a silicon nitride reinforced gelatin/chitosan cryogel system (SiN-GC) by loading silicon nitride microparticles into a gelatin/chitosan cryogel (GC), with the aim to produce a biomimetic scaffold with antibacterial and osteogenic properties. In this scaffold system, the GC component provides a hydrophilic and macroporous environment for cells while the SiN component not only provides antibacterial properties and osteoconductivity, but also increases the mechanical strength of the scaffold, to provide enhanced mechanical support for the defect area and a better osteogenic environment.

Experimental Methods
First, we analyzed characteristics of SiN-GC groups with different SiN concentrations such as interconnected porosity, mechanical properties and swelling ratio, then we checked apatite forming capacity in simulated body fluid (SBF) and protein adsorption capacity. Next, we started in vitro experiments and investigated an antibacterial effect of SiN-GC against Escherichia coli (E. coli) and Staphylococcus aureus (S. aureus) by checking bacterial proliferation rate and attachment to the scaffold. Then, we seeded MC3T3-E1 pre-osteoblast cells to study the cellular activity by examining viability, cell proliferation and morphology. Also, we seeded cells on SiN-GC to investigate mineralization and osteogenic gene expression (ALP, COL1, RUNX2 and OCN) by Alizarin Red S (ARS) staining and RT-qPCR. Finally, we developed a bioreactor to culture cell-laden scaffolds under cyclic loading (1 hour/day of cyclic compression with 1 Hz of frequency and 10% of strain) to mimic physiological conditions and analyze osteogenic effect of SiN-GC with ARS staining and RT-qPCR.

Results and Discussion
Characterization of SiN-GC demonstrated that incorporation of SiN in the scaffold led to higher elastic modulus, apatite formation in SBF and protein adsorption capacity while keeping the similar level of highly interconnected porosity as GC has which allows easier cell migration and nutrition flow. For antibacterial experiment, we confirmed that all SiN-GC groups showed significantly reduced bacterial proliferation and attachment compared to GC and increase of SiN concentration in SiN-GC groups led to improved anti-bacterial effect. In addition, for in vitro experiment with MC3T3-E1, the groups with higher SiN concentrations exhibited improved cell proliferation and enhanced morphology. Finally, results from ARS staining and RT-qPCR showed the improved mineralization and upregulated osteogenic gene expressions from SiN-GC compared to GC under both static and cyclic loading condition in bioreactor. Furthermore, we confirmed that scaffolds with higher SiN concentrations resulted higher mineralization and enhanced osteogenesis.

Conclusion

Page 858 of 2028
Overall, we confirmed the antibacterial and osteogenic effect of a silicon nitride reinforced cryogel system and the results indicate that silicon nitride has a promising potential to be developed further for bone tissue engineering applications.

**Acknowledgement**

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 812765 and the grant LA 4572/1-1 from Deutsche Forschungsgemeinschaft.

**Graphical Abstract**

Schematic illustration of silicon nitride (SiN) reinforced gelatin/chitosan cryogel (GC) system (SiN-GC) study. After (SiN-GC) fabrication, characteristics and bioactivity of SiN-GC with different concentration were analyzed. Then, in vitro experiments were carried out to investigate anti-bacterial properties, cellular activity and osteogenic effect under static and cyclic loading condition by bioreactor.
Lure and kill lethal ovitraps for tiger mosquito control based on biomimetic biomaterial based hydrogel and growth of entomopathogenic fungus *Beauveria bassiana* as biopesticide.

**Marco Friuli**¹, Marco Pombi², Riccardo P. Lia³, Claudia Cafarchia³, Christian Demitri¹

¹ University of Salento, Department of Engineering for Innovation, Lecce, IT; ² Sapienza University of Rome, Department of public health and infectious diseases, Rome, IT; ³ University of Bari, Bari, Italy, Department of Veterinary Medicine, Bari, IT

**Introduction**

Tiger mosquito (*Aedes albopictus*) is a vector of extremely serious pathologies for humans. Actually, traditional control methods (e.g. sprinkling of insecticides) presents more drawbacks (risk for human health and for environment) than efficacy, thus more targeted and specific are needed. Among them there are the precision pest management methods, relaying on “lure and kill” approaches based on semiochemical attractant or feeding stimuli (baits). However, *Aedes albopictus*, are semiochemicals and baits non-responsive, then the approach fails. A possible alternative for tiger mosquito are ovitraps and natural bioactive substances, including entomopathogenic fungi. Nevertheless, both methods have limits of applicability and effectiveness that, in relation to the higher costs, do not make them competitive with respect to insecticide spraying (low cost/effectiveness). Cost/effectiveness can be improved either by lowering costs and/or by increasing traps effectiveness (increasing lure). On the other hand, natural bioactive substances have a poor persistence at field, strongly influenced by the surface and the method of application. The work explores a connection between materials engineering and pest management to propose a new approach, called biomimetic, aiming to lure insects without semiochemical but rather imitating an insect-specific microenvironment. At the same time, biomaterials biocompatibility can be exploited to host inside the microenvironment a natural living bioinsecticide such as fungi, bacteria etc. Consequently, is possible to obtain the lure and kill effect bypassing both pesticide and semiochemical use.

The aim of the work was to create and optimize a lure and kill substrate acting as biomimetic oviposition substrate for tiger mosquito and as matrix for the growth and deliver *Beauveria bassiana* (an entomopathogenic fungus lethal for *Aedes albopictus*), with the aim to employ it inside a lethal ovitrap, suitable for use in large-scale control campaigns, industrially scalable and low-cost.

**Experimental Methods**

For the purpose, a macromolecular hydrogels was engineered and first tested for tiger mosquito in oviposition assay and then was evaluated as matrix for the survival, growth and delivery of *Beauveria bassiana*. The work focused first on identifying the main drivers of tiger mosquito’s oviposition and to reproduce them on the substrate. Furthermore, the effects of the material properties on the deposition and trap applicability were evaluated in order to optimize the substrate. Finally, oviposition in field condition was assessed by using a low-cost trap setup employing the materials that gave the best lab results. Successively, the compositions optimized for the lure were tested as a biocompatible matrix for the growth of *Beauveria bassiana* in order to assess the existence of a possible overlapping between oviposition and growth parameters. Furthermore, their effectiveness on *Aedes albopictus* eggs was tested through hatching tests using a 24 days old bioinsecticide, growth inside the matrix under controlled conditions. Finally a relation between fungal growth and material properties was explored.

**Results and Discussion**

Trials proved that a cellulose based physical hydrogel shows a superior efficacy in terms of reached eggs and lasting (up to 30 days vs few days) compared to common ovitraps and standard substrates Masonite and absorbing paper.
Furthermore, it has been verified that it can be effectively applied inside a low cost cardboard made trap. From oviposition assays pH, Salinity, turbidity and water evaporation resulted to influence the attractiveness of the substrate. Consequently, influencing parameters can be managed both with the composition of the hydrogel (e.g. preparation media, polymers choice or with the addition of humectants) but also by varying some properties of the gel such as viscosity or degree of crosslinking. This allows to regulate a parameter capable of amplifying (or suppress) lure directly through the engineering of the substrate. The tests verified the biocompatibility between hydrogel and *Beauveria bassiana*. A particular affinity was found between *Beauveria* and some compositions that showed to stimulate fungal proliferation. Furthermore, the lethality of the matrix (due to fungal and material action on the eggs and larvae) was verified. The highest lethal effect for *Bb/Gel* system was obtained using cellulose based compositions in particular preparations presenting high viscosity values. This was probably due to the presence of the fungus that seems to lead to a reduction in viscosity involving a lower trapping effect but also to a higher proliferation of infecting fungal structure in more viscous gels.

**Conclusion**
Trials proved that is possible to produce a cellulose based physical hydrogel acting both as oviposition substrate (based on biomimetic lure) and as biocompatible matrix *Beauveria bassiana*.

Introduction

*Helicobacter pylori* (*H. pylori*) is a gastric pathogen that infects the stomach of 50% of the world’s population (≈ 4 billion people). *H. pylori* infection is the etiological agent of several gastric disorders and accounts for 90% of all diagnosed gastric cancers (5th most common and 4th deadliest cancer worldwide)1. *H. pylori* is one of the sixteen bacteria that ranks higher in what concerns antibiotic resistance and as a threat to human health1. Antimicrobial peptides (AMPs) are an interesting alternative to antibiotics due to their broad-spectrum of activity and low propensity to induce bacterial resistance. AMPs immobilization onto biomaterials is an advocated strategy to overcome some of the AMPs drawbacks in vivo, namely proteolytic degradation and aggregation with proteins2. MSI-78A, an analog of Pexiganan, is one of the few reported bactericidal AMPs against this gastric pathogen3. Within this work, MSI-78A grafted chitosan microspheres (AMP-ChMic) were developed to eradicate *H. pylori* infection in situ (surface of gastric epithelium cells). A pH-responsive system was designed to prolong the gradual gastric release of AMP-ChMic.

Experimental Methods

Chitosan, a natural cationic biomaterial, was chosen due to its mucoadhesive properties, which also favor the electrostatic interactions with the negatively charged *H. pylori* membrane4. Chitosan (acetylation degree of 6%) was purified and, to prevent its dissolution in gastric acidic conditions, crosslinked with genipin (2.5 mM). Chitosan microspheres (ChMic), ranging from 2 to 7 μm in diameter, were produced by spray drying technique. Afterwards, a heterobifunctional spacer (NHS-PEG-MAL) was grafted onto the ChMic (PEG-ChMic) for MSI-78A immobilization with controlled orientation (MSI-78A-SH; modified on C-terminal with a terminal cysteine). Low acyl gellan gum (LAGG) hydrogels (1.5% w/v) were tested as possible ChMic carriers. LAGG hydrogels were prepared according to Pereira et al.5 and ChMic (1 mg/mL) were added. After the gelation process, small discs were cut with a puncher (diameter of 9 mm). To evaluate mass and diameter changes, as well as the ChMic release, stability tests were done over one week (37°C, 150 rpm) and in different pHs (from pH 2.6 to pH 7.0).

Results and Discussion

AMP-ChMic were successfully engineered, as shown by Fourier Transform Infrared spectroscopy analysis. The yield of the immobilization reaction was set at 91% (indirect determination by UV-Vis spectrophotometry). The developed AMP-ChMic were stable in acidic and neutral pH, supporting this approach for gastric settings. AMP-ChMic were bactericidal against *H. pylori* J99 (highly pathogenic human strain) at lower concentrations than the free peptide in...
solution (=277 μg vs 512 μg, respectively), even in simulated gastric conditions. AMP-ChMic killed *H. pylori* through membrane destabilization and cytoplasm release. Also, bacteria attraction to chitosan promoted this interaction and enabled that ≈10 bacteria were killed by 1 single microsphere.

Concerning the pH-responsive system, the mass loss was higher in pH 2.6 than in neutral conditions (pH 7.0), which indicates a different behavior according to the pH of the medium, as expected. The AMP-ChMic delivery occurred in all conditions tested, demonstrating the potential of this strategy for ChMic delivery in situ.

**Conclusion**

This microsphere-based innovative strategy boosted the activity of MSI-78A and AMP-ChMic demonstrated high potential for *H. pylori* infection management. Also, the pH-responsive delivery system engineered for microspheres release is expected to further boost efficiency *in situ*. Altogether, this is a promising approach within the scope of non-antibiotic therapeutic strategies against this gastric pathogen.

Bacteria Material relationship – it’s complicated! Bacterial behaviour in Pluronic based bioinks for Living Therapeutic Devices

Shardul Bhusari¹,², Shrikrishnan Sankaran¹, Aránzazu del Campo¹,²

¹ INM - Leibniz Institute for New Materials, Dynamic Biomaterials, Saarbruecken, DE; ² Saarland University, Chemistry Department, Saarbruecken, DE

Introduction

Engineered living materials have driven a major shift in the paradigm of materials research in the recent years. The incorporation of living cells within a non-living matrix is emerging as a new approach for drug delivery. Such living therapeutic materials include genetically programmed living organisms for performing enhanced functions like productive, adaptable, on-demand drug delivery with replenishable repositories.¹,² However, much is yet to be understood in the effects of encapsulation on bacterial performance. To address this issue, we used a bacterially-orthogonal hydrogel system based on Pluronic F127, in which network stabilization could be established with both non-covalent and covalent interactions that could be proportionally tuned. The interplay between the dynamic viscoelastic properties of the pluronic and the functional performance of the encapsulated bacteria was studied. The effect of the dynamic mechanical properties of the surrounding biocompatible and scale-up friendly hydrogel matrix on the growth behaviour, microcolony growth kinetics, viability and functionality of the encapsulated microbial cells was studied providing essential cues for living materials applications. We demonstrate the development of this tunable hydrogel system to encapsulate genetically engineered E. coli bacterial strain, in core-shell 3D bioprinted scaffolds, leading to a light-regulated, localized, tunable and prolonged drug/protein release.

Experimental Methods

Pluronic F127 polymer was chosen as a bioink. Pluronic hydrogel forms physically assembled gel networks at room temperature and its diacrylated derivative, pluronic diacrylate, can be chemically crosslinked upon UV light exposure using a free-radical photoinitiator. Hydrogel matrices with a range of viscoelastic properties were obtained by mixing pluronic and pluronic diacrylate in varying proportions. The dynamic mechanical properties were studied using rheology. A light-regulated dVio drug-producing E. coli strain was engineered by incorporating the genes related to the metabolic synthesis of the drug into a light responsive optogenetic plasmid.² Bacteria was encapsulated in 3D-bioprinted core-shell constructs and the effect of change in the crosslinking density and the resulting mechanical properties on the bacterial growth rate, drug/protein production and viability was studied using epifluorescence and confocal laser scanning microscopy.

Results and Discussion

Bacteria in physically crosslinked Pluronic hydrogels grew unidimensionally, as a chain with cells predominantly arranged along their longitudinal axis (Fig 1a). In contrast, in covalently crosslinked Pluronic Diacrylate hydrogel, the growing chain buckled already in the 2nd or 3rd division cycle, and the dividing bacterial population formed rounded colonies (Fig 1b). These results evidence that the nature of the crosslinks of the hydrogel network influences the growth of the encapsulated microorganisms. The compressive forces imposed by the network as the bacterial colony grows act as physical modulators of bacteria proliferation in the confined state. 3D printed core-shell fibres with violet colored dVio drug producing bacteria were fabricated (Fig 2). The bacteria were viable in the 3D scaffolds stored at various temperature conditions for over 14 months.

Conclusion

We studied the effect of the dynamic mechanical properties of the surrounding biocompatible and scale-up friendly hydrogel matrix on the growth behavior, microcolony growth kinetics, viability and functionality of the encapsulated
microbial cells. This would provide fundamental insights into the mechanisms by which these parameters can be controlled for living materials applications. Also, genetically engineered bacteria were successfully encapsulated inside 3D bioprinted core-shell hydrogel system. We demonstrate the possibility of controlling the bacterial growth by tuning the mechanical properties of the hydrogel and drug release in situ using an optogenetic strategy.

Introduction
Globally, the annual costs for wound care are projected to rise up to 3.5 billion euro in 2021 [1]. Wounds provide an ideal environment for bacterial colonization which often leads to chronic infections. The majority of wound infections are caused by Gram-positive bacteria such as Staphylococcus spp. Notably, the presence of bacterial biofilms has been linked to the induction and persistence of an inflammatory state of wounds and delayed wound healing, responsible for high rates of morbidity and mortality in patients. Moreover, the increase of antimicrobial resistance compromises the antibiotics available to treat the infections in the clinics, and alternatives for antibiotics are required. Wound dressings loaded with antimicrobial agents are emerging as a novel solution to prevent and treat wound infections while improving the healing process [2]. Under this rationale, we developed polycaprolactone wound dressings loaded with niclosamide, a repurposed molecule, originally used as an oral antihelminthic drug for treatment of parasitic infections [3], using the melt electro-writing (MEW) technology. MEW allows to create any type of shape and is solvent-free, making it easier to develop products towards clinical application. Poly-caprolactone (PCL) was selected for its elasticity, hydrophobicity and good mechanical properties and niclosamide was chosen as the antimicrobial agent for its potent antimicrobial activity against multidrug resistant Staphylococcus spp and its thermostability allowing its use in MEW.

Experimental Methods
The ink was prepared by the solvent casting method. PC-12 (medical grade PCL) and niclosamide were dissolved in chloroform and poured in a crystallizer glass. After overnight evaporation, the films were transferred at a low-pressure chamber (50 mbar) for three days. Films were cut in small pieces and loaded into the melt electrowriting syringe. The syringe was pre-heated at 70-80°C for 2 hours. Samples were printed at an angle ranging from 0 to 90 degrees and 0.5 mm distance between fibers. In vitro release studies of niclosamide from PCL were performed using 2 different systems (submersion and transwell model) to better predict the in vivo release kinetics. For both systems, PCL-niclosamide dressings were incubated in 1 mL of phosphate buffer solution with 2 % Tween 80 at 37°C and 120 rpm for 1, 3, 5, 7, 24 and 48 hours. The in vitro antimicrobial activity of the dressings was characterized against S. aureus strain ATCC 25923 and the multidrug resistant S. aureus strain LUH 14614, using a modified Kirby-Bauer method and a 4 and 24 hours bacterial adhesion assay. Moreover, biofilm formation on dressing fibers was visualized at both time points by scanning electron microscopy (SEM). The dressings were also evaluated in an in vitro wound model to evaluate effectiveness for the intended application. The wound model consists of an artificial dermis made primarily from collagen and hyaluronic acid which is partially submerged in a medium supplemented with plasma and blood to simulate the air liquid interface. The artificial dermis was infected with S. aureus strain LUH 14614, the dressing placed on top, and incubated for 4 and 24 hours. CFU counts were obtained from both the dermis and the dressing.

Page 867 of 2028
Results and Discussion
The submersion release profiles showed a burst release of 95% after 1 h followed by low release in the next 3 and 5 hours above the minimum inhibitory concentration (MIC) of niclosamide. Interestingly, the transwell release system showed a sustained release profile over time all above the MIC of niclosamide (Figure 1A). The niclosamide loaded PCL dressings significantly reduced the bacterial colonization of the dressings at 4 and 24 hours for both *S. aureus* strains (Figure 1B). These results were visually confirmed by SEM (Figure 1C). In the wound model, the niclosamide dressings showed significantly lower colonization with bacteria compared to unloaded dressings with 2 log less CFU recovered for the 4 hours and 3.5 log less for the 24 hours experiment. The number of bacteria in the dermis itself was also significantly reduced with a 1.5 log reduction of CFU for the 4 hours and a 2.5 log reduction for the 24 hours experiment (Figure 1D).

Conclusion
In conclusion, the niclosamide loaded PCL dressings produced by MEW technology are a promising combination for the prevention of *S. aureus* infection *in vitro* and with the dermis model. As a next step, we will assess the antimicrobial efficacy of the dressings in a murine skin wound infection model.

Advantages and limits of surface viscoelasticity as a drug-free strategy for the design of new antimicrobial biomaterials

Annabelle Vigué¹, Dominique Vautier¹, Bernard Senger¹, Youri Arntz¹, Vincent Ball¹, Amine Ben Mlouka², Julie Hardouin², Thierry Jouenne², Lydie Ploux¹,³

Introduction
Fighting microbial biofilms on biomaterials is usually addressed by incorporating antimicrobial agents. Nevertheless, as usual in the natural life, intrinsic properties of the material surface can also be a complementary approach. They may drastically reduce the quantity of adhered microorganisms, and these remaining microorganisms can be treated with classical antimicrobial agents. Mechanical properties of material surfaces recently emerged as a possible way to impact biofilm formation [1-5]. However, many questions have not been elucidated so far, and the biological or physico-chemical nature of the underlying mechanisms is still being discussed. We have here especially studied the effects of surface elasticity on microbial behavior, metabolisms and biofilm formation, and attempted to provide significant insight regarding the biological or non-biological origin of the observed phenomena.

Experimental Methods
Materials based on silicone and hyaluronic acid have been considered as typical non-hydrogel and hydrogel biomaterials without microbicide activity. Their viscoelasticity has been varied from a few (for hydrogels and the softest non-hydrogel) to hundreds of kPa (for the stiffest non-hydrogel). Surface properties, including mechanical and hydration, have been thoroughly characterized regarding both the bulk and the surface of the material. The study has been conducted with yeast (Candida albicans) and bacteria species (Escherichia coli -E. coli-). Microbial mobility, adhered or retained quantity, production of pili-like structures as well as the proteome of the adhered bacteria have been specifically investigated by using confocal fluorescence microscopy, modeling and proteomic analyses.

Results and Discussion
A general impact of the viscoelastic properties on adhesion, retention and mobility of cells has been confirmed for both material types, which was usually maintained but reduced for longer-term culture (up to one week). However, the microbial behavior significantly differed on hydrogels and non-hydrogels with even an opposite relationship to elasticity for the adhered quantity at short- and long-term culture. Mobility results highlighted different subpopulations of E. coli cells with different displacement speeds, which varied both with viscoelastic properties and material, and were attributed to different strength of interaction between cells and surface. Cell mobility was drastically modified when inoculated cells were first killed, suggesting the predominant role of biological rather than physico-chemical mechanisms. In that regard, several proteins associated to adhesion, mobility or/and biofilm formation were differently produced according to the material nature, but also to their viscoelastic properties, some of them being known for their involvement in the capacity of E. coli to sense their mechanical environment.

Conclusion
Finally, the overall results offer new insights regarding microbial behaviors and biological mechanisms in response to variations in viscoelasticity of materials. Even though they confirm that viscoelasticity is an additional surface property that can be optimized to tune biofilm formation on materials, they also temper the impact of viscoelasticity in contrast to other properties by comparing microbial behaviors on materials of similar elasticity.

The development of additive manufacturing technologies has enabled the implementation of personalized medicine strategies in the field of bone regeneration. Calcium phosphates (CaP) are among the best performing materials for this application, due to their similarity to the mineral phase of bone. Different additive manufacturing techniques can be used to print CaP 3D bone scaffolds. Among them, microextrusion-based direct ink writing (DIW) consists of extruding a pseudoplastic ink through a nozzle, in order to generate, layer by layer, the desired 3D structure. Different ink formulations have been proposed, most of them requiring a post-printing sintering step. However, self-setting ceramic inks have also been developed, in which the consolidation of the ceramic scaffold is not based on a high-temperature sintering process, but on a cement-like reaction that leads to the hardening of the structure at body temperature. They offer several advantages. In contrast to high-temperature sintering, this mild consolidation setting results in a very small shrinkage, and moreover they can be combined with biological molecules or even cells. Porosity is known to be a decisive factor in the performance of scaffolds for bone regeneration. Not only total pore volume, pore size and pore interconnectivity are relevant parameters. Also pore morphology plays an important role. Numerous studies have demonstrated that the concavity of a surface is a determining factor in its ability to trigger bone formation. We recently demonstrated that calcium deficient hydroxyapatite (CDHA) foams, with an open network of concave pores induced a significantly higher amount of bone in a canine model, both ectopically and orthotopically, than the same CDHA obtained by DIW, which resulted in arrays of cylindrical rods with convex surfaces [1,2]. Thus, although robocasting allows controlling the macroporosity and pore shape of printed scaffolds, the fact that microextrusion results in convex surfaces may be a limitation as far as bone regeneration and osteoinduction are concerned.

In this talk I will describe two strategies that provide greater versatility in the development of calcium phosphate bone grafts by DIW. They consist of either tailoring the internal porosity of the individual strands or modifying the external shape of the extruded filaments. The final goal is to create concavities in the otherwise convex surfaces of the 3D-printed scaffolds fabricated by DIW.

The first strategy is based on the incorporation of microspheres of a sacrificial material in the calcium phosphate ink. This allows creating an additional level of porosity, with concave morphology. Gelatin is a good candidate material when using self-setting inks, as it can be dissolved in the aqueous medium while the hardening reaction takes place. The formation of the characteristic network of needle-like hydroxyapatite crystals is not hindered by the addition of gelatin. The partial dissolution of the microspheres results in spherical pores throughout the filaments and exposed on their surface, increasing filament porosity up to 70%. Moreover, the presence of retained gelatin also has implications for the mechanical properties of the scaffold, reducing the strength but simultaneously conferring an elastic behavior, despite the high content of ceramic as a continuous phase.

3D printing with non-circular nozzles is the second strategy, which adds new degrees of freedom to DIW. Using nozzles with complex morphologies, e.g. star-shaped, not only allows to increase the specific surface area of the
structure, but also to have concave surfaces on the filaments. On the other hand, it requires that the inks exhibit fast elastic recovery, to ensure good shape fidelity of the printed filaments, and some restrictions arise in terms of the printing process. As for the impact of these morphological changes on the \textit{in vivo} behavior of the scaffolds, the results obtained in a study comparing the performance of scaffolds with star-shaped strands to conventional scaffolds with cylindrical strands in a rabbit model revealed that strands with concave surfaces enhance bone regeneration and have better osteoconductive properties, guiding the newly formed bone faster towards the core of the scaffold. Taken together, these results provide relevant inputs for the design of DIW patient-specific scaffolds with superior clinical performance.

Effect of cold atmospheric plasma-assisted surface modification of β-TCP with collagen and bone morphogenetic protein-2 mimetic peptide on osteogenic stem cell differentiation

Günnur Onak Pulat, Utku K. Ercan, Ozan Karaman

İzmir Katip Çelebi University, Biomedical Engineering, İzmir, TR

Introduction

Bone defects caused by trauma, disease, or surgical formations are challenging health issues worldwide. Therefore, there is a high demand for bone tissue engineering solutions such as synthetic grafts to treat bone defects. β-tricalcium phosphate (β-TCP), a synthetic bioerodible ceramic, has a degradable structure and high biocompatibility. Nevertheless, the absence of biological cues on synthetic β-TCP arises the need for further surface modification. β-TCP, which is produced at high temperatures, must be modified with bioactive molecules as a post-manufacturing process commonly by using highly concentrated solutions with physical adsorption methods. Absorbed molecules on β-TCP are not guaranteed to sustain cellular response during bone regeneration while covalently bound bioactive molecules remain on the surface until cell interactions and have a longer retention time after implantation [1]. On the other hand, using peptides as bioactive molecules rather than proteins have some advantages such as easier manipulation during grafting, high resistance to pH or temperature changes, low risk of immunological response, and chemical synthesis that provides precise control over the chemical composition of the peptide. Both bone morphogenetic protein-2 derived peptide (BMP; NSVNSKIPKACCVPTELSA) and collagen mimetic peptides (CMP; GTPGPQGIAGQRGVV) are a promising group with great therapeutic potential among bioactive peptides and known to increase cell attachment and the ability of cells to differentiate into osteoblastic cells. Herein we investigate a new strategy to modify surfaces of β-TCP with cold atmospheric plasma (CAP) to enhance bioactive peptide conjugation. Within the proposed novel approach, we assessed the surface modification of β-TCP ceramics with CAP to induce hydroxyl (-OH) groups and BMP-2 derived peptide (BMP) and collagen mimetic peptides (CMP) were immobilized to β-TCP graft. The proliferation and differentiation of human mesenchymal stem cells (hMSCs) on β-TCP, BMP/β-TCP, and CMP/β-TCP scaffolds were compared.

Experimental Methods

BMP sequence containing NSVNSKIPKACCVPTELSAI and CMP sequence containing GTPGPQGIAGQRGVV were synthesized with 4-Methylbenzhydrylamine (MBHA) resin. CAP was applied on β-TCP discs until maximum hydroxyl (-OH) groups are exposed by determining parameters roughly by FTIR. Peptide sequences were conjugated on β-TCP by silanization with APTES (1x10⁻² M) in anhydrous hexane followed by succinimidyl 3-maleimidopropionate (SMP, 2x10⁻³ M) in DMF and 1 mM peptide in DMF [2]. BMSCs were seeded on β-TCP, BMP/β-TCP, and CMP/β-TCP scaffolds and incubated in an osteogenic medium. Cell proliferation, ALP and DNA quantification assay, q-PCR analysis for collagen type I (COL-I), osteopontin (OPN), and osteocalcin (OCN) genes were evaluated on β-TCP, BMP/β-TCP, and CMP/β-TCP groups by 7d, 14d, 21d, and 28d to compare the effect on osteogenic differentiation of hMSCs. Immunofluorescent staining will be performed to stain COL-I, OPN, and OCN proteins.

Results and Discussion

FTIR results showed that CAP plasma was generated -OH groups with oxidative effect due to the presence of reactive oxygen species and the broad bands appeared at around 3600 and 3000 cm⁻¹ due to the presence of hydroxyl and alkyl groups. Furthermore, a change in the absorption bands at 1460–1200 cm⁻¹ was observed by the effect of nitrogen introduction caused by peptide conjugation. The cell number (Figure 1 A) and DNA content (Figure 1 B) of
all groups increased slightly with incubation time. The cell number and DNA amounts of CMP/β-TCP groups at each time point were higher than other groups. However, the ALP activity of all other groups incubated in osteogenic medium peaked at day 14 and returned to baseline level at day 28 (Figure 1 C). The ALP activity was maximum on CMP/β-TCP groups compared to other groups. The mRNA expression of osteogenic markers such as COL-I, OPN, and OCN were higher in CMP/β-TCP groups compared to BMP/β-TCP and β-TCP according to real-time-PCR amplification. Cell proliferation, DNA, ALP assay, and q-PCR analysis results indicated that CMP sequence is more effective than BMP sequences. The expression pattern of osteogenic markers such as COL-I, OPN, and OCN proteins will be also investigated by immunofluorescent staining to confirm the result.

**Conclusion**

The outcomes of this study would help to enhance biomaterial’s function with the most effective sequence on human MSCs on osteogenic differentiation for further modifications of the synthetic scaffolds for bone tissue engineering. Furthermore, a new strategy to modify surfaces of β-TCP with cold atmospheric plasma (CAP) could be used to enhance bioactive peptide conjugation.

Incorporation of nanoparticles into PEOT/PBT electrospun scaffolds for the treatment of bone fractures

Clarissa Tomasina¹, Giorgia Montalbano², Priscila Melo², Sonia Fiorilli², Paulo Quadros³, António Azevedo³, Chiara Vitale-Brovarone², Sandra Camarero-Espinosa¹, Lorenzo Moroni¹

¹ MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht University, Maastricht, NL; ² Department of Applied Science and Technology, Politecnico di Torino, Torino, IT; ³ FLUIDINOVA S.A., Rua Eng. Frederico Ulrich 2650, Maia, PT

Introduction
Osteoporosis is a bone disease that leads to the loss of bone mass and mineral density making the tissue brittle and increasing the risk of fractures. In particular, osteoporotic pelvic fractures require the patient to undergo extensive surgeries and long bed recovery.

To regenerate the fracture site, we employed solution electrospinning, a technique able to generate nanofibers that resemble the bone extracellular matrix, and that allows also the creation of composite mats by embedding particles during the process. Mesoporous bioactive glasses (MBGs) and hydroxyapatite (HA) particles have both proved to promote bone regeneration, offering a suitable platform for the delivery of ions for osteoporosis treatment such as strontium.

Hence, we fabricated a composite scaffold made of PEOT/PBT with MBGs and HA doped with strontium to boost bone regeneration in pelvic osteoporotic fractures.

Experimental Methods
Two types of MBGs (MBG_SD and MBG_SG doped with 10% strontium) and HA (nanoHA non doped and doped with 50% strontium) were sonicated using a horn sonicator and the morphology, hydrodynamic radius and ion release were characterized by transmission electron microscopy (TEM), dynamic light scattering (DLS) and inductively coupled plasma-mass-spectrometry (ICP-MS), respectively.

For scaffold fabrication, 300PEOT55PBT45 was dissolved at a concentration of 28 wt% in a mixture of chloroform: hexafluoro-2-propanol (75:25) for 24 hours and particles were consequently added to the polymer in concentrations ranging from 5 w/v% to 15 w/v%, and left stirring for 1 hour. Initial electrospinning tests were conducted at a distance of 10-15 cm using a plate collector with voltage and flow rate ranging from 18,5 to 20 kV and 150 to 50 ul/h, respectively. For investigation of the morphology, composition and particle distribution, electrospun scaffolds were imaged using a Jeol JSM-IT200 InTouchScope scanning electron microscope (SEM) at V=10kV equipped with an energy dispersive X-ray analyzer (EDX). Furthermore, Fourier-transform infrared spectroscopy (FTIR) was also performed to remark the presence of particles at different concentrations in the mats.

Mechanical tests were performed on fibrous mats by uniaxial tensile strength using a TA ElectroForce equipped with a 45 N load cell.

Finally, scaffolds were evaluated for their biocompatibility through in-vitro tests and seeded with hMSC at passage 5. hMSCs were cultured for 35 days in maintenance and osteogenic media. At day 14 and 21, ALP assay was performed as an early indicator of osteogenic activity. At day 35, we performed Alizarin red for calcium deposits, immunofluorescence for collagen I, osteocalcin and osteopontin, SEM and qPCR.

Results and Discussion
Particles were sonicated from 5 to 10 min using the horn sonicator, resulted well dispersed after 6 min, and were stable in the electrospinning solvent. MBGs and HA were then embedded in the scaffolds after sonication up to 12,5 w/v% and 15w/v% respectively. In both cases, at the maximum concentration, the particles showed small aggregates.
up to 10 um. The scaffold fibers resulted to have a diameter of $620.07 \pm 111.7$ nm and $356.3 \pm 70.14$ nm for MBGs and HAs, respectively, which was expected considering the size of the two particles. Their incorporation in the scaffolds was further confirmed by EDX and FTIR. Mechanical tests revealed a young modulus below 10 MPa for the scaffolds.

hMSC were cultured on the scaffolds during 35 days, showing at day 14 and 21 higher levels of ALP expression in the composite scaffolds compared to the ones without particles. At day 35, a dense extracellular matrix coverage in composite samples through SEM in osteogenic media as well as an increase in calcium deposits through alizarin red. These results, together with qPCR analysis, prove the biocompatibility and bioactivity of the fibrous mats and their ability to support cell adhesion.

**Conclusion**

PEOT/PBT was successfully spun with two different sizes of MBG and HA particles which were embedded in the mats until 12.5 w/v% and 15 w/v%. The composite scaffolds were morphologically, chemically and mechanically characterized as well as investigated in-vitro for their bioactivity. This characterization highlights the potential for these scaffolds to promote bone regeneration in osteoporotic fractures.

Engineered 3D-printed vascularized hydrogels for efficient presentation of growth factors

Oana Dobre¹, Ruoxiao Xie², Liliang Ouyang³, Molly M. Stevens², Manuel Salmeron-Sanchez¹

¹ University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB; ² Imperial College London, Department of Materials, Department of Bioengineering, Institute of Biomedical Engineering, London, GB; ³ Tsinghua University, Department of Mechanical Engineering, Beijing, CN; ⁴ University of Glasgow, Centre for the Cellular Microenvironment, Glasgow, GB

Introduction

Bone is the second most transplanted tissue after blood and can regenerate by itself to a certain degree, but in cases of critical size defect, an intrinsic capacity of self-regeneration and consequently bone repair is delayed and impaired. This type of lesion is termed non-union bone fracture and requires additional treatment with bone grafts materials in order to restore pre-existing function¹. There is therefore an urgent unmet clinical need for personalized scaffolds that promote the regeneration of large bone defects. Different material-based strategies are being explored to improve the efficiency of growth factor (GF) delivery by recapitulating the characteristics of extracellular matrices for applications in regenerative therapies, including large bone defect repair and regeneration caused by trauma, disease or tumor resection². Vascularization is important for bone grafts to properly integrate at the injury site however it is being underestimated in current management strategies¹.

The aim of this study is to develop a bioink system by incorporating PEGylated full-length laminin (LM) into gelatin methacryloyl (GelMA). The incorporation of LM allows increased availability of cell and GF binding domains. LM is an extracellular protein composed of three chains α, β and γ, that plays a role in multiple cellular process. LM has 16 isoforms with different affinities for various GFs. The abundance of every LM isoform is tissue-dependent³, suggesting that LM has tissue-specific roles. To demonstrate the application of this bioink system in biofabrication and regeneration, 3D vascularized bone tissue will be fabricated by printing LM/GelMA hydrogel with mesenchymal stem cells (MSCs) and human umbilical vein endothelial cells (HUVECs) via extrusion-based bioprinting.

Experimental Methods

3D LM-based bioinks containing different concentrations of PEGylated human LM, GelMA and a photoinitiator (see Figure 1A, B and C) were printed using a multi-nozzle 3D Bioprinter⁴. Then the printed structures were crosslinked via photopolymerization as shown in Figure 1D. Mechanical properties of the bioinks with and without LM with different concentrations of GelMA were characterized by shear bulk rheology. hMSCs and HUVECs with the addition of specific growth factors such as vascular endothelial growth factor (VEGF-A165) and bone morphogenetic protein-2 (BMP-2) were incorporated into the LM bioinks to evaluate cell cytotoxicity, study their release kinetics and potential to drive vasculogenesis and osteogenesis.

Results and Discussion

We investigated the possibility of 3D LM/GelMA to promote bone regeneration by delivering growth factors in a controlled manner. To do this, 3D LM/GelMA with tuneable stiffness and different concentrations of LM 332 were successfully printed to mimic the native bone microenvironment. Other properties such as GF release kinetics and biocompatibility of the bioinks were evaluated to determine if our system could be used as an alternative biomaterial for bone regeneration. Protein (immunofluorescence) and gene expression (qRT-PCR) results of co-culturing hMSCs and HUVECs encapsulated in 3D LM/GelMA bioinks loaded with BMP-2 and
VEGFA-165 showed upregulated expression of osteopontin (OPN) and endothelial cell adhesion marker CD31 after 14 days.

**Conclusion**

These novel bioinks combine LMs with GFs, which are powerful signalling molecules that direct cell response, promoting the regeneration of target tissue that can be used to engineer in vitro tissue models. We report on the development and characterization of 3D LM/GelMA hydrogels with tuneable mechanical and highly efficient growth factor presentation for potential applications such as regeneration of bone defects with an adequate vascularisation.

Introduction
It is well established that the survival and integration of large biofabricated tissues is directly associated with the capacity to achieve rapid oxygenation and nutriment supply. However, the effective fabrication of hierarchical vascularized networks remains a main challenge in the fields of tissue engineering and biofabrication. Many strategies have been developed to overcome this barrier. In particular, numerous approaches have been deployed to design and biofabricate vascularization networks at the macro or mesoscopic scale (Datta et al., 2017). However, the complex architecture of vascularized networks at the microscopical scale has been less studied. This is partly due to the lack of direct applications, but is mostly a result of the technical complexity required to achieve its fabrication and control its evolution from the original design to the resulting function in 3D (Richards et al., 2017). With the advent of new microscopic 3D cell models and advanced micro tissues, the ability to control biofabricated microvascularized networks appears not only relevant but increasingly required.

In this context, we propose a new method to bioprint 3D pre-microvascularisation models, based on the replication of simple endothelial cell (EC) geometries in a microenvironment containing fibroblasts. Bioprinting ECs in coculture with fibroblasts has been largely used in the past. One of the main limitations of previously proposed models lies in a loss of the geometry resolution, at the microscopic scale, during maturation (Kolesky et al., 2014). Here, we used a laser-assisted bioprinting technology to deposit small EC spheroids (tens of micrometers in diameter), in a controlled fashion, within a biocompatible hydrogel (Hakobyan et al., 2020). By controlling the positioning of the spheroids in different 3D conditions, we evaluated the pertinence of this method in terms of cell maturation and geometry resolution.

Experimental Methods
A laser-assisted bioprinter (Novalase) was used in this study (Guillemot et al., 2010). The instrument integrated a nanosecond laser (1064 nm, 30 ns, 7 W, 1-100 kHz), an optical scanner (SCANgine 14, ScanLab), a system of sample positioning, and a graphical user interface that was used to simultaneously control all these elements and to generate various patterns. Human umbilical endothelial cells (HUVEC), expressing a Red Fluorescent Protein, were cultured and amplified in standard conditions, then trypsinized and concentrated at 70.10^6/mL to create the bioink. 33 µL from this bioink were spread on a 30 mm diameter glass plate, previously coated with a thin gold layer and playing the role of a donor. As a receiver, 150 µL of 5% (w/v) methacrylated gelatin (GelMa) were spread on a thin glass slide before bioprinting. The consistency of the GelMa was critical to enable the 3D microinjection of the spheroids inside the hydrogel, since more rigid hydrogels only lead to surface printing. A special compromise was found between the laser pulse energy and the printing distance (donor-receiver) as to control the depth of the spheroid deposition inside the GelMa. Typical parameters were a pulse energy of 60 µJ and a printing distance of 700 µm. To study HUVEC maturation after printing, human skin fibroblasts (HSP) were cultured, amplified and loaded at various concentrations within the GelMa (i.e. 5, 10, 15, 20 and 25 millions/mL) prior to printing. The observation of
the resulting maturation was conducted through confocal microscopy, 15 days post printing. Stacks of images were analyzed using Imaris to reconstruct the pre-vascularization in 3D.

Results and Discussion
We first assessed the spheroid volumes as a function of laser energy. We showed that we were able to control the size of the bioprinted spheroids. We thus adjusted the parameters to get a spheroid diameter about a few tens of micrometers. In order to facilitate the analysis, 10 to 15 lines of spheroids, spaced by 2 mm, were printed for each sample. This allowed us to easily quantify and compare the number and the directionality of the pre-vascularization connections generated in different conditions. The highest concentration of HSFs tested induced a decrease in the number of connections, resulting in better connection interactions between individual spheroids within the printed lines, and along the line direction. Keeping these optimized conditions, we finally exploited the bioprinting high throughput capability and versatility to create more complex geometries.

Conclusion
We have established a new approach to biofabricate microvascularized networks with a printing resolution close to 50 µm. These networks can be replicated on demand, with any desired geometry. This innovative laser-assisted bioprinting technique enabled us to increase by a factor of 10 the post-printing resolution compared to 2D laser printing, while allowing the deposition of very high localized cell concentration in 3D, a key parameter to support cell maturation in 3D.

3D bioprinting of vascularized bone with inherent spatial controlled release of osteogenic and angiogenic factors

Meric Goker, Pinar Y. Huri
Ankara University, Biomedical Engineering, Ankara, TR

Introduction
Bone tissue is capable of self-repair after a fracture or a damage. Yet, critical-size defects may remain unrepaired and filler materials is used in order to support the defect site structurally and mechanically [1]. In this study, 3D printed vascularized grafts were produced with and inherent spatiotemporal growth factor delivery system, where ASCs were utilized as the only cell source to produce the complex structure. The ASC osteogenic differentiation, and vascular network formation by the endothelial cells within the ASC population was provided by controlled spatial release of BMP-2 and VEGF, respectively. Growth factor-laden microparticles were placed in predetermined positions during 3D printing for the controlled formation of mineralized tissue and vessels (Figure 1).

Experimental Methods
The 3D model was uploaded to the 3D Bioplotter (Envisiontec) which has two simultaneous print heads. One of the heads was used to 3D print poly(ε-caprolactone) (PCL) to provide the mechanical stiffness. The other print head was used to print alginate which carries microparticles that are loaded with BMP-2 and VEGF. Release kinetics from the hybrid grafts was studied by using a model protein. 3D printed samples were seeded with ASCs, cultured in vitro and then fixed on days 7, 14 and 21 for immunofluorescence staining for osteopontin and CD31.

Results and Discussion
Print parameters of the PCL/alginate hybrid scaffolds were optimized including linear speed of the head, pressure, temperature, and concentration of the polymer. Highest resolution for the 3D print was achieved with 2mm/s linear speed and 0.5 bar pressure for alginate. Different concentrations varying from 1% to 4% w/v were tested for determining the printability of capsule-laden alginate solution. It was observed that 2% w/v is preferable as alginate concentration in terms of printability and embeddability of capsules.

Results of immunofluorescence staining from the same sample reflected that vascularization in the canal section and osteogenesis in the rest of the scaffold was successfully induced due to spatiotemporal delivery of growth factor cues (Figure 2).

Conclusion
With this work, it was aimed to fabricate an off-the-shelf construct produced from simpler components (PCL as the only load bearing component, alginate as the bioink material and ASCs as the single source of cells) to produce a vascularized bone graft. A novel approach was proposed, and 3D printed to mimic the complex architecture of the tissue. The spatial delivery of BMP-2 and VEGF was applied by positioning capsules release them within the specific regions of the 3D printed construct. In conclusion, this work offers a novel yet simple vascularized bone graft production procedure that can possibly be adapted to the clinic in the future.

**Introduction**

Dental restorations have experienced a great development throughout the last decades. Historically, the most employed materials have been gold and its alloys. However, due to the high cost of these materials, non-precious metallic alloys like Co-Cr alloys appeared. Nowadays, Co-Cr alloys are the predominant preference for dental fixed restorations in the dental industry. There are several techniques currently employed for manufacturing these restorations, being the milling technique the one that gives better mechanical properties. However, in the recent years, some additive manufacturing technologies have emerged in this industry due to the benefits of the free form generation. Co-Cr alloys are expensive materials, therefore, additive manufacturing technologies allowing reduction of material waste, are very interesting alternatives in this field. The Laser Directed Energy Deposition (LDED) is a technique which can be implemented in the dental industry, merging the advantages of Additive Manufacturing technologies and the high overall performance of the materials generated by this technique.

The main objective of this study is to evaluate the viability of the Laser Directed Energy Deposition (LDED) technique as a manufacturing alternative for the metallic structure of the dental prostheses. To do so, LDED has been compared with the manufacturing techniques currently employed in the dental industry: lost wax casting, milling from commercial disks and Selective Laser Melting (SLM).

**Experimental Methods**

Four manufacturing techniques were employed to manufacture the samples: lost wax casting, LDED, milling from commercial disk, and SLM.

Specimens obtained by casting (CAST) were obtained using a centrifugal casting machine by melting ingots of Heraenium Pw alloy with a casting torch.

Specimens obtained by Laser Directed Energy Deposition (LDED) were generated using a proprietary LDED manufacturing device with a high power near-infrared continuous wave laser used as energy source. Co-Cr Starbond Easy Powder 30+ powder was used as precursor material. The near-net-shape specimens were machined until final dimensions in a commercial CAD/CAM milling system. The angle between tensile tests directions and building direction was 90°.

Milled specimens were obtained from Co-Cr Kera® dental discs using a CAD/CAM milling machine. The angle between tensile tests directions and axial disc direction was 90°.

Selective Laser Melting (SLM) specimens were generated using an EOS M 270 machine, with a high power near-infrared continuous wave laser used as energy source. The material employed was Co-Cr EOS SP2 powder. The angle between tensile tests directions and building direction was also 90°, as in the LDED alloy.

**Results and Discussion**

Microstructural analyses (Fig.1) showed that samples obtained from different techniques possess different microstructures with different segregation behaviors. CAST specimens showed a typical dendritic matrix with high
segregation size. LDED samples showed columnar grains with reduced intergranular segregation. Mill samples are composed by equiaxial grains with segregations aligned with the axis of the disc. SLM samples showed small cellular grains with a homogeneous segregation evenly distributed along the whole material. Mechanical results (Fig.2) demonstrate that the materials obtained by LDED possess a similar behavior of the milled disks material. Both materials performed better than the ones obtained by casting and SLM, absorbing nearly twice the energy before rupture, as well as a significant elongation after fracture in comparison with materials obtained by casting or SLM. It should be noted that all materials comply with the type 4 of ISO 22674 ISO standard for dental materials, which is recommended for dental fixed restorations.

Conclusion

LDED is an additive manufacturing technique that can be implemented in the restorative dental industry with high overall performance. This manufacturing process can compete directly with the best quality techniques, and taking the best part of each of them, mechanical properties from milling disk, and freeform generation from SLM processes.

Understanding the Regenerative Response Induced by Biomaterials Systems: Insight into the Role of Glycosylation

Abhay Pandit

National University of Ireland, Galway, CÚRAM-SFI Research Centre for Medical Devices, Galway, IE

Biomaterials are no longer considered innate structures and using functionalisation and biofabrication strategies to modulate the desired response whether it is a host or implant is currently an important focus in current research paradigms. Fundamentally, a thorough understanding of the host response will enable us to design appropriate strategies. The input from the host response needs to be weighed in depending on the host disease condition. Our current inputs have been through a deliberate understanding of glyco-proteomics based tools that we are developing in our laboratory.

In addition, biomaterials themselves provide immense therapeutic benefits which need to be accounted for in the design paradigm. Using functionalisation strategies such as enzymatic and hyperbranched linking systems, we have been able to link biomolecules to different structural moieties. The programmed assembly of biomolecules into higher-order self-organized systems is central to innumerable biological processes and the development of the next generation of scaffolds. Recent design efforts have utilized a glycobiology and developmental biology approach toward both understanding and engineering supramolecular protein and sugar assemblies.

The iPSpine project: smart biomaterials escorting iPS cells to rejuvenate the degenerate disc

Marianna A. Tryfonidou

Utrecht University, Faculty of Veterinary Medicine, dept Clinical Sciences, Utrecht, NL

Over 40% of the cases of low back pain is due to degeneration of the intervertebral disc. In the Horizon 2020 iPSpine project, 21 partners joined forces to develop an advanced therapy medical product (ATMP) for the treatment of chronic low back pain caused by disc degeneration. For this strategy, induced pluripotent stem (iPS) cells are differentiated into notochordal-like cells (iPS-NCs). Notochordal cells (NCs) reside only in human juvenile discs. They have been shown to have high regeneration capacity. Biomaterials have in this strategy an essential role: they are designed to carry and also to provide iPS-NCs with the necessary cues and physically support them in the hostile degenerate disc environment. For this purpose, we follow a strategy inspired by nature. New (semi)synthetic biomaterials are developed based on components of naturally derived NC-derived biomaterials that have already been shown to have regenerative properties. iPS-NCs escorted by these biomaterials should thrive within the degenerate disc. Hereby iPSpine hopes to achieve biologic disc repair and ultimately offer improved quality of life for millions of patients, through long-lasting reduction of low back pain.

These technological advances are addressed within this multidisciplinary consortium. The project brings essential elements together in a chain of translation. This includes biomaterials and biomedical scientists working closely together with regulatory experts, biologists, and clinicians. Cell-biomaterial interactions are evaluated in a set of in vitro models with increasing complexity. Ultimately, bioreactor technology mimicking loading of the human intervertebral disc during daily life and proof-of-concept studies in large animal models of disc degeneration will be employed to test the potency of the iPS-NCs escorted by the biomaterials inspired by nature. During the keynote, I will elaborate on cornerstones of this iPSpine concept, the results of the consortium thus far, with particular focus on how the iPSpine consortium selects the best performing biomaterials in a collaborative effort.

**Introduction**

Intervertebral disc (IVD) degeneration and the consequent low back pain affect over 80% of the world's population\(^1\), constituting a tremendous socio-economic burden and largely impairing patient's life quality. Current therapies include conservative approaches (which only relieve pain and control inflammation) and surgical procedures (which have limited success and several associated risks). With the lack of effective and long-term treatments, tissue engineering strategies, particularly the use of decellularized extracellular matrix (ECM)-based biomaterials, has emerged with undeniable promise for IVD regeneration\(^2\). We have shown that fetal nucleus pulposus (NP) ECM is enriched in pro-regenerative proteins (Collagen type XII and type XIV), when compared to adult and aged tissues\(^3\). Thus, we evaluated the potential of fetal decellularized NP (dNP) – based scaffolds to promote ECM synthesis *ex vivo*.

**Experimental Methods**

IVDs collected from fetal (~8 months of gestation), young (~1 year old) and old (~12 years old) bovine tails, obtained from local abattoirs, were dissected and NP punches decellularized using an optimized SDS 0.1% - based protocol. After decellularization, NPs were characterized for: presence of cells and DNA content (DAPI staining and DNA quantification, respectively); biochemical composition (glycosaminoglycan (sGAG) quantification and Alcian Blue/Picro-Sirius Red staining, western blotting for the fetal proteins Collagen type XII and type XIV); structural organization (cryo-scanning electron microscopy) and biomechanical properties (rheology). Afterwards, NP cells were isolated from adult bovine IVDs, as previously described\(^4\), and used for the recellularization of dNPs from different ages. NP cells were seeded on top of the matrices and cultured *ex vivo* for 7 days, under hypoxia (6% O\(_2\) and 8.5% CO\(_2\)). After 24 hours of seeding, repopulation efficiency was assessed by DNA quantification. Metabolic activity was also monitored during culture using the resazurin assay. At day 7, the response of NP cells was evaluated in terms of cell survival (Live/Dead), and ECM production (collagen type II and aggrecan) at both the molecular and protein level. Finally, collagen changes were analyzed by Picro-Sirius Red staining, under polarize light and quantification of birefringent fibers.

**Results and Discussion**

An optimal decellularization method for bovine NPs from different ages was developed. This was efficient in removing cells and DNA while preserving native ECM architecture and composition, namely collagen (in particular, Collagen type XII and XIV) and to some extent sGAG. Fetal native NPs were shown to be softer than young and old ones and this trend was preserved after decellularization. Acellular matrices from different ages were able to support adult NP cell culture after recellularization. Nevertheless, fetal and young ECMs were characterized by higher DNA content after 24 hours of cell seeding and increased cell viability at day 7 of *ex vivo* culture, as compared to old ones. Bovine NP cells cultured on the fetal scaffolds showed the greatest collagen type II and aggrecan gene expression levels. At the protein level, collagen type II decreased, while aggrecan increased in both fetal and young scaffolds, when compared to old ones. This may indicate increased matrix remodeling. Finally, after repopulation, fetal ECMs showed...
an increased ratio of thicker (mature)/thinner (immature) collagen fibers than young and old ones. The biomechanical properties of repopulated matrices are currently being investigated.

**Conclusion**

Decellularized matrices from different ages were able to support adult NP cell culture. However, softer fetal NP – based scaffolds were shown to have an increased capacity to promote ECM de novo synthesis. This is the first report demonstrating a higher pro-regenerative potential of fetal NP matrices, thus opening new avenues for the development of minimally invasive IVD therapeutic strategies.

Characterising Behaviour of Biomaterials Using Viscoelastic Models

Samantha Hayward, Anthony Miles, Patrick Keogh, Sabina Gheduzzi

University of Bath, Department of Mechanical Engineering, Bath, GB

Introduction

Biological materials typically exhibit non-linear viscoelastic behaviour, and this includes isolated intervertebral disc specimens (ISDs) [1, 2]. Loaded cyclically, ISDs produce non-linear, S-shaped hysteresis loops characterised by stiffening effects [1]. Fully defining the viscoelastic characteristics of spinal specimens under load is critical to understanding their biomechanical behaviour.

A method to tune non-linear viscoelastic models to the load-displacement behaviour of spinal specimens is proposed which improves on that introduced by Panjabi (1991) [2]. Viscoelastic models have been used to describe creep response of many materials under quasi-static or impact loading [3,4], but their use for cyclic loading is less documented.

The model comprising a non-linear Kelvin element is implemented as proof of concept (Figure 1), with the implication that this method could be applied to a variety of viscoelastic biomaterials to achieve their full characterisation.

Experimental Methods

Three two-vertebrae thoracic segments were obtained from porcine spines. The segments were dissected with musculature and all posterior elements removed. During testing, the specimens were wrapped in moist tissue followed by plastic wrap to prevent disc dehydration. A preload of 500N was applied with a 30-minute equilibration period prior to 6 axis stiffness testing at a constant rate of 0.1 Hz with displacement (u/θ) amplitudes (Figure 2) appropriate for the spinal level of specimens.

The proposed model was implemented in MATLAB R2020b using the SimScape library (Figure 1). The coefficients required to tune the model to the test data were determined using an optimization cost function defined by sum of squared errors (SSE) with a non-linear least squares optimization method and a Trust-Region-Reflective algorithm [5].

Results and Discussion

Figure 2 shows an example of the resulting fit obtained by the model for a single loading cycle in axial rotation. Fits of similar quality were observed for tension-compression, anterior-posterior shear, and lateral bending, though decreased fit quality was noted for flexion-extension and medio-lateral shear due to variability in experimental data.

The mean % difference between area enclosed by the model and experimental curves is below 4%, indicating the model's ability to represent dissipated energy.

Lower values of the optimization cost function and absolute maximum residuals at solution indicate a better model fit. These values can be used to compare the fit obtained for different specimens and by various model configurations.

Conclusion

The similarity between the model and experimental curves demonstrates potential for using MATLAB’s SimScape to characterize viscoelastic behaviour of biomaterials. Further work should include additional model configurations and a larger sample size of data.

Disclosing new therapeutic targets in disc degeneration: insights from a pro-inflammatory intervertebral disc organotypic culture

Joana R. Ferreira¹,²,³, Catarina Meireles¹, Jaime Freitas¹,², Mário A. Barbosa¹,²,³, Meriem Lamghari¹,²,³, Graça Almeida-Porada⁴, Raquel M. Gonçalves¹,²,³

Introduction
Cell therapies are emerging as regenerative therapies to treat intervertebral disc (IVD) degeneration, particularly those using Mesenchymal Stem/Stromal Cells (MSC). Yet, the effects of MSC on target IVD cells is still unknown, precluding their fully clinical translation. Due to their close similarity to human, bovine organotypic cultures can be used to disclose MSC mechanisms of action in degenerated IVD. As such, using a standardized bovine IVD organ culture under pro-inflammatory conditions [1] we have demonstrated that MSC exert an immunomodulatory effect through paracrine intercellular communication [2]. A similar effect was observed with the MSCs secretome, that further potentiated aggrecan deposition [3]. However, IVD cellular therapeutic targets are still poorly understood. In this study we propose to investigate IVD's cell target profile of an MSC-based immunomodulatory therapy for IVD.

Experimental Methods
Bovine nucleus pulposus (bNP) were isolated from 1-yr old animals immediately after sacrifice, needle-punctured and cultured in the presence of IL-1b, as described [1]. After 48h, the NP cell phenotype was evaluated by flow cytometry, as described [4]. bNP gene expression was evaluated in IVD organ control cultures vs IL-1b-stimulated conditions, up to 14 days. The distribution and co-localization of bNP cell surface markers in response to IL-1b, were evaluated by immunofluorescence staining. IL-1b-stimulated bNP cell surface marker distribution and gene expression were evaluated upon treatment with MSC secretome.

Results and Discussion
IL-1b-stimulation of bNP organ cultures significantly increased CD44 surface expression from 40 to 80%. This was confirmed at the transcriptomic level, with an upregulation of CD44 gene expression, accompanied by CD14, IL-6 and IL-8. All the CD44+ bNP cells co-express CD14 and CD45, while only 60% of the CD44- bNP cells are CD14+CD45+. Fresh bNP cells were sorted based on CD44 expression, revealing that CD44+ bNP cells express more IL-8 and TIMP1, while CD44- cells express higher levels of MMP2, MMP3, ADAMTS5, TIMP2, AGG and COL2. When treated with MSC secretome, bNP inflammatory markers (IL-6, IL-8, PGE2) decreased, and was accompanied by reduced CD14 gene expression, but not CD44. These results are currently being investigated at the protein level.

Conclusion
The results obtained suggest that CD44+ bNP cells are associated to the inflammatory process, while CD44- cells reflect extracellular matrix's dynamics. This study discloses CD44 as an important therapeutic target on the degenerative IVD, revealing a sub-population of bNP cells with a macrophage-like signature, possible to be targeted by MSC secretome therapy for IVD.

Controlling angiogenesis via functionalized electrospun scaffolds: H$_2$S donors and VEGF peptide mimetics

Tianyu Yao$^1$, Rebeca Rivero$^1$, Ryan Carrazone$^2$, Lorenzo Moroni$^1$, John Matson$^2$, Matthew Baker$^1$

$^1$ Maastricht University, Maastricht, NL; $^2$ Virginia Tech, Chemistry, Blacksburg, US

Introduction
Control over angiogenesis of tissue engineering implants remains a major challenge. In order to drive and control angiogenesis, one must mimic both the physical and chemical cues found in the native extracellular matrix (ECM). While most successful angiogenesis approaches use powerful natural materials (fibrin, Matrigel) and growth factors (VEGF), a simple and fully synthetic approach is lacking. Electrospinning allows a simple and scalable approach to creating nanofibers like found in the native ECM; however, electrospun scaffolds need closely engineered chemical functionality to control angiogenesis. By engineering in small functional handles into electrospun scaffolds, we envisioned that we could incorporate either small peptide mimetics of VEGF, or novel H$_2$S releasing agents in order to stimulate angiogenesis. These simple synthetic systems can provide a route toward controlled angiogenesis.

Experimental Methods
Small (2k) bifunctional polymers of PCL were synthesized with either azide or acrylate end groups for further functionalization. By mixing in small amounts of these functional polymers into higher molecular weight PCL (80k), controlled compositions of functionalized electrospun fibers could be created. Fluorescence dyes were used to test the functionalization of the fibers post electrospinning, and then series of functional scaffolds were made with either a QK mimetic peptide or NTA, a novel H$_2$S releasing agent. HUVECs were cultured on the functional scaffolds and proliferation, metabolic activity and endothelial markers were measured. Promising scaffolds were then tested in the chick chorioallantoic membrane assay (CAM).

Results and Discussion
Mixing in the functionalized polymers was able to create a series of electrospun fibers with different density of functional groups, but similar fiber diameters and morphologies. In the scaffolds with the acrylate functionality, light-activated thiol-ene chemistry was able to controllably functionalize and pattern the scaffolds. In the scaffolds with the azide functionality, azide-alkyne cycloaddition was successful in controlled functionalization of the scaffolds. Both the QK peptide (thiol-ene) and the NTA (azide-alkyne, H$_2$S donor) functionalized scaffolds showed a dose-dependant response in vitro for the proliferation and growth of HUVECs. Also, both the QK peptide and the NTA scaffolds showed an increase in vessel growth in the CAM assay, with the NTA scaffolds showing slightly better early results.

Conclusion
Both the scaffold with the peptide mimetic QK and the newer gasotransmitter H$_2$S releasing agent showed promise to control angiogenesis in vitro and in ovo. Though a direct comparison is difficult, early results showed that the H$_2$S approach is surprisingly powerful compared alongside the QK mimetic. This study shows the potential power of the poorly studied gasotransmitters in control of angiogenesis in tissue engineering scaffolds.

Introduction
Since its first appearance in the early 21st century, bioprinting technologies have come a long way to create biological structures for regenerative medicine and in vitro drug testing. Such applications require the creation of functional biological structures. To do so, it is desirable to provide a microenvironment suitable for the growth of desired cell types. While conventional 3D bioprinting technologies excels at creating larger, anatomical like structures (from 100 of microns to the cm scale), it lacks the ability to recreate the architecture of the niche surrounding living cells at a microscale (submicron up to tens of micron). Attempts have been made to create such cellular microenvironments by using non-conventional biofabrication processes, such as electrospinning and electrohydrodynamic jetting processes. However, due to the lack of biologically relevant material platforms, neither of these techniques could simultaneously meet the requirements to reproduce the intrinsic morphologies and local composition of cellular microenvironments, i.e. the three-dimensional (3D) patterning, the deposition of fibers with micron/ sub-micron size diameters and the maintenance of high cell viability. Here, we describe the precise patterning of cell-laden, microscale biomaterial fibers via a new hydrogel-based bioink platform for Cell ElectroWriting (CEW).

Experimental Methods
Two photocrosslinkable bioinks based on proteinaceous polymers, i.e., gelatin and silk fibroin, were developed using visible light-mediated thiol-ene click reactions and di-tyrosine oxidation photo-chemistries. Both bioinks were optimized for gelation kinetics, viscosity and electrical conductivity in order to obtain stable fibers with reproducible fiber diameters and ordered 3D structures. Their processing compatibility was systematically investigated according to key electrowriting process parameters (e.g. voltage, collection speed, dispensing pressure) using an in-house built electrohydrodynamic set-up. Subsequently, swelling and mechanical characteristics of CEW scaffolds were investigated and benchmarked against scaffolds of the same composition prepared by conventional extrusion-based printing. Finally, the ability to pattern gelatin and silk fibroin hydrogels into 3D organized microfiber networks with encapsulated cells was assessed. For this, bone marrow-derived mesenchymal stromal cells (MSCs) were used, and cell viability, distribution and morphology was studied.

Results and Discussion
This process offers opportunities to mimic the hierarchical structure and composition of native tissues, which cannot be realized with the existent conventional bioinks and biofabrication technologies. We engineered two novel photo-responsive hydrogel bioinks based on protein-based polymers with different gelation chemistry, i.e., gelatin and silk, that are compatible with electrodeposition principles and simultaneously support and maintain living cells. The rapid photo-mediated crosslinking mechanisms, electrical conductivity and viscosity of these two engineered bioinks allow the fabrication of 3D ordered fiber constructs with small pores (down to 100 µm) with different geometries (e.g. squares, hexagons and curved patterns) of relevant thicknesses (up to 200 µm). Importantly, the biocompatibility of the gelatin- and silk fibroin-based bioinks enable the fabrication of cell-laden constructs with reduced fiber sizes (5 to 40 µm), while maintaining high cell viability post-printing. Another important implication of our results is the
potential development of multiple tissue type microenvironments as the investigated stem cells possess the ability to differentiate towards different lineages (e.g. myoblasts, tendon and neural-like cells) which we are currently exploring.

**Conclusion**

In summary, the unique biocompatibility of both the gelatin and silk materials, the promising mechanical performance when compared with conventional extrusion bioprinting, the reduced cell-laden fiber sizes and the unprecedented resolution and patterning precision, open promising avenues for the high-resolution printing of labile biological moieties and living cells.

Development of a new driven system for melt electrowriting technologies

Amit Chandrakar, Lorenzo Moroni, Paul Wieringa

Maastricht university, MERLN, Maastricht, NL

Introduction
Here we introduce a new auger-driven polymer melt extrusion system for Melt electrowriting (MEW), improving the consistency, reproducibility, and versatility of this exciting new technology. MEW is a manufacturing technique of producing ultra-fine fibers using electrical instabilities from polymer melts contrary to electrospinning (ESP) process that uses polymer solution. In MEW, the polymer melt delivery to the nozzle outlet is typically provided by a pressure-driven system; this gives the system good control over the flow rate of the polymer melt through a nozzle and improved startup time, compared to a piston-driven piston. However, with trying to process high molecular weight polymers, the resulting increase in polymer melts viscosity requires unachievable extrusion pressure on the order of MPa. It is also challenging to extrude polymer melts through a small nozzle and maintain a consistent small flow rate. To ensure a consistent polymer flow, the raw material is typically preheated overnight to ensure polymer melt homogeneity and to remove any pockets of air, thus ensuring an uninterrupted supply of polymer can be maintained. However, for a thermally sensitive polymer, preheating for a prolonged time can degrade the polymer, drastically change its viscoelastic properties and the mechanical and molecular properties of the resulting polymer scaffold. Due to the above drawbacks of the current pressure-driven system, we designed a new auger-driven polymer melt extrusion system for MEW.

Experimental Methods
The auger was designed to achieve a minimum and consistent flow rate. Auger modelling and simulation is performed with the help of COMSOL. Here, the manufacturing limitation of fabricating an auger screw is also taken into account. After simulation and optimizing different auger parameters, the auger dimensions were finalized, as shown in figure 1. The commercially available K8200 3d printer was modified, and an auger-driven melt head is integrated into the printer, as shown in Figure 2A. The polymer flow rate of polycaprolactone (45kDa) exiting the nozzle at different speeds and temperatures was recorded and a good correlation between simulation and experimental results were observed. The auger-driven MEW system was then characterized and compared with pressure-driven MEW system at different flow rates while keeping all other MEW parameters constant. We saw no significant variation between pressure and auger-driven systems on the measured fiber diameters, ranging from 5µm to 30µm, and our new auger system displayed excellent manufacturing reproducibility.

Results and Discussion
In MEW, the diameter of the fabricated scaffold depends both on flow rate and initial jet thickness. With a lower flow rate and small jet thickness, one can expect a lower filament diameter. With this new auger-driven system, we could extrude and control the molten polymer via a small nozzle, resulting in nanofiber production and making a hybrid scaffold consisting of nano and micro scaffold using a single run and single melt head for the first time, as shown in the figure 2B. We also observed that the new system was also effective at removing air and vapor pockets within the molten polymer via compression and upward pressure due to centrifugal force during extrusion and spinning. This was noticeable for the PLLATMC polymer, which has a hydroscopic nature that leads to vapor bubbles within the polymer melt. This polymer also cannot be maintained at a high temperature without significant polymer degradation, precluding an overnight preheating step. When this polymer is extruded via the pressure-driven system, we observed a regularly interrupted jet spinning and with noticeable air pockets within fibers. In contrast, our auger-driven system...
generated smooth uniform fiber. This confirmed our ability to supply the MEW process with an uninterrupted polymer supply and use raw materials without preheating.

Our computational modelling determined that our system was theoretically capable of generating consistent polymer melt flow rates that were invariant to melt viscosity. We were therefore inspired to extrude highly viscous material of viscosity greater than 25,000 Pa.s via an auger driven system, something which is currently not possible with any other drive system used for MEW. Successful deposition was achieved, resulting in fibers diameters on the order of 50 to 60 µm; while larger than typical MEW fibres, this was attributed to the polymers rapid solidification rate.

**Conclusion**

New designed auger driven MEW system provides several advantages compared to the pressure-driven system while maintaining the same fiber consistency as the pressure-driven system. Auger driven system can significantly increase the complexity of the scaffold fabricated by MEW. Future work will focus on tuning the auger rotation motion to the fabricated scaffold by varying fibre diameter in a single run.

Melt electrowritten fiber scaffolds as in vitro culture systems for nervous tissue engineering

**Ezgi Bakirci**1, Dieter Janzen2, Annalena Wieland3, Andrei Hrynevich1,5, Biranche Tandon1,4, Natasha Schaefer2, Pamela L. Strissel3, Reiner Strick3, Carmen Villmann2, Paul D. Dalton1,4

1 University of Würzburg, FMZ, Würzburg, DE; 2 University Hospital Würzburg, Institute of Clinical Neurobiology, Würzburg, DE; 3 University Hospital Erlangen, OB/GYN, Laboratory for Molecular Medicine, Erlangen, DE; 4 University of Oregon, Eugene, US; 5 University Medical Center Utrecht, Utrecht, NL

**Introduction**

Nervous tissue has a wide and complex environment that provides many biochemical and topological stimuli, which define the advanced functions of the tissue. The biochemical and mechanical properties of the nervous tissue microenvironment play an essential role in both neuron regeneration and cancer progression. A new manufacturing concept to help replicate this environment *in vitro* is additive manufacturing (AM). One such AM technology, melt electrowriting (MEW), provides control over microscale structures. The modification of fibers with different biochemical cues makes MEW scaffolds very suitable for 3D culture systems.

**Experimental Methods**

Square and octagonal-shaped MEW scaffolds were modified with biochemical cues, including RGD and IKVAV peptides, while a custom-built MEW printer was used to produce *in vitro* culture systems. Medical grade polycaprolactone (PCL), (Purasorb PC 12, Purac Biomaterials, Netherlands) was melted to 77 to 85°C depending on the scaffold's design. The printing parameters were 25G nozzle, 2 to 3 bar applied air pressure, 6 to 7 kV applied voltage, and 4.5 mm collector distance. The fibers were coated with peptides using a methodology previously reported. Peptide content was measured with Pierce Peptide assay and specific peptide bonding examined with FTIC-conjugated peptides using a confocal microscope. Glioblastoma cells U-87 MG (ATCC® HTB-14™) and primary mouse astrocytes were used in the study. The cell morphology was analyzed by ImageJ and MIPAR software.

**Results and Discussion**

The scaffold coating stability was confirmed with FTIR, a peptide assay, and confocal imaging after 4 days. The fluorophore/peptide assays showed intensity significantly higher with FTIC- and peptide-conjugated scaffolds than NaOH treated and unmodified PCL controls, while U87 cells and astrocytes showed different cell morphology on the peptide-coated scaffolds. We examined the impact of the design and biochemical cues on *in vitro* culture systems in terms of the area and circularity of the cells. The glioblastoma cells showed more neurosphere-like colonies on non-coated PCL scaffolds. The cells on octagonal-shaped scaffolds have larger cell areas compared to square pores, either with or without peptides. The circularity of the cells is more visible on non-coated square and octagonal shaped scaffolds 0.70 and 0.76, respectively. The length of the cell processes increases when peptide-coated rather than on non-coated scaffolds. Primary astrocytes showed a stellate cell morphology on octagonal-shaped scaffolds. The in vitro systems fabricated by MEW showed promising accuracy and flexibility to alter the 3D microenvironment of cells.

**Conclusion**

The influence of peptide-coating suggested that MEW scaffolds can be used as in vitro systems to understand the complex in vivo behavior of U87 cells and astrocytes due to the adjustable fiber diameter and the capacity of modification of the fiber with different biochemical cues.

Introduction
Melt electrowriting (MEW) is an additive manufacturing technology capable of producing high-resolution fibre scaffolds. Recently, MEW scaffolds have been described as promising delivery substrates for cardiomyocytes in bioengineered myocardial constructs (BMC). Scaffold microarchitecture and mechanical properties have to be precisely tailored to recapitulate myocardial organization and allow for scaffold deformation under myocardium contraction. However, MEW fibre scaffolds typically show printing defects that increase with each added layer, such as wall slanting and printing path distortion, which alter scaffold architecture and mechanical performance and ultimately reduce control over the induced cell behaviour, especially in thick scaffolds. To address this challenge on printing accuracy, this study aimed to develop an adaptive toolpath g-code for fabricating melt-electrowritten fibrous scaffolds with well-defined and stretchable geometries with clinically relevant thicknesses.

Experimental Methods
MEW poly(ε-caprolactone) scaffolds (0.25, 0.5, and 1 mm thick) with hexagonal and auxetic shaped pores were designed in MATLAB using two different repetitive units, namely, basic and diagonal. Next, an adaptive toolpath g-code based on in-line adjustment of printing parameters (voltage, collector distance and speed) and printing path micro-shifting was developed to minimise fibre wall slanting. The micro-shifting approach compensates the natural smoothening of printed fibre path corners by gradually displacing corner pinnacles. The obtained scaffolds were analysed by scanning electron microscopy, and their mechanical performance was evaluated under uniaxial tensile testing. Finally, in order to study the effect of pore and repetitive unit geometry on in vitro cell alignment and construct mechanics, hexagonal and auxetic scaffolds with basic and diagonal repetitive units were combined with 5% GelMA hydrogels loaded with fibroblast/cardiomyocyte mixtures and cultured in vitro for 21 days. During culture, contraction rate and cell alignment were monitored by brightfield microscopy, and mechanical properties of the seeded scaffold after 21 days were evaluated under uniaxial tension at 25% strain, in order to approximate physiological strain levels.

Results and Discussion
MEW hexagonal and auxetic architectures (Figure 1) yielded a wide range of anisotropic mechanical responses, including an increase in stiffness of up to 100% from the orthogonal to the parallel tensile orientation. Scaffold cross-sectional area was used as an indicator of wall slanting, and it was reduced by up to 25% with path micro-shifting and by up to 32% with collector speed adjustments. The effect of printing path modification on cell alignment and contraction was demonstrated, since cell-seeded fibre/hydrogel scaffolds with basic repetitive units showed an increase in tensile stress by about 35% with respect to diagonal scaffolds. Considering that pore shape is crucial for cardiomyocyte alignment, the scaffold’s mechanical properties were shown to be adjustable by adjusting the printing path and the repetitive unit geometry, while keeping pore shape and size constant. This will allow for tailored manufacturing of scaffolds that comply with different infarction locations and myocardium layers.
Conclusion

Altogether, the findings of this study push the current thickness and resolution limitations in MEW of complex geometries and provide strategies for adjusting the mechanical properties of MEW scaffolds. This approach allows for complex optimisation of anisotropic BMC mechanics and microarchitecture for enhanced function and delivery of induced pluripotent stem cell-derived cardiomyocytes to the infarcted heart.

Introduction

Tympanic membrane (TM) perforations can be caused by multiple reasons like chronic middle ear inflammations (COM), explosions, or traumata. Worldwide 32 million people suffer from COM alone, half of which have severe consequential damage to their hearing. TM defects are commonly repaired using autologous materials like perichondrium, fascia, or cartilage. In addition to damaging the donor site, these materials lack the mandatory mechanical and oscillatory properties needed for a complete restoration of the patients' hearing ability. Therefore, new artificial materials that meet the biomechanical and biological requirements for replacing the human TM are necessary to greatly improve the quality of life of millions of affected people worldwide.

The human TM is a funnel-shaped membrane mainly consisting of collagen and elastin fibers. Radial, circumferential, and random fiber alignment can be found in three different layers with a total thickness between 30 – 150 µm. Its fiber morphology and structure have a major impact on its oscillation properties. Therefore, the aim of the presented study was to develop biomimetic membranes that match the acousto-mechanical properties of human TM, and suitable technologies to realize those. Electrospinning was performed to generate randomly oriented nano- to microsized fibers. By manipulating the electrical field through the integration of additional electrodes, isolators, and/or relative movement between electrode and collector radial and/or circumferential fiber orientation was achieved. Additional precrystallized microfilaments were incorporated into the fiber mats to enhance mechanical properties. A model was developed using the finite element method (FEM) and validated to predict influences of electrospinning parameters and structural design on the acousto-mechanical properties. At first, the in medical applications like sutures or drug-release systems well established synthetic polymer polycaprolactone (PCL) was used to generate the TM implants due to its suitable mechanical and biological properties. Additionally, silk fibroin (SF) of the silkworm bombyx mori was blended into the material to further enhance mechanical and cell adhesion properties.

Experimental Methods

The generated membranes were characterized by tensile tests, acoustic vibration tests, enzyme catalyzed degradation studies, rheometry, cell culture, as well as light and scanning electron microscopy. Silk fibroin spinning solutions were additionally characterized by FTIR and gel electrophoresis to evaluate influences of the degumming process and electrospinning solvents on protein degradation and β-structure content (crystallinity).

Results and Discussion

The studies showed that by manipulating the electrical field biomimetic fiber structures can be achieved via electrospinning. Radial and circumferential fiber orientations were generated. By tuning spinning solution concentration, SF-content and spinning parameters the fiber diameter could be adjusted between 30 nm and 2,5 µm, therefore being able to mimic the natural collagen fiber dimensions. Tensile tests showed that by altering these parameters a broad range of E-moduli can be set from 10 MPa – 100 MPa, which exceeds the range of the E-modulus of human TM that lies between 20 MPa – 60 MPa. Various fiber arrangements and the incorporation of
precrystallized fibers in defined patterns to further enhance mechanical properties were investigated by the developed FEM-model. Especially the oscillation properties were simulated to match those of human TM. Therefore, the position of the first resonance frequency is a good indicator of accordance. We were able to develop membranes with an exceptional good match compared to natural TM specimen after reconstruction (Fig. 1). The amplitude of oscillation was found to be higher by approximately a power of ten for the plain ungraded 2D membranes, which would result in rise in hearing volume of ~10 dB. By replicating the typical 3D-funnel shape of the TM and incorporating precrystallized filaments, this value could be lowered. Finally, we demonstrated the biocompatibility and degradability of the developed SF-PCL-implants by culturing primary keratinocytes and bronchoalveolar epithelial cells on the membranes as well as by enzymatically catalyzed degradation studies over two weeks, using protease XIV and lipase.

**Conclusion**

In conclusion, by modifying the electrospinning technology to mimic the fiber morphology of the human TM and its 3D-funnel shape (Fig. 2), we were able to produce drum implants that can be tuned to match the mechanical and especially acoustic properties of the native tissue, using SF-PCL-blends. Furthermore, the material displays excellent cell adhesion and proliferation properties. No cytotoxic effects were observed during the cell culture studies. Surgeons specifically praised the handling of the new TM-implants due the similarity between the wetting behavior of silk and the native TM.

**Acknowledgement**

The authors would like to express appreciation for the funding of the research projects 20533BR (MyringoSeal) of the DECHEMA through the AiF within the program for supporting the „Industrielle Gemeinschaftsforschung (IGF)” from funds of the Federal Ministry for Economic Affairs and Energy (BMWi) by a resolution of the German Bundestag.

![Figure 1: Oscillation properties of electrospun PCL-/SF-PCL-membranes compared to human TM specimen](image)

The oscillation properties of the generated electrospun membranes match those of the native human TM. Furthermore, by adjusting electrospinning parameters like voltage, solution concentration, or spinning distance the first resonance frequency and amplitude can be specifically modified.
Figure 2: Electrospun 3D-PCL-membrane with graded fiber structures in an ossicular chain model

Through modifications of the electrospinning setup, the production of 3D membranes with integrated areas of radially and/or circumferentially oriented fibers, as well as the incorporation of precrystallized filaments was enabled. Therefore, TM-implants with bimimetic structural design and adjustable acousto-mechanical properties can be generated.

Delivery of a microRNA ‘cocktail’ by electrospun PVA/alginate/ciprofloxacin nanofibres: a genetic nanomedicine for impaired wound healing

Adrian D. Juncos Bombin¹, Helen McCarthy¹, Nicholas Dunne²,¹

¹ Queen’s University Belfast, School of Pharmacy, Belfast, GB; ² Dublin City University, Dublin, IE

Introduction

Delays in wound healing are a significant financial burden to the NHS with annual costs estimated to be £3.2 billion (1). Wound healing is regulated by microRNAs (miRs), which impact multiple aberrant genetic pathways (2). miR-21 and miR-132 can promote re-epithelialisation and anti-inflammatory responses by targeting different molecular pathways (3,4) and miR-31 promotes angiogenesis and re-epithelialisation (2). In this study, single-stranded RNA (ssRNA) encoding miR-21, miR-132 and miR31 were condensed into nanoparticles (NP) using the RALA peptide via electrostatic interactions (5). These NPs were then incorporated into a nanofibre wound healing patch which has been electrospun. The nanofibre blend consisted of 89% w/w Polyvinyl alcohol (PVA) as the main electrospun polymer, 10% w/w sodium alginate (ALG) to promote wound healing and 1% w/w ciprofloxacin (CIP) as a wide-spectrum antibiotic.

Experimental Methods

RALA was complexed with miRs at a range of different N:P ratios. RALA/miR NP cocktails were fluorescently labelled with Cy3 and Cy5 and used to transfect NCTC-929 fibroblasts (ATCC, USA) and HaCaT keratinocytes (CLS, Germany). Cells were imaged with a Nikon 6D Widefield microscope (Japan). Viability of individual and cocktail NP formulations was assessed in vitro via MTS assay (ThermoFisher, USA). PVA and ALG were dissolved in water at 9% and 1% w/v and mixed at a 1:1 v/v ratio. CIP was added at concentrations of 1 wt.% of total polymer weight. The blend solution was electrospun using a 20 kV electrospinning kit (Spraybase, Ireland) and crosslinked in a 1% v/v glutaraldehyde and 0.1% v/v HCl solution in methanol for 24 h. The antimicrobial activity of the fibres was tested via disk diffusion against Pseudomonas aeruginosa ATCC 27853, Staphylococcus aureus ATCC 29213 methicillin-sensitive (MSSA) and S. aureus ATCC 43300 methicillin-resistant (MRSA). As-spun and crosslinked nanofibres were incubated in opti-MEM media (ThermoFisher, USA), which was subsequently used to incubate NCTC-929 and HaCaT cells for cytotoxicity measurements. RALA/miR NP were incubated with crosslinked nanofibres and NP release was studied in UltraPure water via the Quant-iT™ microRNA Assay Kit (ThermoFisher, USA). Cells were incubated with NP released from nanofibre patches, and functionality of internalised miR-31, miR-21, and miR-132 was studied by (1) qRT-PCR with miRNeasy Mini Kit (Qiagen, Germany) and TaqMan™ MicroRNA Reverse Transcription Kit (ThermoFisher, US); (2) VEGF-A Human ELISA Kit (ThermoFisher, US), and (3) wound scratch assay with wound scratch culture inserts (Ibidi, UK).

Results and Discussion

RALA condensed miR into NP ≤200 nm with a zeta-potential of ≥10 mV at N:P ratio ≥ 4 (Figure 1a), ideal for cellular uptake (5). A significant increase in cell metabolic activity was detected in NCTC and HaCaT for both individual miR NPs and cocktail NP formulations (Figure 1b). Cocktails 1-3 were composed of two miRs, whereas cocktail 4 included the three miRs. NCTC cells were fluorescent under the optical microscope post-incubation with a miR cocktail containing labelled miR (Figure 1c), indicating efficient internalisation of NP which was confirmed by FACS analysis. As-spun ALG/PVA and ALG/PVA/CIP nanofibres were crosslinked (CL) with glutaraldehyde to confer stability in aqueous media, showing optimal morphology (Figure 2a). Average diameter was found to be 518.83 ± 101.23 and
552.37 ± 89.69 nm for CL ALG/PVA and ALG/PVA/CIP nanofibres. As-spun nanofibres were found to inhibit growth of *P. aeruginosa* and *S. aureus* (Figure 2b). Crosslinking impaired CIP release from the nanofibrous patch, thus creating an area of inhibition identical to the nanofibre patch. CL ALG/PVA nanofibres also inhibited microbial growth due to glutaraldehyde. Metabolic activity of NCTC and HaCaT was >80% when incubated with extraction media from CL nanofibres, indicating biocompatibility of the material (Figure 2c). RALA/miR NP containing 10 µg of total miR were incubated with CL ALG/PVA and ALG/PVA/CIP nanofibres. A burst release of >80% was obtained within the first 8 h with a 100% release achieved by 2 days (Figure 2d).

**Conclusion**

RALA/miR NP were successfully condensed and demonstrated excellent physiochemical characteristics for cellular uptake in fibroblast and keratinocyte. A range of *in vitro* studies have determined the optimal combination of RALA/miR NP to take forward *in vivo*.

An ALG/PVA/CIP nanofibrous wound patch has been prepared using electrospinning. This patch has shown antimicrobial properties, with crosslinking promoting a controlled CIP release from the patch. Moreover, it has been shown to be biocompatible with fibroblast and keratinocyte cell lines.

Taken together, this work proposes a holistic approach towards chronic wound healing based on the synergistic effects of a miR ‘cocktail’ genetic therapy delivered from a multifunctional, nanofibrous wound dressing that mimics the extracellular environment and protects against microbial infection.
Fabrication and characterisation of electrospun nanofibres
(a) ALG/PVA and ALG/PVA/CIP nanofibres were electrospun and crosslinked (CL) with glutaraldehyde, obtaining smooth and beadless nanofibres; (b) CL nanofibres inhibited microbial growth owing to CIP and glutaraldehyde; (c) CL nanofibres were shown to be biocompatible with fibroblast and keratinocyte cell lines; (d) RALA/miR NP were loaded into CL nanofibres and the release profile was studied, showing a burst release within the first 8 hours.

Surface potential a key parameter for electrospun polymer fibers scaffolds in tissue engineering

Urszula Stachewicz

AGH University of Science and Technology, Faculty of Metals Engineering and Industrial Computer Science, Krakow, PL

Introduction
Surface charge is one of the most important biomaterials property driving cell adhesion and tissue formation [1] and in electrospun scaffolds can be tuned by applying positive or negative voltage polarity during their production [2,3]. We study commonly applied in bone tissue engineering polycaprolactone (PCL) and piezoelectric polyvinylidene fluoride (PVDF) fibers with controlled surface potential verified in ambient and physiological conditions to investigate cell adhesion and proliferation.

Experimental Methods
PCL and PVDF fibers were electrospun applying 14-15 kV to the stainless needle keeping the constant distance of 20 cm to the collector and the solution flow rate at 0.5-1.5 ml·h⁻¹. Surface potential was examined using Kelvin probe force microscopy (KPFM) and via zeta potential measurement in SBF in pH 7.4. Cell proliferation and integration with fibers were verified with the scanning electron microscope (SEM) and 3D tomography based on SEM with focused ion beam (FIB-SEM).

Results and Discussion
