Zeta potential measurements were found in correlation with the KPFM results showing higher surface potential for fibers produced with negative voltage polarity [4]. Higher surface potential increased the initial cell adhesion and enhanced their proliferation on PCL and PVDF scaffolds. Additionally, the 3D tomography has shown extended cell filopodia overlapping the electrospun PCL and PVDF fibers, whereas on porous PCL scaffolds cells internalized into the individual pores on fibers surfaces.

Conclusion
Electrospinning with positive and negative voltage polarities allows controlling surface potential and produce scaffolds without any additional surface modifications. The scaffolds made of PVDF and PCL fibers with the controlled surface potential promoting bone growth for next-generation tissue scaffolds tuning the nucleation process of collagen mineralization in osteoblasts culture for bone tissue regeneration.

Identifying key parameters for the transmission of visible light through electrospun nanofibrous PCL scaffolds for ophthalmic applications

Marcus Himmler\textsuperscript{1,2}, Dirk W. Schubert\textsuperscript{2}, Thomas A. Fuchsluger\textsuperscript{1}

\textsuperscript{1} University Medical Center Rostock, Ophthalmology, Rostock, DE; \textsuperscript{2} Friedrich-Alexander University Erlangen-Nuremberg, Polymer Physics and Processing, Erlangen, DE

Introduction
The cornea is the window of the eye and its transparency is essential for it. Recently, electrospun scaffolds have been discussed for the use in ophthalmic applications as wound dressings after corneal surgery or artificial DMEK grafts for treating patients with corneal endothelial cell pathologies. Concerning wound dressings, transparency is of crucial importance for the immediate improvement of the patients’ vision after surgery. In comparison to homogenous films, nanofibrous scaffolds not only reflect and absorb electromagnetic waves but scatter them. The scattering depends to a higher extend on the ratio of the wavelength to the dimension of the scatterer. Therefore, in this study light transmission through nanofibrous scaffolds is evaluated for varying fiber diameter in the nanometer range. Furthermore, the influence of refractive indices of the surrounding medium and scaffold thickness is examined. Eventually, based on theoretical considerations a formulation is provided for a better understanding of the underlying mechanism of light transmission through nanofibrous scaffolds.

Experimental Methods
PCL scaffolds were produced via electrospinning from the solvent system formic acid/acetic acid in the ration 7:3. Different PCL concentrations were used with 5 \text{ w/v}, 8 \text{ w/v}, 10 \text{ w/v}, 12 \text{ w/v}, 14 \text{ w/v} and 16 \text{ w/v}. For each solution, the working window depending on applied voltage, collector-to-needle distance and flow rate was defined to obtain a bead-free and homogenous fiber morphology. Based on these preliminary spinning experiments, scaffolds with varying thickness between 2 \text{ µm} to 50 \text{ µm} were fabricated for each concentration. Fiber diameter and scaffold thickness were measured using SEM images and a contact sensor, respectively. Transmission measurements were conducted using UV/Vis spectroscopy in the range of visible light from 380 nm to 780 nm. Therefore, the scaffolds were fixed in tissue carrier rings and then placed in an adjusted cuvette filled with ethanol or phosphate buffered saline (PBS). With the scaffold fully covered in medium, differences in the refractive indices of the surrounding medium could be evaluated. By plotting the light transmission of a sample type as function of the scaffold thickness for a fixed wavelength, an exponential decrease in light transmission could be identified following a Lambert-Beer law and a specific extinction coefficient could be calculated. The extinction coefficient was then further analyzed regarding the contributions of reflectance, scattering and absorption depending on the scaffold characteristics and ambient medium.

Results and Discussion
Transmission measurements from UV/Vis spectroscopy provide transmission versus wavelength curves for almost continuous wavelength values, covering the range of visible light from 380 nm to 780 nm. From the single measurements it can be seen, that the transmission is highly wavelength dependent for a given scaffold thickness. With increasing wavelength, the transmission of the electromagnetic wave increases. Merging the transmission measurements from one sample type confirms the exponential decrease in light transmission with increasing scaffold thickness. With a light transmission close to 100 \%, the transmission decreases to almost 0 \% for all scaffolds at a certain scaffold thickness. For comparison of different fiber diameter and surrounding medium, transmission values for interpolated 10 \text{ µm} scaffolds were taken from the charts. It is shown, that with increasing fiber diameter the transmission decreases. For the scaffolds from the lowest spinning concentration, fibers with a diameter of 35 \pm 13 \text{ nm}
nm were fabricated and resulted in a light transmission for a interpolated 10 µm membrane from 47.6 % at 380 nm to 72.0 % at 780 nm. In comparison, scaffolds fabricated from the highest spinning concentration provided significantly thicker fibers with diameter of 167 ± 35 nm and lower light transmission from 18.6 % at 308 nm to 54.8 % at 780 nm. Based on theoretical considerations, the ratio of reflectance, scattering and absorption shifts from high reflectance and low scattering for thin fibers towards low reflectance and high scattering ratios for thicker membranes. Absorption seems to be only a minor contribution to the extinction coefficient. Besides, it could be shown, that light transmission depends to a high extend on the difference in refractive indices, with increasing transmission for matching refractive indices.

**Conclusion**

Since for ophthalmic applications transparent grafts are sought, scaffolds should be designed as thin as possible and fabricated from polymers with refractive indices close to the refractive index of the human cornea. Concerning fiber diameter, smaller fiber diameters should be favored for maximizing graft transparency and thus improving the patients’ vision after surgery. From analyzing more than 200000 different experimental transmission data points it was possible to give a detailed physical model.

Introduction

Although growth factors (GF) have a very promising therapeutic potential, their exogenous administration has proven costly and ineffective. Recent extracellular matrix (ECM)-inspired biomaterial approaches have sought to sequester labile therapeutic molecules, thus regulating their activity and presentation via heparin, aptamers or other actives. However, additional limitations call for the development of cost-effective, scalable, and stable alternatives to the abovementioned systems with similar recognition specificity. Our hypothesis is that molecularly imprinted nanoparticles (MINPs) can fulfill these requirements.[1] As proof-of-concept, here we prepared and tested MINPs against transforming growth factor (TGF)-β3, a known regulator of stem cell chondro- and tenogenesis.

Experimental Methods

MINPs were produced by inverse microemulsion polymerization using different combinations of acrylic monomers and a TGF-β3 N-terminal epitope as template. MINP affinity and selectivity for TGF-β3 were evaluated in non-competitive (single GF) and competitive assays (platelet lysate), using dot blot and Western blot. Substrates functionalized with selected MINPs were used to culture adipose tissue-derived stem cells (ASCs) in basal conditions, and their biological performance was evaluated by gene expression and immunocytochemistry assays. Finally, MINPs were incorporated in ASC pellets and their influence studied by histological analysis.

Results and Discussion

Among the different formulations investigated, amine-containing MINP-2 showed higher affinity for rhTGF-β3 than their non-imprinted counterpart (NINP-2). Western blot demonstrated that MINP-2 selectively recognized and bound TGF-β3 in the hard protein corona over other GFs of platelet lysate, suggesting that the imprinting process significantly increases the capability to capture and retain the target GF. This process results in significantly higher expression of SOX9 by ASCs in MINP-2- than in NINP-2-functionalized substrates. SCX expression is also increased for MINP-2 at an earlier time point, but it significantly decreases over time. The trend observed in expression of these two transcription factors is consistent with the commitment of ASCs toward the chondrogenic lineage by activation of SMAD pathways through TGF-β3 signaling. Concomitantly, ASC pellets cultured with MINP-2 produced more abundant collagenous matrix than those with NINP-2, corroborating this chondrogenic behavior.

Conclusion

The results obtained in this study demonstrate that MINPs can modulate autocrine and paracrine stem cell signaling via GF sequestration, thereby directing their phenotypic commitment. The principles of this strategy may be applied for biomaterial functionalization and extended to other tissue engineering and regenerative medicine applications, thus benefitting from the advantages of MINPs in terms of stability and cost-effectiveness. Hence, in upcoming work we will explore this concept in biomaterial scaffolds with controlled topographical microenvironments, thereby
combining specific biophysical and biochemical cues to guide the tenogenesis of ASCs and tenogenic differentiation in bioengineered tendons.

Antioxidant polydopamine nanoparticles in the treatment of autosomal recessive spastic ataxia of Charlevoix-Saguenay

Matteo Battaglini1, Alessio Carmignani1,2, Chiara Martinelli1, Stefano Doccini3, Fillipo M. Santorelli3, Gianni Ciofi1

1 Italian Institute of Technology, Smart Bio-Interfaces, Pontedera, IT; 2 Scuola Superiore Sant’Anna, The Biorobotics Institute, Pontedera, IT; 3 IRCCS Fondazione Stella Maris, Molecular Medicine for Neurodegenerative and Neuro-muscular Diseases Unit, Calambrone, IT

Introduction

Reactive oxygen species (ROS) are molecules that play a "double-edged sword" role in our metabolism: on one side they are pivotal components of several biological reactions, on the other, excessive production of ROS can lead to damages to important biological molecules with the consequent onset of pathological conditions. Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is a neurodegenerative disease associated with mutations in the SACS gene.1,2 Some of the molecular hallmarks of the disease include mitochondrial impairments, reduced activity of the respiratory chain with a consequent overproduction, and over sensitivity to ROS.3,4 In this work, we evaluated the use of antioxidant polydopamine nanoparticles (PDNPs) as a countermeasure to the ROS-induced damage typical of ARSACS.5 In particular, we tested the effect of PDNPs comparing human dermal fibroblasts derived from healthy subjects and from ARSACS patients.

Experimental Methods

Polydopamine nanoparticles were prepared using a Stöber reaction5 and then characterized in terms of size (dynamic light scattering measurements), surface charge (Z-potential analysis), morphology (scanning electron microscopy - SEM-). The biocompatibility of PDNPs was evaluated on healthy fibroblasts combining Pico-Green analysis of DNA content and live/dead assay. The interaction of PDNPs with human fibroblasts, in particular their internalization and intracellular localization, was evaluated by combining confocal microscopy, SEM/focused ion beam (FIB) imaging, and flow cytometry. The protective effect of PDNPs upon both healthy and ARSACS patients derived fibroblasts against pro-oxidative insult caused by the treatment with TBH was measured in terms of ROS production and apoptosis/necrosis levels through flow cytometry, and in terms of mitochondrial functionality (in particular, mitochondrial morphology and membrane potential were analyzed in presence and absence of both PDNPs and TBH). Lastly, an in-depth proteomic analysis was carried out to assess the differential protein expression among all experimental conditions (namely healthy and ARSACS patient-derived fibroblasts with or without PDNPs and TBH treatment).

Results and Discussion

Characterization of the PDNPs dispersions demonstrates the presence of well-dispersed and homogeneous structures with an average size of 260 ± 35 nm (Figure 1). PDNPs showed good biocompatibility without any adverse cellular effect on human fibroblasts up to 250 µg/ml. Confocal analysis (figure 2), flow cytometry measurements, and SEM/FIB imaging confirmed the uptake of the particles by human fibroblasts. Flow cytometry analysis showed the ability of PDNPs to reduce the ROS production caused by an acute treatment (90 min) with 2.5 mM TBH, and to reduce the levels of both apoptotic and necrotic cells in presence of a chronic pro-oxidative stimulus (100 µM TBH for 24 h). PDNPs showed the ability to partially prevent the loss of mitochondrial morphology and membrane potential upon TBH treatment. Lastly, the proteomic analysis demonstrated how healthy and patient-derived cells have a different response to pro-oxidative stimuli, with the protein expression in patients’ cells being more affected by the
stimulus when compared to healthy fibroblasts. Finally, PDNPs showed the ability to partially prevent the effects caused by TBH treatment causing a partial recovery of the protein expression basal levels.

Conclusion
PDNPs showed good biocompatibility and high uptake levels by human dermal fibroblasts. Moreover, all our analyses indicate how PDNPs can partially prevent both the production and the molecular damage caused by ROS on healthy and ARSACS patient-derived cells. Future analysis involving a more complex in vitro cellular model of the disease and in vivo tests could potentially open the way for the exploitation of PDNPs as a countermeasure for the impairments caused by ARSACS disease.

Interaction of antioxidant nanoparticles with myoblasts in simulated microgravity: possible strategies for muscle maintenance under mechanical unloading

Giada Graziana Genchi\textsuperscript{1}, Melike Belenli\textsuperscript{1,2}, Matteo Battaglini\textsuperscript{1}, Mirko Prato\textsuperscript{3}, Gianni Ciofani\textsuperscript{1}

\textsuperscript{1}Istituto Italiano di Tecnologia, Center for Materials Interfaces, Smart Bio-Interfaces, Pontedera, IT; \textsuperscript{2}Scuola Superiore Sant'Anna, Biorobotics Institute, Pontedera, IT; \textsuperscript{3}Istituto Italiano di Tecnologia, Materials Characterization, Genova, IT

Introduction
Muscle loss for disuse associated to mechanical unloading (like prolonged bed rest, and permanence in low Earth orbit) can be hindered through several measures ranging from physical exercise, to electrical stimulation and drug administration [1-3]. Physical constraints (like flight on space vessels) however may limit accessibility to devices or medications for muscle maintenance, and have motivated the exploration of novel approaches based on nanotechnology for effective and long-standing muscle loss prevention [4,5]. In this context, cerium oxide nanoparticles -also termed nanoceria-NC, characterized by self-renewing catalytic behavior that mimics activity of superoxide dismutase and catalase- can provide useful antioxidant support against oxidative stress-OS, recognized as a significant etiology player in muscle loss under mechanical unloading [6]. An investigation on OS induced in a muscle cell model by simulated microgravity-SM as a mechanical unloading condition and on NC interacting with muscle cells cultured under SM is therefore proposed, in view of a potential application of these nanomaterials to musculodegenerative conditions both on Earth and in space.

Experimental Methods
NC were synthetized by ethylene glycol-assisted direct precipitation. Briefly, Ce(NO$_3$)$_3$ $\times$ 6H$_2$O salt (5.16 gr) was dissolved in a 8% (v/v) ethylene glycol solution in water (100 ml). The solution was heated at 50°C, and then a 28%-30% NH$_3$OH solution in water was added dropwise under mild stirring until pH became 9.2. After 1 h of incubation, nanoparticles were collected by several cycles of centrifugation (at 8,000 g for 20 min) and resuspension in water. Nanoparticles were then desiccated and dispersed in water at a desired concentration by sonication at 8 W for 3 min. Transmission electron microscopy-TEM analysis was carried out to assess nanoparticle size, X-ray photoelectron spectroscopy were conducted to verify obtainment of CeO$_2$, and a colorimetric assay (Merck MAK187) was also done to quantify antioxidant property. Fetal-bovine serum coated nanoparticle dispersions were then obtained at a concentration of 100 µg/ml in a 10% FBS solution in water, and characterized in terms of colloidal stability by dynamic light scattering. C2C12 myoblasts (10,000 cells/cm$^2$) were seeded on Thermanox substrates positioned in ad hoc-prepared silicone multiwell plates (well size: 20 $\times$ 10 $\times$ 5 cm$^3$). Adhesion was allowed for 12 h and then cultures were administered a proliferation medium composed by high glucose DMEM, 10% FBS, 25 mM HEPES and antibiotics, either added or not with FBS-coated nanoparticles (0, 100 and 200 µg/ml NC). Cultures were sealed with adhesive foil, placed on the stage of a random positioning machine (Airbus) and rotated at 20 deg/s for 48 h. Control cultures with and without NC were also kept in static conditions. OS induced by 3D clinorotation was assessed on cultures stained with 2.5 µM CellROX Green reagent through flow cytometry. Nanoparticle internalization was investigated on fixed cells by confocal microscopy (after nuclei staining with 1 µM DAPI).

Results and Discussion
TEM analyses of uncoated nanoparticles demonstrated that the synthetic process yielded loosely aggregated, monodispersed nanoparticles (~5 nm size range) (Figure 1a). X-ray photoelectron spectroscopy-XPS revealed the presence of elements expected in the nanoparticle chemistry, with modest persistence of unreacted nitrate (Figure Page 921 of 2028
1b). Ce$^{3+}$ amounted to ~15%, whereas Ce$^{4+}$ to 85%. Raman spectroscopy confirmed the attainment of the desired CeO$_2$ chemistry. Dynamic light scattering analyses demonstrated a 1.4-fold increase of the nanoparticle hydrodynamic radius after coating, and a transition from a highly positive (+38 mV) to moderately negative zeta potential (-13 mV) after coating, still denoting good colloidal stability. Antioxidant property quantification demonstrated equivalence of 1 mg of NC to 17 nmol of Trolox. After 24 h of culture, C2C12 cultures exposed to SM underwent a mild OS (~3X) compared to cultures under static conditions, whereas no OS could be detected with the chosen assay after 72 h of culture, likely due to compensation mechanisms activated by cultures during clinorotation. Administration of NC at increasing concentrations apparently had no detrimental impact on cell viability within the observation period of 48 h, both in cultures exposed to microgravity and to normal gravity. Internalization occurred in both sample types, although at a lower extent in cells exposed to SM, denoting nanoparticle perinuclear accumulation (Figure 1c).

**Conclusion**
The chosen muscle model exhibited OS within a short time frame from exposure to SM for reasons yet to be ascertained. NC were internalized by C2C12 myoblasts under both normal gravity and SM. Further studies will aim at identifying nanoparticle internalization mechanisms and relevant time frames for NC to exert antioxidant activity against OS induced by mechanical unloading under SM.

Introduction

Wound care has become a critical issue in modern society. Indeed, the extension of average life expectancy and consequent increase of aging-related diseases have raised the probability of a skin wound to develop chronic inflammation [1]. This has prompted the development of advanced wound dressing materials able to act as temporary skin substitutes and aid skin regeneration. An ideal construct for wound healing should adsorb wound exudate, promote cell proliferation and exhibit antimicrobial activity. Electrospinning has been emerging as a cutting-edge technique to produce non-woven high-specific surface gauzes able to mimic the extracellular matrix, due to the possibility to tune fibre’s morphological and structural properties [2]. In this context, Polycaprolactone (PCL) and Polyhydroxybutyrate (PHB) polymeric blends stand as a suitable choice to ensure a proficient balance among biodegradability, biocompatibility, easy processability, good stiffness and tensile strength as well as controlled hydrolytic degradation. However, PCL/PHB polymer blends are exposed to pathogen contamination and exhibit marked hydrophobicity, which limits their capacity to adsorb wound exudate. In the attempt to design new-generation biologically active moieties, valuable inspiration comes from nature. Notably, melanin, a class of negatively charged hydrophobic pigments, widespread in living organisms exhibit multifunctional properties and multiple biological roles, including photoprotection, anti-inflammatory, antioxidant action and potent antimicrobial [3]. These features can be markedly improved if melanin formation occurs in the presence of a ceramic nanostructured phase, acting as a catalyst and a structure-directing agent for the organization of the polymer. This approach was effectively exploited to design hybrid Melanin-TiO$_2$ nanostructures with significant antimicrobial activity even under environmental light [4]. In this work, Melanin-TiO$_2$ nanoparticles were electrospayed over PCL/PHB electrospun mats. The obtained dressings mats were investigated for morphology, hydrophilicity and in-vitro bioactivity. Finally, biological tests were also carried out to estimate antibacterial activity as well as cytotoxicity.

Experimental Methods

PCL/PHB mats were obtained by single-needle electrospinning procedure. Briefly, appropriate amounts of PCL and PHB were dissolved in a CHCl$_3$-Ethanol solution. The polymer solution was loaded into a glass syringe and connected to a syringe pump. After that, the fibrous layers were fabricated by applying 3 kV DC voltage between the syringe tip and the collector, at a pump feeding rate of 1400 μL h$^{-1}$. The fibres were deposited onto conductive filter paper, obtained by soaking into a PEDOT:PSS water solution. Melanin-TiO$_2$ nanoparticles were synthesized following a hydrothermal route previously described [4]. The electrospary of a Melanin-TiO$_2$ water-ethanol dispersion over one side of bare PCL/PHB mats resulted in Coated Melanin-TiO$_2$/PCL/PHB samples. Water-uptake behaviour and the bioactivity of the mats were tested in simulated body fluid (SBF) at 37°C to simulate physiological conditions. TiO$_2$-
Melanin NPs were deposited onto circular glass slides and put in contact with single colonies of Gram (+) and Gram (-) bacteria, to assess biocide activity. Cytotoxicity was evaluated towards human keratinocyte (HaCat) cells.

**Results and Discussion**

SEM images display the morphology of the electrospun fibres (Fig. 1). Bare PCL/PHB fibres are 1.9 μm in diameter and their surface appears smooth (Fig. 1a). On the contrary, Coated Melanin-TiO$_2$/PCL/PHB mats are 46 μm thick (Fig. 1c) and sprinkled with clusters of Melanin-TiO$_2$ nanoparticles (Fig. 1b), which produce a rough surface with marked hydrophilicity. Indeed, the water contact angle of bare PCL/PHB fibres is 118 ± 2°(Fig. 2a), confirming their hydrophobicity, while it could not be appreciated for the coated sample since the water drop spread on the surface as soon as it touched the fibres (Fig. 2b). The high surface area of the fibres is responsible for the huge weight gain (300 % wt) exhibited by both the samples, showing their ability to absorb wound exudates. FTIR spectroscopy assessed the bioactivity of Coated Melanin-TiO$_2$/PCL/PHB, suggesting the deposition of a hydroxycarbonatoapatite thin layer after soaking in SBF. Furthermore, Antimicrobial assays revealed biocide power of the coated mats against both Gram (+) and Gram (-) bacteria (Fig. 2c). Finally, the dressings exhibited no cytotoxicity towards HaCat eukaryotic cells, ensuring safety for future medical applications.

**Conclusion**

This study exalts electrospinning as a suitable strategy to produce high-absorbent gauzes from polymer blends. Moreover, coating the fibres with hybrid melanin-ceramic nanosystems lend the mats hydrophilicity, biocompatibility and marked wide-spectrum antimicrobial activity, paving the way to the design of smart multifunctional wound dressings.

Hyaluronic acid based non-spherical nanoparticles by microfluidics for the active targeting of chemotherapeutics

Antonio Fabozzi¹, Francesca Della Sala², Assunta Borzacchiello², Luigi Ambrosio²

¹ Altergon Italia S.r.l., Morra De Sanctis (AV), IT; ² National Research Council, Institute for Polymers, Composites and Biomaterials, Naples, IT

Introduction

Hyaluronic acid (HA), a naturally-occurring anionic polysaccharide, is widely studied in active tumour targeting research for its ability to bind CD44 receptor, overexpressed in a varied set of cancer cells [1]. Shape of nanoparticles (NPs) is emerging as an important design parameter influencing considerably nano-biointeractions [2]. In literature, a manufacturing technique to generate non-spherical (NS) NPs, from the spherical (S) NPs, such as film-stretching method, has been described [3]. Unfortunately, the film-stretching method, based on the immobilizing spherical polymeric NPs in a thin plastic film, does not lead to gain reproducibility in physicochemical properties of NPs, as size distribution, polydispersity index (PDI) and consequently in vitro and in vivo drug delivery tests. Newly continuous-flow nanoprecipitation assisted by microfluidic systems, in contrast to conventional NPs synthetic methods, are widely investigated for their unique properties including precise control, rapid mass transfer, mixing efficacy, large reaction interfaces [4]. In the microfluidic system, the nucleation and growth steps for the NPs formation can be separated as a function of distance from the position where solution mixing occurs to obtain an absolute control of the particle size and morphology [5]. In this work, blank and irinotecan-loaded (IRI) NS and equivalent (E) S NPs composed of poly(lactic-co-glycolic acid) (PLGA) have been formulated and coated with HA by means of microfluidics for active tumor targeting. The stability of the formulated NS and ES blank and IRI-loaded NPs was evaluated by measuring their size and the in vitro IRI release. z-potential analysis and ELISA tests were further employed to investigate polymer assembly in NP formulations. Finally, in vitro cell uptake on L929 cell line was performed.

Experimental Methods

NS and ES blank and IRI-loaded NPs were prepared by a nanoprecipitation–aid assisted by microfluidic method. Briefly, for the NS and ES NPs organic phase (OP) PLGA (RG504H) 50:50) and poloxamers (PP) (PF68/PF127) (1:0.3:0.3) powder were solubilized at 3.0% (w/v). Afterwards, the dispersion was placed into a 15 mL tube connected to the micromixer chip having 12 mixing phases. In particular, PLGA/PP solution was introduced in the internal channel pumped at 250 μL min⁻¹. A solution of HA (803 kDa) at 0.08% (w/v), was used in the external channels with fluxes of 1250 μL min⁻¹ to set a flow ratio (i.e., internal flow/external flow) equal to 0.2. In the case of drug-loaded NPs, IRIN (1 mg) was solubilized in the OP. NPs sizes and z-potential were evaluated by DLS, and morphologies by TEM. Drug entrapment efficiency was evaluated by UV-vis and in vitro release kinetic of IRI by spectrophotometric assay. In vitro cell uptake of IRI-loaded NPs was performed on L929 cells.

Results and Discussion

TEM micrographs of NS and ES HA/PLGA/PP NPs fabricated by microfluidics are reported in fig 1. The NP HA/PLGA/PP show a regular and reproducible shape of an oblate ellipsoid (a=b>c) with dimensions 240.31x101.2 nm (fig. 1a), while their ES shown a diameter d=260 nm (fig. 1b). Single peaks and a PDI lower than 5 % have been found in all NPs size distributions, which was in agreement with TEM micrographs. In NS NPs HA addition resulted into a significant reduction of z potential from ∼−41.7 mV (ES HA/PLGA/PP) to ∼−51.7 mV. In the case of NS HA/PLGA/PP NPs, the drug entrapment efficiency (EE) was found to be 92.3%, while for their ES was 87.3% that is higher than EE obtained for the spherical HA/PLGA/PP synthesized by a traditional nanoprecipitation (62.7%).

Page 925 of 2028
Moreover, it was observed a decreasing for NP HA yield from 97.8%, for ES HA NPs, to 92.3%; in any cases the yield values of all NP formulation resulted higher than the traditional nanoprecipitation fabrication NPs method (48%). ELISA data revealed a loss of 6.4% w/w of HA in the supernatant. In vitro assay release profiles of IRI for ES and NS HA/PLGA/PP showed that IRI is completely released in less than two weeks, with >95% of the loaded drug eluted within 7 days. Cell uptake studies of ES and NS HA/PLGA/PP were performed on an L929 cell line up to 48h of incubation and reported in fig. 2. In both cases, internalization increases with exposure time, reaching a plateau after approximately 24 hours. Furthermore, from the analysis of biological assays it is clear that the NS HA/PLGA/PP NPs show a higher cellular uptake than their ES NPs, especially evident in the longer times of exposure. This trend of biological assay can be due to the greater surface area exposed by NS NPs.

Conclusion
We developed a novel non-spherical and equivalent spherical blank and IRI-loaded HA/PLGA/PP NPs by means of microfluidics. In vitro assays of HA/PLGA/PP NPs revealed that the non-spherical NPs allow better internalization than their ES NPs on the L929 cells. The obtained results highlight the potential application of novel non-spherical HA/PLGA/PP NPs for cancer therapy.

Effect of the zeta-potential of oxide particles in the thermal stability and hydrolytic degradation of polylactides

Iulia Caraseva, Jone Muñoz, Jose R. Sarasua, Ester Zuza

Basque Country University UPV/EHU, POLYMAT, Department of Mining and Metallurgic Engineering and Materials Science, Faculty of Engineering in Bilbao, Bilbao, ES

Introduction

Poly(L-lactide) (PLA) is one of the most studied and used biodegradable, bio-absorbable and thermoplastic aliphatic polyester derived from renewable products. These characteristics make PLA useful to be employed in the biomedical applications.

However, the processing of PLA presents still some challenges as it shows a poor thermal stability which must be improved. Many strategies such as copolymerization or blending have been proposed in literature [1-3]. In our work we are going to add inorganic particles to PLA, as previous reports have shown that the thermal degradation of PLA is affected by the presence of inorganic fillers, due to the chemical interaction between particle and matrix [4]. Moreover, we studied the effect of the inorganic particles on the hydrolytic degradation of PLA and PLA composites at simulated human body conditions. The understanding of the biodegradation process is vital for their proper use as biomedical devices.

The objective of the work is to foresee the thermal and hydrolytic behaviour of the composites based on previously measured zeta-potential of the particles. To reach this goal, we tested four different inorganic oxides; uncoated and coated with polydopamine (PDA) (if protection was necessary).

Experimental Methods

Composites of PLLA (Mw= 175,000 g/mol) with 1wt% of Bi$_2$O$_3$, Bioglass (BG), MgO, and 10 wt% of Fe$_2$O$_3$, Fe$_3$O$_4$ respectively were prepared by injection moulding. Additionally, Bi$_2$O$_3$, BG, MgO particles were coated with PDA; they are denoted as PDBG and PDBi$_2$O$_3$. For the in vitro hydrolytic degradation study films of PLA composites having 10 mm of diameter were totally immersed in Falcon tubes containing a phosphate buffered saline (PBS). Three samples for each composite were analysed. Each sample was placed in an oven at 37 °C during 6 months. The zeta-potential of the particles was measured with a Dynamic Light Scattering and the physical-chemical characterization was carried out by thermogravimetric analysis, differential scanning calorimetry, gel permeation chromatography and infrared spectroscopy.

Results and Discussion

The changes in molecular mass are compared for the different composites in order to assess the effect on the thermal degradation of the different fillers (see Table 1). Results reveal a higher decrease in molecular weight of composites with MgO, BG and Bi$_2$O$_3$ which are particles with a negative zeta-potential. However, when reversing the zeta-potential of those particles by coating them with PDA the thermal degradation is delayed. The same results are obtained with both iron oxides, which have a positive zeta-potential. Particles with negative Z-Potential could not be process above 1% of particle content due to high thermal degradation caused. Therefore, composites having particles with negative Z-potential are studied at 1wt% and those having positive Z-potential, including PDA-coated ones, at 10wt%.

Particles with negative Z-potential values degrade the PLA matrix whereas the positive one stabilized it. The degradation mechanism can be explained shortly attending the scheme shown in Figure 1. The ester group of PLA has a delocalized negative charge between its oxygens leading its carbon with a slight positive charge. This delocalized negative charge of the ester bond is stabilized when positive zeta-potential particles are coordinated with...
PLA, while the negative charge of the ester linkage is located separated between the two oxygens when the particles have negative zeta-potential, weakening the ester bond.

**Conclusion**

Negative Z-potential is found to be the responsible for thermal degradation. The polydopamine coating could be employed to reverse Z-potential sign and consequently get more thermally stable composites. These findings enable the control of the thermal degradation of the PLA matrix by knowing the zeta-potential of the particle. However, no relationship is observed between hydrolytic degradation and the zeta potential value, revealing that the chemical nature of inorganic particles has no influence in the hydrolytic behaviour.

**Introduction**

*Helicobacter pylori* (Hp) is a gastric pathogen that infects around half of the world’s population [1]. Hp is responsible for the development of several gastric disorders, being linked to 90% of gastric cancers [2]. The main treatments to counteract Hp infection consist in the administration of antibiotics and proton-pump inhibitors. However, these treatments are failing in up to 40% of the patients, mainly due to the increase of antibiotic resistance [2]. Drug-free nanostructured lipid carriers (NLC) have been studied for Hp eradication, showing bactericidal effect against Hp both in vitro/vivo [3,4,5]. The main goal of this work is to optimize NLC efficiency by fine-tuning its physicochemical characteristics, in order to achieve complete Hp eradication.

**Experimental Methods**

The previously developed NLC were composed by the lipids Precirol ATO5® & Miglyol-812® and Tween®60 as surfactant, having an average size of 200-300 nm. In this work the effect of size, surfactant and surface charge in NLC bactericidal activity was evaluated. In NLC preparation, the lipid content was maintained and different surfactants were tested: the non-ionic Tween®60 & Tween®80 (NLC60 and NLC80) to access the effect of a different surfactant; and the cationic Cetyltrimethylammonium bromide - CTAB (NLC CTAB) to access the effect of charge. NLC were produced by hot homogenization followed by ultrasonication. For size optimization, different sonication parameters were tested. NLC characterization was done by dynamic light scattering (DLS) and electrophoretic light scattering (ELS), to determine size and charge, respectively. Concentration was measured by nanoparticle tracking analysis (NTA). The effect of the different surfactants was assessed. Moreover, the effect of size was evaluated in NLC60 by testing three different sizes: a smaller size (<200 nm), the previously developed (≈260nm) and a bigger size (>400 nm). All NLC were tested in vitro against the human pathogenic Hp J99 strain. Additionally, NLC were tested against other gut bacteria, namely *Escherichia coli* ATCC®25922™ and *Lactobacillus acidophilus* -01 strains.

To access if a potential NLC protein corona would influence the nanoparticles bactericidal activity, NLC60 were incubated in different media: *phosphate buffered saline* (PBS), *Mueller Hinton Broth* (MHB) and MHB+10%(v/v) inactivated fetal bovine serum (FBS). Then, they were washed in PBS and tested against Hp. Also, in order to determine the adsorbed protein content, these NLC were analyzed by liquid chromatography–mass spectrometry.

**Results and Discussion**

The NLC60 and NLC80 had sizes between 140-486nm and 190-237nm, respectively. In terms of charge, both had negative surface charge between -25 to -30mV. NLC CTAB had sizes from 107-211nm and a positive surface charge around 25 to 76mV. All NLC stocks had a final concentration of 10\(^{13}\) particles/ml. NLC were tested against Hp J99 and, after 24h of incubation, all formulations achieved bactericidal effect. Regarding size optimization, NLC80 and NLC CTAB didn’t show a substantial alteration of size, having a variation of 47nm and 104nm, respectively. However, in NLC60 a significant variation of size was observed. Bigger NLC60 (>400 nm) showed a better bactericidal performance (when compared with the NLC60 (≈260nm)) and no bactericidal effect was seen for the other gut bacteria. NLC60 incubated in medium supplemented with 10% FBS showed less bactericidal activity than the same
NLC incubated in homologous medium without FBS. Mass spectrometry results showed that when NLC60 are incubated in medium with FBS, more proteins adsorb to the nanoparticles surface. Thus, the protein corona present in the nanoparticles leads to a decrease in NLC activity.

**Conclusion**

In conclusion, the NLC were successfully optimized in terms of size and charge. All formulations were effective against Hp. Preliminary results indicate that size and surface protein corona may influence the NLC bactericidal activity. Overall, these results further support the therapeutic potential of these nanoparticles for a non-antibiotic management of Hp gastric infection.

Introduction

Statins, 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors, are a class of lipid-lowering drugs widely prescribed for regulation of cholesterol levels, and notably contributing to the prevention of cardiovascular diseases[1]. The oral administration of statins has been associated to beneficial effects on the eye conditions due to their pleiotropic effects, as anti-inflammatory, anti-proliferative and neuroprotective activities among others [2]. The present work relies on the hypothesis that hydrogels that can mimic the active site of HMG-CoA might exhibit enhanced affinity for statins. Thus, the aim of the work was to design for first time atorvastatin-loaded contact lenses using functional monomers that bear chemical groups that resemble those present in HMG-CoA and to optimize the loading and release of atorvastatin calcium while still preserving the properties required for contact lenses, mainly in terms of ocular tolerance, light transmission, and mechanical properties.

Experimental Methods

Non-imprinted and imprinted hydrogels were prepared from mixtures of 2-hydroxyethyl methacrylate (HEMA), ethylene glycol phenyl ether methacrylate (EGPEM), 2-aminoethyl methacrylate hydrochloride (AEMA) and methacrylamide hydrochloride (APMA) at various ratios. The hydrogels were characterized in terms of suitability as contact lenses (solvent uptake, light transmission, mechanical properties, and biocompatibility). Atorvastatin loading was carried out by soaking the dried discs in 10 mL of drug solution (0.04 mg/mL in ethanol:water 20:80 v/v) at room temperature under magnetic stirring. Atorvastatin release was monitored in 10 mL of simulated lacrimal fluid (SLF), at 37º C and under agitation. The most promising hydrogels were evaluated regarding cytocompatibility with Balb/3T3 fibroblasts, and ex-vivo accumulation/permeability of atorvastatin into/through porcine cornea and sclera tissues. The permeability experiments were evaluated following the BCOP test protocol in order to evaluate their capability of providing therapeutic amounts of atorvastatin to the eye structures. The amount of atorvastatin released from the hydrogels towards the donor chamber, and then diffused towards cornea and sclera tissues and the receptor medium were monitored by HPLC.

Results and Discussion

Dried discs rapidly sorbed SLF and the equilibrium was reached in one hour. The solvent uptake in atorvastatin solution was significantly higher (about 90%) than that recorded in SLF (about 50%), due to the addition of 20% of ethanol. All hydrated hydrogels were transparent in the visible range (400-700 nm), with transmittance values close to or above 90% and were considered non-irritant for the ocular surface. The elastic modulus obtained remained within the typical values for soft contact lenses. Addition of EGPEM did not further improve the loading. The uptake was remarkably higher for hydrogels prepared with AEMA and, particularly APMA (up to 11 mg/g loaded). Permeability studies through cornea and sclera revealed that the amount of atorvastatin in the receptor chamber was below the quantification limit. This means that atorvastatin mainly accumulated into the cornea and sclera tissues, but do not progress further.

Conclusion
We can conclude that the incorporation of APMA as functional monomer may endow contact lenses with sufficient affinity for the drug. Permeability studies through porcine cornea and sclera tissues revealed that the amount of atorvastatin accumulated could be effective to treat ocular surface diseases.

Design of in situ crosslinkable protease-sensitive alginate 3D matrices via thiol–maleimide “click” chemistry

Mariana Magalhães¹,²,³, Nataliya Débera¹,², Rúben Pereira¹,²,³, Cristina C. Barrias¹,²,³, Silvia J. Bidarra¹,²
¹ INEB, Porto, PT; ² i3S, Porto, PT; ³ iCBAS, Porto, PT

Introduction
Alginate, a naturally occurring polysaccharide, has been widely used in the biomedical field, particularly to build three dimensional (3D) systems. Although alginate is a bio-inert biomaterial, it can be chemically modified to promote highly specific cell-ECM interactions [1]. We have previously showed that molecularly-designed alginate 3D matrices recap key features of native ECMs supporting tissue morphogenesis [2-4]. Here, we aim to develop a novel methodology to synthesize and characterize functional alginate hydrogels based on thiol–maleimide “click” chemistry. The potential of these peptides-conjugated hydrogels as ECM-like matrices for 3D cell culture was also evaluated.

Experimental Methods
Ultra-pure low viscosity alginate (ALG) with high guluronic content was modified with maleimide (MAL) by amidation of the carboxyl groups of alginate with the amine groups of 1-(2-Aminoethyl)maleimide. ALG was modified with variable amounts of MAL (ALG-MAL). Degree of substitution was assessed by ¹H-NMR. Thiol-flanked (bi-functional) protease-sensitive peptides (MMP-pep, CGPGIWGQC) and thiol-terminated cell-adhesion peptide (CGGGGRGDSP) were grafted to ALG-MAL via thiol-maleimide Michael addition click reaction. To confirm peptide double-end grafting and consequently crosslinking, dynamic viscosity of ALG solutions was analyzed by oscillation rheometry. Also, the extent of effective crosslinking was indirectly estimated by quantifying the amount of free thiols in dually crosslinked hydrogels by Ellman’s test. The amount of grafted RGD-pep was quantified using the BCA Protein Assay (Pierce). Gelation kinetics with different amounts of MMP-pep crosslinker was evaluated by single frequency oscillation assay. Primary human mammary fibroblast (hMF) were mixed with alginate and peptide solutions and hydrogels were casted as small discs. 3D cell response to different amounts of MMP-pep and RGD-pep were studied at different time points. Cell viability (live-dead assay) and morphology (F-actin staining) were assessed. Mechanical characterization of these cell-laden hydrogels was also performed.

Results and Discussion
Alginate was successfully functionalized with different amounts of maleimides (theoretical degree of substitution, tDS from 1 to 10%) that was qualitatively confirmed by ¹H-NMR. The presence of maleimide was identified by the appearance of a new peak ~6.9 ppm corresponding to the protons in the double bond of the maleimide group. The efficiency of the reaction was approximately 10%. We observed that high degrees of maleimides lead to poor solubility of alginate derivatives, so we only used derivatives with up to 3% of tDS. The addition of bi-functional MMP-pep should expectably increase the hydrogel viscosity due to the formation of a chemically crosslinked gel network. We observed an increase in viscosity and consequently gel formation between 120 and 480 µM of MMP-pep. Concentrations higher than 480 µM did not alter the viscosity of the solution, probably because at such high density, MMP-pep were preferentially bound only by one side, occupying the maleimides but without bridging two alginate chains. In fact, the presence of free thiols in these higher MMP-pep concentrations was confirmed by the Ellman’s test. hMF were successfully embedded within MMP-pep/RGD-modified alginate matrices, presenting an elongated morphology and forming extensive multicellular network, in contrast to control MMP-insensitive hydrogels, where cells remained essentially round.

Conclusion
A novel methodology for the synthesis of alginate polymer containing maleimide functional groups was established. The covalently grafted maleimides allow the biofunctionalization and in situ crosslinking of alginate by thiol-Michael addition reaction. The incorporation of proteases sensitive peptides significantly enhances 3D cell-cell interactions in alginate hydrogels, improving their performance as ECM-mimics.

Hybrid Multicomponent Laminaran/Platelet lysate-based hydrogels

Mehrzad Zargarzadeh, João F. Mano, Catarina Custódio

CICECO, University of Aveiro, Department of Chemistry, Aveiro, PT

Introduction
Hydrogels possess the capability of holding a large amount of water in a three-dimensional (3D) network and mimicking many features of the native extracellular matrix (ECM) which makes them attractive materials for biomedical applications[1]. Laminaran-based hydrogels are interesting due to their tuneable mechanical properties and high cytocompatibility[2]. Recently, photo-crosslinkable platelet lysates (PL)-based hydrogels have exhibited to support distinct human-derived cell cultures owing to their high content of bioactive molecules, such as cytokines and growth factors[3]. Aiming at taking advantage of all features of both PL and laminaran hydrogels, here we combine UV responsive laminaran-methacrylate and PL-methacrylate derivatives plus an adequate enzyme to fabricate a multicomponent hybrid hydrogel (GLMPL) (Fig1.a). This hydrogel is newly designed as a scaffold material for the sustained delivery of glucose produced via enzymatic degradation of laminaran and granting cell adhesin by presence of PL. Such innovation is expected to circumvent the limitations of the current hydrogels strategies that lack on nutrients diffusion and adhere motifs, boosting the application of hydrogels in diverse biotechnological contexts.

Experimental Methods
Methacrylated Laminaran (MeLam) and methacrylated PL (PLMA) were synthesized following the previous reports [2, 3]. The hydrogel precursor solution was prepared by dissolving different MeLam/PLMA mixtures (Fig1.b) in PBS at the final concentration of 10%. The resulting solution (40μL) was pipetted to cylindrical PDMS molds and afterwards irradiated by UV for 2 min. The fabricated hydrogels (LMPL) were investigated in terms of the cell’s adhesion and metabolic activity by encapsulating human adipose-derived stem cells (hASCs). In order to obtain sustained degradation and consequently, a gradual production of glucose over time in such hydrogels, glucoamylase (GA) enzyme was incorporated into the selected LMPL hydrogel solution before UV exposure. In vitro studies were performed on GLMPL hydrogels by culturing encapsulated hASCs in Dulbecco’s Modified Eagle Medium (DMEM) without glucose. As such, any difference in cells response could then be attribute directly to the presence of enzyme and consequently glucose accessibility for the encapsulated cells.

Results and Discussion
The metabolic activity of the hASCs in LMPL was determined by a CellTiter-Glo assay. ATP intracellular activity significantly increased in the function of increasing PLMA content (Fig1.c). As shown in Fig. 1.d, cells maintained their spherical morphology when encapsulated in 75% and 100% hydrogels after 21 days. In contrast, in the rest of the hydrogels, cells attached to the matrix and continued spreading over time. These effects were more pronounced for the 25% hydrogels in which cells form an interconnected network. Therefore, 25% formulation was chosen to fabricate multicomponent hybrid hydrogels. Live-Dead viability assay confirmed encapsulated hASCs, cultured in glucose free culture medium, retained their spherical shape, while in the presence of GA and consequently available glucose, cells stretched inside of the hydrogel (Fig1.e). DAPI/phalloidin staining have confirmed that cells readily elongated in GLMPL hydrogels and forming interconnected networks with neighbouring cells (Fig2.f).

Conclusion
In conclusion, these results, combined to the fact that most current bioscaffolds suffer from lack of nutrient diffusion and adhere motifs, clearly suggest the potential of this hydrogel in future developments of 3D structures in a wide range of biotechnological applications as an autonomous cell supporting system. This self-maintained and
biocompatible material could potentially be used as a closed culture system for living cells and any other microorganisms, as a novel platform for cell delivery, or to be used in bioreactors.

Biomimetic hydrogels for bioprinting: combining dynamic and static networks

Ana A. Aldana¹, Francis L.C. Morgan¹, Sofie Houben², Marta Redondo¹, Louis Pitet², Lorenzo Moroni¹, Matthew B. Baker¹

¹ Maastricht University, Department of Complex Tissue Regeneration, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; ² Hasselt University, Institute for Materials Research, Hasselt, BE

Introduction
Hydrogels are promising candidates for the recapitulation of the native extracellular matrix. Yet recreating molecular and spatiotemporal complexity remains a challenge. Double network (DN) hydrogels have shown interesting properties to recapitulate the complexity of native tissues.[¹] Combining networks also show advantages in terms of remarkable mechanics, shear-thinning, and self-healing attributes. These properties combined with smart cross-linking strategies can make DN hydrogels great candidates for 3D bioprinting. 3D bioprinting allows the creation of a spatially defined object, but the field is currently dominated by static, unresponsive materials (synthetic and natural).[²] Here, we aim to create biomimetic DN hydrogels for bioprinting applications by combining dynamic and static bonding in the individual networks. Furthermore, these materials will allow us to explore the presentation of bioactive cues on either the static or dynamic network (within the same material) providing a handle to mimic the dynamic ECM complexity. We investigated the combination of oxidized alginate cross-linked by Schiff base reactions (OA, dynamic network) and polyethylene glycol diacrylate (PEGDA, static network) cross-linked by UV irradiation.

Experimental Methods
OA (10% theoretical degree of oxidation) [3] and PEGDA (20kDa) were synthesized and characterized by NMR and GPC. DN and single network (SN) formulations were prepared by adding varying proportions of each polymer: OA 0/2/2.5/3 wt% and PEGDA 0/10/15/20 wt%. One equivalent of hydrazide and Irgacure 2959 (1% w/v) were added in all formulations. Hydrogel (OA 2.5% - PEGDA 10%) formation was explored at various PBS (without Mg²⁺ and Ca²⁺) concentrations (0, 13.5, 30, 84 and 149 mM).

To investigate printability, we used the BioX bioprinter (CellInk, Sweden). Conical needles (ID 0.41 mm) were fixed to cartridges and printed via pressure. We then imaged each print (16 megapixel camera) and used ImageJ (NIH, USA) software to process them.

For cell culture experiments, 0.75 mM RGD (aminooxy-RGD or thiol-RGD for attaching to dynamic or static networks, respectively) was added to the hydrogel formulation to facilitate cellular adhesion. DN hydrogels were irradiated with UV light (365 nm, 30 s) to crosslink the static network. Human dermal fibroblasts (HDFs) were cultured under standard conditions on OA 2.5% - PEGDA 10% hydrogels.

Results and Discussion
Effect of PBS concentration on dynamic hydrogel formation. The pH and ionic strength were determined for each PBS solution. With an increase of PBS concentration, the hydrogel formulations (before photocrosslinking) change from soft and sticky to tough and brittle. Whereas OA single network formulations formed a gel after Schiff-base reaction (hydrazone bonds) only in presence of PBS. The results show that the ionic strength affects the dynamic crosslinking. For further characterization, hydrogels were prepared in 13.5 mM PBS solution.

Injectability and printability. The injectability of a small library of DN hydrogel formulations (OA 0/2/2.5/3 wt %; PEGDA 0/10/15/20 wt %) was tested. The overall polymer concentration affects the hydrogel properties. The higher the polymer concentration, the more pressure needed to extrude the gel through the nozzle and/or the higher nozzle inner diameter needed. OA 2.5 wt % and PEGDA 10 wt % showed the best balance between filament formation,
applied pressure and nozzle diameter, important for injection and bioprinting. Therefore, we selected a series of DN hydrogels based on the best formulation for further characterization (OA 2.5 wt % - PEGDA 10 wt %) The printability of DN formulations with varying amounts of OA(2/3 wt %) or PEGDA (0/5/10/15 wt %) were tested and the printing parameters were optimized.

**Self-healing.** We previously reported that the dynamic crosslinking of oxidized alginate with adipic acid dihydrazide gives self-healing properties to gels,[3] yet the effect of a second static network on this property is not known. Macroscopic self-healing of the hydrogels was tested (Figure 1.b). All DN hydrogel formulations were able to heal even at a high concentration of PEGDA.

**Cell response and structure relationships.** Human dermal fibroblasts (HDFs) were seeded on top of gels for 7 days to explore cell viability and morphology. HDFs were alive and migrated in the hydrogels (Figure 1.c), a crucial necessity for tissue maturation. By attaching RGD to dynamic or static networks, HDFs exhibited differences in morphology and spreading.

**Conclusion**

By combining dynamic and static networks, we developed hydrogels with better printability attributes than single networks and with tunable cell behavior by RGD conjugation. These complex dynamic hydrogels show potential for bioprinting applications and give unique opportunities to tune the artificial ECM environment. Currently, we are further characterizing the mechanical properties of the hydrogels, and developing these materials for applications in cell delivery and model tissue fabrication.

Using SPAAC for the Synthesis of Versatile Covalent Hydrogels: Outperforming Them All?

Vianney Delplace1, Nathan Lagneau1, Pierre Tournier1, Boris Halgand2, François Loll1, Jérôme Guicheux1,2, Catherine Le Visage1,2

1 Inserm, UMR 1229, RMeS, Regenerative Medicine and Skeleton, Université de Nantes, ONIRIS, Nantes F-44042, FR; 2 CHU Nantes, PHU 4 OTONN, Nantes F-44042, FR

Introduction
Hydrogel design is a booming field of research. Hydrogels are the most suited scaffolds for cell encapsulation, owing to their properties that can best mimic the natural cell microenvironment. Yet, while many crosslinking strategies have been proposed to allow cell encapsulation, most of the existing approaches (i) require external stimuli or catalysts/activating agents, (ii) are not entirely bioorthogonal or compatible with physiological conditions, or (iii) have inherent limitations such as limited stability or slow gelation rate. Thus, a class of hydrogels that would be fully tunable, fast-gelling, biocompatible and, yet, easy to synthesize and use, remains to be designed. In this context, we hypothesized that using the strain-promoted azide-alkyne cycloaddition (SPAAC) «click» reaction as a bioorthogonal crosslinking mechanism would allow the synthesis of versatile polysaccharide-based hydrogels, addressing all design criteria and offering new opportunities.

Results and Discussion
We first investigated the development of SPAAC hyaluronic acid (HA)-based hydrogels, using azide and bicyclononyne (BCN) as complementary moieties. Each of the two components, i.e., HA-azide and HA-BCN, were easily synthesized in single-step reactions from commercially available compounds, with tunable degrees of substitution. Mixing the two HA components together, we successfully obtained hydrogels that form under physiological pH and temperature. Optimizing the HA molecular weight, component ratio, polymer content and substitutions, we designed tunable hydrogels that form within seconds to tens of minutes under physiological conditions, with a Young’s modulus tunable over orders of magnitude (0.5 to 40 kPa). Interestingly, we found that the crosslink density and polymer concentration of these gels can be finely tuned to obtain minimally-to-non-swelling materials with tunable stiffness, all stable over months. Finally, we demonstrated that all HA-based gels degraded enzymatically within hours to days. We further confirmed that SPAAC crosslinking can be easily applied to other polysaccharides, such as alginate or chondroitin sulfate, as a most versatile platform for hydrogel design.

Using a murine cell line (L929 fibroblast cells), we demonstrated excellent cytocompatibility of these gels (cell viability > 90%) via live/dead confocal imaging. We further investigated the effect of 3D encapsulation on the viability, metabolic activity and proliferation of human mesenchymal stem cells. These materials are now being investigated for a breadth of in vitro and in vivo applications, spanning from organoid culture to microgel design and bioprinting.

Novel thermosensitive hydrogel for the delivery of reactive species generated by cold atmospheric plasma

Xavi Solé-Martí, Cédric Labay, Francesco Tampieri, Maria-Pau Ginebra, Cristina Canal

Universitat Politècnica de Catalunya (UPC), Department of Materials Science and Engineering (CEM), Biomaterials, Biomechanics and Tissue Engineering Group (BBT), Escola d’Enginyeria de Barcelona Est (EEBE), Barcelona, ES

Introduction

In the last years, the use of cold atmospheric pressure plasma (CAP) to treat tumors has been widely investigated as a novel potential anti-cancer therapy [1]. CAP is an ionized gas that consists of a mixture of ions, UV photons, electromagnetic radiation, free electrons, radicals and excited molecules that, in presence of air and water, leads to an environment rich of reactive oxygen and nitrogen species (RONS). These CAP-generated RONS can be transferred to liquids by diffusion or generated inside them through secondary reactions, thereby generating a plasma-conditioned liquid (PCL). PCL represent a very interesting alternative to direct CAP treatment, because they may allow treatment of malignant tumors located in inner organs of the body by means of an injection. However, PCL injection in the tumor site may result in fast diffusion throughout the body due to extracellular fluids and blood flow. Therefore, the design of efficient vehicles that allow a controlled release of RONS to the diseased site is a fundamental requirement.

Injectable hydrogels that allow in situ gel formation have attracted much attention as drug delivery systems. Not only can they be conveniently injected with minimal invasive surgery, but also they are capable to fill irregular shaped defects, sometimes created after a tumor resection. Methylcellulose (MC) is a water-soluble cellulose derivative that can form a thermo-reversible hydrogel in water upon heating. At low temperature water molecules form a cage-like structure surrounding the methoxyl groups and thus solubilizing MC [2,3]. However, high temperatures cause the destruction of the cage structure of water and a three-dimensional hydrogel network is formed due to hydrophobic interactions of the methoxy groups of MC. Sol-gel transition of pure MC is ~60 °C, too high for in vivo purposes as an injectable hydrogel. However, the gel point can be altered by the addition of salts, based on the Hofmeister series [4].

The aim of this study is to develop a thermosensitive hydrogel with the ability to generate, store and release plasma generated RONS, and evaluate the effects of this release on cancer cells. To do so, we optimized the composition of the hydrogel to confer ability to form a gel at physiological temperatures while remaining in liquid phase at room temperature to allow the suitable formation of plasma-generated RONS. The physico-chemical properties of the hydrogel were characterized before and after plasma treatment and the in vitro effects of the RONS in the novel MC formulation were investigated against osteosarcoma.

Experimental Methods

MC solutions where prepared by dispersing MC powder in hot deionized water (approx. 80 °C) and then transferred into an ice bath under continuous stirring in order to allow the dissolution of the MC. The sol-gel temperature was tuned by incorporation of different concentrations of Na₂HPO₄ in a 1 wt % MC (1MC) solution and studied by rheology and microDSC analysis. Plasma treatment of MC was performed by means of a kINPen® plasma jet (1 L/min Ar gas flow, 10 mm gap). H₂O₂ and NO₂⁻ generated in the plasma-treated MC were determined by Amplex Red® and Griess methods, respectively. Also, the detection of OH radicals during plasma treatment was quantified with a coumarin probe. Chemical modifications of the MC backbone due to CAP treatment were investigated with nuclear magnetic
resonance (NMR) and size-exclusion chromatography. Cell viability was evaluated by metabolic activity quantification and Live Dead Assay was assessed by confocal microscopy.

Results and Discussion
With a gel point of ~ 36 °C, 3.5% Na₂HPO₄ in 1% MC (1MC3.5HP) was selected for plasma treatment. Plasma treatment times from 30 s up to 180 s were evaluated, leading to concentrations of ~170 μM and ~40 μM of H₂O₂ and NO₂⁻, respectively, for the longest plasma treatment (Fig 1). Hydroxylcoumarin production rate was 24 times lower in 1MC3.5HP compared to the 3.5% Na₂HPO₄ solution without MC. The gelling ability of the hydrogel was not affected by the CAP treatment. Cell viability at 24 h for the 1MC3.5HP samples decreased in a dose-response manner, down to 30% cell viability for longest treatment time (Fig 2. i). Confocal microscopy images also revealed compromised cell morphology after exposition to plasma-treated MC (Fig 2. ii).

Conclusion
MC hydrogels are able to generate, store and release plasma generated RONS. The anticancer effects of plasma-treated MC are time-dependent in MG63 osteosarcoma cells, showing a direct relation with the concentration of RONS at increasing plasma treatment time. It is the first time that a thermosensitive hydrogel is used as a delivery system of RONS generated by plasma, proving that plasma-treated hydrogels have a promising applicability in cancer therapy.

Introduction
Mechanical strength is an important consideration in the design of biomaterial platforms for bone regeneration in load bearing defects. Hydrogels with in situ gelation properties are attractive biomaterials for minimally invasive tissue engineering applications. This is due to their ability to transition from liquid state to solid at physiologically temperatures, and suitability for administration via injection[1]. Whilst hydrogels provide an ideal platform for tissue regeneration in terms of biocompatibility, biodegradability and handling properties, their mechanical and structural properties often deem them unsuitable for bone[2]. The aim of this study was to formulate a chitosan-collagen (CS-COL) hydrogel, reinforced with carboxylated single wall carbon nano-tubes (SWCNTs) to develop mechanically robust hydrogels for load-bearing applications.

Experimental Methods
Hydrogel systems comprising of chitosan/collagen polymeric matrix reinforced with SWCNT were prepared by mixing acid solubilized chitosan with Type I collagen and different concentrations (0, 0.5, 1, 3 and 5 wt/v%) of SWNT in presence of β-glycerophosphate (β-GP), a gelling agent at pH~7.4. Thermoresponsive behaviour of the prepared hydrogels was confirmed by using rheology technique. Porous behaviour and change in structural properties with SWCNT was assessed by using different physiochemical techniques including X-ray Diffraction, Fourier Transform Infra-Red Spectroscopy, Scanning and Transmission Electron Microscopy. Quantitative analysis of mechanical strength was performed on Zwick Roell Materials Testing machine with 5N load. Effect of SWCNT on thermal behaviour of hydrogels was evaluated via Thermal Gravimetric Analysis (TGA), in vitro weight loss and mineralization was performed in phosphate buffer saline (PBS) and simulated body fluid (SBF) at physiological conditions respectively. To determine the compatibility of the prepared hydrogel systems for bone tissue engineering, osteoblast cell line MC3T3-E1 was used. In vitro cell cytotoxicity and proliferation was analyzed by using Lactate dehydrogenase activity (LDH) and Pico Green assay respectively.

Results and Discussion
All formulations were thermoresponsive and injectable in nature as confirmed by rheology analysis. It was speculated that addition of SWCNT led to porous structure (Figure 1), significantly increased mechanical strength from kPa to mPa (63% increase, Figure 2), high interconnectivity (85±0.5%) and crosslink density. The weight loss analysis indicated that the weight loss ratio can be varied by changing the concentrations of chitosan, collagen and SWCNTs. Physiochemical characterization results confirmed the presence of SWCNT at the expected diameter (0.85–1.30 nm) with strong molecular interactions between polymeric matrix (+ve zeta potential) and SWCNTs (-ve zeta potential) which led to the formation of more aligned and crystalline network with lower zeta potential values (Figure 1). Gelation mechanism of prepared hydrogels at physiological conditions was also elucidated. Results demonstrate that β-GP and temperature are the two most important driving factors for the transformation of hydrogels from solution to solid gel at physiological conditions. Hydrogels showed the presence of hydroxyapatite layer on the surface of the samples even after 1 day of incubation in SBF, which indicates the biocompatible nature of the prepared hydrogels. This was...
Further demonstrated by an absence of cytotoxicity and increased cell proliferation over 7 day culture period (Figure 2).

Conclusion
This study presents novel thermoresponsive, injectable and mechanically robust hydrogels formulations. For the first time, our results showed that β-GP and temperature are important for gelation at physiological conditions and the reinforcement of CS-COL hydrogels with SWCNT significantly change the structural morphology to more porous and aligned network which leads to high crystallinity and ultimate increased the mechanical strength from kPa to mPa which is closer to mechanical strength of the bone. So, these hydrogels are suitable for application as mechanically robust and injectable biomaterials in bone tissue engineering especially in load bearing area.

Tuning dynamic hydrogels via molecular engineering: Equilibria constants in Schiff base hydrogels

Francis Morgan, Floor Ruiter, Lorenzo Moroni, Matthew Baker

Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL

Introduction
Robust control on the mechanical properties of hydrogels has become important for the development of new soft materials for tissue engineering and regenerative medicine. Dynamic cross-linking has emerged as a promising approach to tune hydrogel stiffness and impart both dynamic biomimetic properties and enhanced injectability and processability to the materials. (1) Recent studies have explored the fundamental relationship between molecular constants such as the equilibrium constant and material stiffness by varying the pH and simple changes to the molecular structure. (2) However, to successfully translate these findings more information is needed to fill out the toolbox available for material design under physiologic conditions. Here, we investigate the relationships between molecular equilibria and rate constants on the stiffness of alginate hydrogels formed through Schiff-base formation.

Experimental Methods
Alginate was modified via oxidation or covalent attachment of aldehydes to the backbone. Crosslinks with various modified amines were either purchased from Sigma-Aldrich, or synthesized via end modification of poly(ethylene glycols). Monomeric model amines were purchased or synthesized for determination of binding constants. Thermodynamic and kinetic measurements were performed via $^1$H NMR and/or UV-vis. Rheological properties were determined using a 20 mm cone-plate geometry on a DHR-2 rheometer (TA).

Results and Discussion
By molecularly engineering the interactions and the hydrogel architecture, we can varied physical constants like $K_{eq}$ and $k_1$ by several orders of magnitude by changing only the chemical environment of the amine and/or aldehyde participating in the reaction. The difference in stiffness corresponds well to the difference in measured equilibrium constants, emphasizing the importance of molecular parameters for dynamic systems. Furthermore, via using competitive cross-linkers we are able to uniquely tune the hydrogel. In some specific regimes, adding more cross-linker to the material can actually decrease the stiffness of the hydrogel, a unique property to dynamic hydrogels.

This work is a step towards the mainstream adoption of reversible Schiff-base formation as a stable platform for the design of novel biomaterial hydrogels leveraging molecular constants to achieve the desired mechanical properties.

Conclusion
The ability to control mechanical properties over several orders of magnitude without changing polymer content, molecular weight or temperature also has significant implications for numerous applications from tissue formation to biofabrication. Dynamically cross-linked hydrogels provide unique opportunities for tuning of materials properties, which are not available to covalently cross-linked materials. This work shows a path forward for rational design of dynamic hydrogel architectures, and uncovers unique opportunities.

Introduction
Nonalcoholic fatty liver disease (NAFLD) represents a leading cause of chronic liver disease worldwide. Its multifactorial nature and its potential evolution from simple steatosis to the more severe steatohepatitis, eventually leading to cirrhosis and hepatocellular carcinoma[1,2], define a critical scenario, still demanding for effective therapeutic treatments. Hydroxytyrosol (HT) has been shown to contrast the development of hepatic steatosis through its lipid-lowering, antioxidant and anti-inflammatory activity. The efficient delivery of HT to hepatocytes remains a crucial aspect, which could be addressed by using smart nanocarriers.

Experimental Methods
We propose the design of traceable nanogels (NGs) as a promising tool to promote the intracellular HT release, avoiding metabolic alterations and the loss of the active molecule in the extracellular environment. NGs were synthetized from polyethylene glycol (PEG) and rhodamine-labeled polyethyleneimine (PEI), using a single o/w emulsion and solvent evaporation technique [3]. The nanosystems were characterized by a hydrodynamic diameter around 250 nm, and the HT loading was performed exploiting the NG swelling behavior from the dry state: in this way, we encapsulated HT within the NG meshes by steric hindrance, without any chemical modification of the drug that could affect its therapeutic potential. The performance of nano-encapsulated HT was evaluated in an in vitro model of hepatic steatosis (induced by an overload of free fatty acids, FFAs) and compared to that of pristine HT using high-content analysis tools [4].

Results and Discussion
NG specimens presented a sustained HT release over time and a significant decrease in the intracellular triglyceride accumulation was detected only when HT was delivered by the nanovectors, restoring cell viability and outperforming the efficacy of HT in its non-encapsulated form (Fig. 1).

Conclusion
The formulated nanogels represent a more promising strategy compared to the conventional drug administration routes for protecting liver cells from the development of NAFLD.

Pedalling variability in cyclists of different competitive levels

Alba Herrero-Molleda¹, Pablo Floría², Juan García-López¹

¹ Universidad de León, Faculty of Physical Activity and Sport Sciences, León, ES; ² Universidad Pablo de Olavide, Physical Performance & Sports Research Center, Sevilla, ES

Introduction
Movement variability in sports has been extensively studied in the last few years. Previous cycling studies observed relationships between movement variability during pedalling and both competitive level and pedalling intensity. Expert cyclists showed a lower coordination variability than novice ones [4], and a decreasing in the muscle action variability as pedalling intensity increased [1]. Several approaches have been proposed in the literature to analyse movement variability highlighting the linear and non-linear measures [3]. However, it has been suggested that their behaviour could be different [5]. Therefore, the purposes of the present study were (1) to analyse the effect of the cyclists’ competitive level and pedalling intensity on the crank torque variability, and (2) to examine whether there would be a different interpretation when multiple-trial variability and complexity measurements are used to analyse movement variability.

Experimental Methods
Seventy-two cyclists participated in the present study (24.7 ± 5.4 yr, 69.0 ± 6.0 kg and 178.7 ± 5.0 cm). They were divided in three homogeneous groups (n= 24) of competitive levels (Level 1= club; Level 2= elite; Level 3= professionals), according to their cycling training volume per season (5000-15000, 15000-30000 and more than 30000 km, respectively) [2]. They performed three sets of 5-min submaximal pedalling (200, 250 and 300 W) at a constant cadence (90 rpm) with a 6-min rest in between. The tests were carried out on an electromagnetically braked cycle ergometer (Lode Excalibur Sport), using their own cycling shoes and bike geometries.

To assess the multiple-trial variability, an ensemble average curve from 20 complete cycles of crank torque series from the right leg (symmetry between both legs was assumed) were calculated for each cyclist and pedalling intensities, as well as mean and standard deviation of each data point on average curve. The average standard deviation across all points composing the average curve was calculated. Thus, the total variability of the continuous curve was represented as a single value. To examine the time-dependent structure of crank torque dataset, the sample entropy (SampEn) was calculated [3]. A two-way repeated measure of analysis of variance was performed on the SampEn and multi-trial variability values to test the effects of competitive level (between-participant factor) and pedalling intensity (within-participant factor) on movement variability.

Results and Discussion
The primary outcome was to demonstrate a clear effect of pedalling intensity on crank torque multiple-trial variability (i.e.; it increased) and complexity (i.e.; it decreased) (Figures 1 and 2). The decrease of SampEn as pedalling intensity increased (Figure 2) agree with previous studies that observed a low muscular activation variability when the pedalling power was increased [1]. Another important finding was that, as pedalling intensity increased, multiple-trial variability increased (Figure 1), while complexity showed an opposite trend (Figure 2). This is in accordance with previous studies that observed a different effect of exercise intensity on both variables [5], so these two parameters of movement variability must be interpreted in a different way. Non-linear analysis (SampEn) was more sensitive than linear one (multiple-trial variability) to detect the effect of pedalling intensity and performance level on crank torque variability. According to the results of SampEn (Figure 2), a small effect of competitive level on complexity was observed. It could be possible that high-level cyclists show an adaptation to their highest training volume, decreasing the SampEn. On the contrary, according to the results of multiple-trial variability (Figure 1), it could be...
possible that variability within the perceptual-motor system is not functional for cycling performance, being pedalling a task that does not need variability [4]. However, the fact that pedalling intensity was identical for all cyclists could support the hypothesis that the competitive level had an effect on SampEn, because Elite and Professional cyclists pedalled at a lower relative intensity than Club cyclists did (i.e.; their maximal aerobic power is presumably higher).

**Conclusion**

In conclusion, crank torque multiple-trial variability (standard deviation) and complexity (SampEn) are affected by pedalling intensity, which could be due to the changes in biomechanical constraints and to the minimal intervention principle. The SampEn analysis is more sensible than the multiple-trial variability analysis to detect the influence of pedalling intensity and cyclists’ competitive level. Taking into account the complexity results, it seems that the crank torque time series regularity increases (SampEn decreases) as competitive level increases, which could be due to an adaptation to the highest training volume. However, further studies should confirm this hypothesis using similar relative pedalling intensities.

Inter-limb differences in bilateral CMJ peak force is not associated with inter-limb differences during unilateral CMJ height performance

Sergio Miras-Moreno¹, Alejandro Pérez-Castilla¹, Amador García-Ramos¹, Mar Cepero², Danica Janicijevic³, Juan Carlos De la Cruz¹, F.Javier Rojas¹

¹ University of Granada, Department of Physical Education and Sports, Granada, ES; ² University of Granada, Department of Teaching Body Language, Granada, ES; ³ University of Belgrade, Faculty of Sport and Physical Education, The Research Centre, Belgrade, RS

Introduction
The concept of inter-limb asymmetries has attracted considerable attention among researchers, physical therapists, and strength and conditioning professionals and it refers to the differences in mechanical performance of one limb with respect to the other [1]. This attention is warranted because inter-limb asymmetries may provide valuable information related to muscle function, injury risk, and decision regarding return to play. Numerous studies have compared the forces exerted by both limbs during jumping-based tasks [1,2,3]. Therefore, it is possible that the associations between the inter-limb differences in force production during the bilateral countermovement jump (CMJ) and the inter-limb differences in unilateral CMJ performance could be stronger in athletes who are frequently performing vertical jumps during their sport activity (e.g., basketball players) [2,4].

Previous studies have used the terms “limb preference” (i.e., the self-reported leg that subjects choose to complete a particular task) or “limb dominance” (i.e., the leg that provides a greater mechanical performance) as the criteria to analyze inter-limb differences following a jumping activity [5]. Therefore, the lack of agreement between the self-reported preferred leg and the dominant leg emphasizes the importance of considering this methodological factor when interpreting the jumping asymmetry profile of athletes [6].

Specifically, the main objective of the present study was to determine whether the inter-limb difference in unilateral CMJ height performance is significantly associated with the inter-limb difference in peak force production detected during the bilateral CMJ. A secondary aim was to elucidate whether the self-reported preferred leg is the extremity that contributes more to force production during bilateral and unilateral CMJs.

Experimental Methods
A repeated-measures design was used to explore the relationship between CMJ inter-limb asymmetries in force production and unilateral CMJ height performance in twenty-three amateur senior basketball players. In a single session, subjects performed eight unilateral CMJs (four trials with each leg) and four bilateral CMJs. Dual force platforms (Type 9260AA6; Kistler, Winterthur, Switzerland) were used for recording peak force values during bilateral CMJs and jump height during unilateral CMJs. The average value of the four trials of each CMJ type was considered for statistical analyses.

Results and Discussion
No significant differences between the legs were observed for the magnitude of any mechanical variable (p ≥ 0.215, ES ≤ 0.11), but they presented nearly perfect correlations (r ≥ 0.916; Figure 1). The inter-limb asymmetries reported during the bilateral CMJ peak force are not associated with the inter-limb differences in unilateral CMJ height performance (r = 0.149; Figure 2).

Many of the actions that are performed in basketball training and competitions (e.g., jumping, changing of direction, or pivoting) are generally performed unilaterally [4,5]. Therefore, it seems logical to expect inter-limb asymmetries in basketball players due to the specific demands of the sport [4]. It has been suggested that the evaluation of inter-limb asymmetries during different jumping tasks might provide useful information to reduce the risk of injuries and to
improve physical and sport-specific performance \cite{5}. However, an open research question is whether the inter-limb asymmetries should be preferably evaluated using bilateral or unilateral jumps. Therefore, considering the available scientific evidence, regardless of the studied population, clinicians and coaches should not expect a high agreement between the asymmetries detected in bilateral and unilateral CMJs. A possible explanation to this phenomenon appears to be related to neural factors instead of mechanical capabilities of the limbs. Therefore, the present study adds more evidence about the variable nature of inter-limb asymmetries, which do not only depend on the metrics and tasks, but also on the variant (unilateral or bilateral) of the task evaluated.

Another finding is that for most of the subjects the \textit{self-reported preferred leg} was generally weaker than the non-preferred leg during both bilateral and unilateral CMJs (self-reported preferred leg only revealed a higher performance in 7 out of 23 subjects for the unilateral CMJ height and in 6 out of 23 subjects for the bilateral CMJ peak force. Therefore, it seems that the subjective expression of the leg dominance cannot be used as a predictor of unilateral vertical jump performance because leg dominance may be in function of the type of activity \cite{5}.

\textbf{Conclusion}

These results encourage practitioners to evaluate asymmetries in tasks that resemble as close as possible the specific demands of their sport. The self-reported preferred leg should not be considered as the leg with higher vertical jump capacity. Therefore, it is necessary to objectively assess the leg that contributes more to vertical jump performance.

Deep Squat analysis: Functional Movement Screen criteria vs. biomechanical parameters related to global stability (preliminary results)

Pedro Aleixo¹, Sidnei Ramalho², João Abrantes³

¹ CIDEFES/CICANT/Universidade Lusófona de Humanidades e Tecnologias, Lisbon, PT; ² Faculdade Educação Física e Desporto/ULHT, Lisbon, PT; ³ CICANT/Universidade Lusófona de Humanidades e Tecnologias, Lisbon, PT

Introduction

The Functional Movement Screen is a screening system that identifies mobility and stability dysfunctions, as well as pain, during the performance of seven movement patterns exercises. This screening is fulfilled by visual observation and based on standardized criteria, scoring the exercises as: “0” if the subject presents pain during performance; “1” if the subject is unable to complete the exercise or is unable to assume the position to perform it; “2” if the subject is able to complete the exercise but must compensate in some way to perform it; “3” if the subject performs the movement correctly without any compensation [1]. However, according to Warren et al. [2], there is a research gap regarding the validation of the Functional Movement Screen’s criteria. In this way, a 3D motion analysis model may be very useful concerning the validation of criteria related to mobility and stability. The Deep Squat is one of the seven Functional Movement Screen’s exercises and assesses global stability as well as joint mobility of the lower limbs joints and shoulders [1].

Global stability indicates the ability to maintain adequate sustainability of the body along the movement [3]. According to a previous study [4], the relationship between cartesian coordinates of the center of mass projection (CoMp) and center of pressure (CoP) in the horizontal plan of reference may be an important way to analyze global stability. To the best of our knowledge, only one research [3] studied the relation between Deep Squat’s score and biomechanical parameters related to mobility during the Deep Squat’s performance (using a 3D motion analysis). Nonetheless, none research studied the relation between Deep Squat’s score and biomechanical parameters related to global stability. Thus, the aim of this study was to associate the Deep Squat’s scores (assessed according to the Functional Movement Screen’s criteria) with the values of the biomechanical parameters related to global stability.

Experimental Methods

For this observational study, the subjects were selected according to the following inclusion criteria: male; 18-40 years; undergo physical exercises at least three sessions per week for six months before assessment; absence of injuries at assessment time. The following exclusion criterion was also defined: Deep Squat’s exercises scored as “0”. The Deep Squat exercises were developed according to the Functional Movement Screen’s guidelines [1]. In order to achieve the Deep Squat’s scores, videos of three subjects’ performances in sagittal and frontal plans were collected. These videos were observed by two researchers with Functional Movement Screen’s certification and scored according to its criteria. A 3D motion analyses during the Deep Squat exercises were carried out using the Vicon® Motion Capture MX System – 9 MX cameras at 200Hz (Oxford metrics, UK; 7×1.3 MP; 2×2.0 MP). It was also used a force plate at 1000Hz (model BP400600, AMTI, Watertown, MA, USA), which was synchronized with the Vicon® System. Ten trials were collected from each subject. Biomechanical parameters related to global stability were assessed during the descendent displacement of the center of mass – determined from the Plugin Gait Full-Body model (from the instant that center of mass’s vertical values began to decrease to the instant that subject achieved the lowest vertical position of the center of mass): duration of the period (s); mean distance between CoMp and CoP during period (mm); mean medio-lateral distance between CoMp and CoP during period (mm); mean antero-
posterior distance between CoMp and CoP during period (mm). Kruskal-Wallis and Mann-Whitney tests were used to compare subjects with the same Deep Squat’s score and to compare different Deep Squat’s scores, respectively.

Results and Discussion
Six subjects were selected to this preliminary study: two were scored as “1”, two as “2”, and two as “3”. Figure 1 shows the CoMp and CoP displacements in the horizontal plan during the ten trials of a subject scored as “1”. The observed variability of the CoP displacements is also observed in the other five subjects. Table 1 presents data regarding the comparison between subjects with the same score. As can be seen, differences were observed regarding the biomechanical parameters related to global stability (p<0.05). Table 2 presents data regarding the comparison between different Deep Squat’s scores: no differences were observed in the biomechanical parameters concerning the comparisons between scores “1” and “2” and between scores “2” and “3” (p<0.05). To the best of our knowledge, this was the first study that studied the relation between the Deep Squat’s scores and the biomechanical parameters related to global stability. Data lead us to question the validity of the FMS to objectively measure global stability deficits.

Conclusion
Despite the small sample size, data point to FMS’s difficulties to objectively assess global stability in Deep Squat, however, more research is needed to answer this issue.

Different muscle activation according to type of muscle contraction in male and female professional soccer players: preliminary results

Estrella Armada-Cortés, Gonzalo Torres, Javier Rueda, Alejandro San Juan Ferrer, Enrique Navarro

University Politécnica de Madrid, Health and Human Performance, Madrid, ES

Introduction

Injuries are one of the most prominent concerns in football. Male soccer players get 1.9 times more hamstring injuries than female soccer players, with a 12% absence rate in the season compared to a 6% for female counterparts [1]. Moreover, female soccer players have two times more quadriceps injuries than male soccer players, with an 8% absence rate compared to 3% for males [2]. There are basic exercises used to strengthen the hamstring and quadriceps muscles, and their study can provide information about the activation pattern of these muscle groups during the different execution phases of each exercise [3]. This study of the different exercises may be decisive for soccer players, considering the muscle group they are targeting, since recording the electrical activity of each of the muscular bellies would help reduce the time in the process of recovery from an injury and also help in its prevention [3].

Therefore, the main objective of this study was to determine if there are differences in the muscular activation according to the type of muscle contraction between professional female and male soccer players during the execution of a Bulgarian squat.

Experimental Methods

Muscle activation was recorded with surface electromyography (Trigno Wireless System, Delsys, Inc., Boston, USA) in 8 professional soccer players (age = 23.3 ± 3.5, height = 170.4 ± 3, weight = 63.9 ± 5.4), divided in two groups by sex (i.e., 4 males and 4 females). The players performed 5 repetitions of the Bulgarian squat with an external load of 30% of the body weight. Vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), semitendinosus (ST), and biceps femoris (BF) were analysed.

For the statistical analysis, SPSS 23.0 software (Armonk, NY: IBM Corp) was used, the dependent variable of the study was the electrical activity of each muscle belly (RMS) in relation with the total activation of hamstring muscle group [4]. A comparison of means was performed using the repeated measures ANOVA test, with the independent variables muscle with 5 levels (RF, VM, VL, BF, ST); phase with 3 levels (eccentric, isometric and concentric) and gender (male and female) as an inter-subject factor. The significance value was set at 0.05.

Results and Discussion

No significant differences were found between dominant and non-dominant leg (F1,19=0.10; p>0.05). Posteriori comparisons were made without taking into account the leg variable. Significant differences were found in muscle activation in each of the muscles, between phases and between the two sexes (F8,152=3.3; p=0.002; partial η2=0.14). Specifically, differences were found in the electrical activity (RMS) of the eccentric and isometric phases of the VM, being higher in boys than in girls (p=0.02 and p=0.005 respectively) (Figure 1).

Conclusion

In general, it seems there are not differences in the electrical activity (RMS) between professional female and male soccer players during the execution of a Bulgarian squat, except in the eccentric and isometric phases of the VM (i.e., Being higher in males than females). More research is needed with a larger population to clarify which are the differences of muscle activation between sex according to the type of muscle contraction in order to improve the prevention and recovery of musculoskeletal injuries.

Spatiotemporal analysis of the approach run phase in the 60 m indoor hurdles race

Pablo González-Frutos¹, Santiago Veiga², Javier Mallo³, Enrique Navarro²

¹ Universidad Francisco de Vitoria, Facultad de Ciencias de la Salud, Pozuelo de Alarcón, ES; ² Technical University of Madrid, Health and Human Performance Department, Madrid, ES; ³ Technical University of Madrid, Health and Human Performance Department, Madrid, ES; ⁴ Technical University of Madrid, Health and Human Performance Department, Madrid, ES

Introduction
The technical analysis of the hurdle’s races has been focused on two- and three-dimensional kinematic analyses of the hurdle unit phase [1,2]. In recent years, the approach run phase has been subjected to specific analysis [3], highlighting the large relationship of the time in this phase with the final time in both men (r = 0.91) and women (r = 0.92) [4]. In addition, elite-level athletes performed different step length, step time, support time and/or flight time during approach run phase (p < 0.05), either in men or women, compared to elite-level athletes [4]. The aim of this study is to analyze the relationships between spatiotemporal parameters with the approach run phase split time in eight steps hurdlers.

Experimental Methods
All the races were filmed during the 44th Spanish Indoor Championship and 12th IAAF World Indoor Championship (Valencia 2008) and analyzed with 2D-DLT [5]. The best result of the athletes who performed an approach run phase of eight steps (Males: n=55; Females: n=51) was included in the study. The variables calculated were approach run phase split time, step length, step width, step time, contact time and flight time.

Results and Discussion
The largest correlation with approach run phase split time was found in mean step time in both men (r = 0.89; p < 0.01) and women (0.94; p < 0.1). Moreover, approach run phase split time had small correlation (r = 0.28; p < 0.05) with mean contact time of men hurdlers, and moderate relationship (r = 0.48; p < 0.01) with mean flight time of women hurdlers. Although no other statistically significant correlations were obtained, the small relationships found in men for the average step length (r = 0.24; p = 0.07) and flight time (r = 0.25; p = 0.07) can be highlighted. Additionally, the mean step time showed a moderate relationship with contact time in men (r = 0.30; p < 0.05) and flight time in women (r = 0.46; p < 0.01).

Conclusion
Eight step hurdlers with a shorter time in the approach run phase obtained lower values in the passing time, both in men and women. This variable seems to be related to contact time in the case of men, and flight time in the case of women.

Dominant kicking limb kinematics between kicks in futsal. One subject case.

Gonzalo Garrido López, Alberto Galisteo Pedraz, Enrique Navarro Cabello

Universidad Politécnica de Madrid, INEF (Health and Human Performance Department), MADRID, ES

Introduction
Kicking is a determining action during a match. Defining kicking from a biomechanical way, it is a kinematic chain of the limb in which the player pretends to give the maximum linear velocity to the kicking surface (1). The maximum velocities of different joints or segments are obtained sequentially, proximal parts earlier than distal ones (1,2). There is not too much scientific information regarding futsal. Some studies consulted compare stationary ball kicks with rolling ball ones, kicks with different surfaces, or dominant or non-dominant limbs (3,4). However, we have not found studies about different ways of kicking in futsal. Although, there is more information about soccer kicking and other gestures. The main objective of this work was to compare the timing, linear velocities, and angular positions of the kicking leg joints during instep, side foot, and toe kick performed by a futsal player.

Experimental Methods
The subject was a futsal male player of 23-year-old, 1.81 meters tall, and a weight of 90 kilograms. His dominant leg was the right. At the time of the study, he had 7 years of experience playing futsal at the category of preferred of the Madrid Futsal Federation and was free of injuries. A motion capture system (VICON®) operating at 250 Hz was used. Ten shots were recorded (five with each leg) during three different ways of contact surfaces: instep, side foot, and toe kicks. The variables analyzed were the joints angles of the hip, the knee, and the ankle on different moments of the kick; and the maximum velocities of body segments obtained during the kick.

Results and Discussion
There have not been found differences between the normalized times of the kicks. The hip is the first joint to reach its maximum (33% ±3), followed by the knee (69%±1), ankle (90%±1), toe (89% ± 1), and ball (110% ± 2). Interestingly the times of joint ankle and the toe are not significantly different. Similarly, there were no differences in the joints velocities among kicks. The hip had 5.3 m/s ± 0.2, the knee had 10.1 m/s ± 012, the ankle had 16.8 m/s ± 0,1 and the toe reached 18.2 m/ ± 0.1. Also, the ball speed (26.4 ± 0.6) and the impact factor (1.5 ± 0,0) were not different between kicks.

However, joint angles variables were significantly different between kicks, showing a very high effect size in the sagittal, frontal, and transversal planes (all partial eta square above 0.3). At the sagittal plane (Figure 1), the knee did not present differences between kicks, while the hip during instep (p=0.000) and side foot (p=0.023) kicks showed 8.3° and 4.7° smaller angles of flexion than during toe kicks at the foot strike instant. Also, at the impact, the instep kicks had smaller flexion angles than toe kicks. Interestingly, the angles of hip flexion were similar during the instep and side-foot kicks. The way of kicking is affecting mainly the ankle flexion-extension, showing the more flexed position (p=0.000) during toe kicks. At the frontal and transversal plane (Figure 2), kicks present differences mainly around the anteroposterior axis of the hip joint, where toe kicks showed a lower angle of abduction (p=0.01) at toe-off, foot strike, and impact (Figure 2). About the longitudinal axis, the most remarkable difference is that the hip joint presented higher (p=0.001) internal rotation during the toe kicks than during instep (5.0°) or side foot (5.1°) kicks at the beginning of the kicking phase. The knee joint present also higher (p=0.031) internal rotation during the toe kicks at the beginning. The foot was more (p=0.001) supinated during instep kicks than inside foot kicks (13.5°) and toe kicks (18.4°), while side foot and toe kicks were not significantly different.

Conclusion
Page 974 of 2028
The player showed a similar pattern of movement during the kicks reaching joints and ball velocities with no significant differences. There has been found that the technique of the movement presented large differences between kicks. At the sagittal plane, the hip was less flexed, the ankle was more flexed during the toe kicks, while the knee was not affected. In the frontal plane, the hip is less abducted during the toe kicks clearly. Around the longitudinal axis, the hip showed bigger internal rotation at the beginning of the kicking phase. As expected, the foot behaved differently during kicks showing more supinated angles during instep and toe kicks than inside foot kicks.

Asymmetries in force production between unilateral and bilateral standing broad jumps in young senior amateur basketball players

Iago Rojas-Cepero¹, Alejandro Pérez-Castilla¹, Francisco Yuste-Hidalgo², Danica Janicijevic³, Sergio Miras-Moreno¹, Amador García-Ramos¹

¹ University of Granada, Department of Physical Education and Sport, Granada, ES; ² University of Granada, Department of Didactics of Musical, Plastic and Corporal Expression, Granada, ES; ³ University of Belgrade, Faculty of Sport and Physical Education, The Research Centre, Belgrade, RS

Introduction

The assessment of inter-limb asymmetries has been a frequent source of investigation in recent years in the fields of rehabilitation and strength and conditioning. Previous studies have suggested that lower inter-limb asymmetries may be associated with a lower injury incidence and a safer return to play. For that reason, it has been recommended that clinicians and coaches frequently evaluate inter-limb differences throughout a training cycle in order to ensure that their patients or athletes do not exceed an arbitrary “high risk threshold” (e.g.10-15%). Since multiple strength and jumping tests have been used to monitor the existence of inter-limb asymmetries, of special interest should be the identification of the most appropriate test and metric for an accurate diagnosis of inter-limb differences.

The standing broad jump (SBJ) likely is the test most frequently used for detecting inter-limb differences in the ability to apply force in a horizontal direction. The main goal of any variant of the SBJ is to jump as far as possible. The high applicability of the SBJ tests comes from the fact that a simple tape measure can be used to determine the main performance but to know in depth, the possible origin of asymmetries, analysis using force platforms is necessary. Due to the lack of similar studies, it seems reasonable to explore the consistency in the magnitude and direction of asymmetries between consecutive sessions during the unilateral and bilateral SBJs. To address the existing gaps in the literature, specifically, the aim of this study was to clarify whether single-leg performance and inter-limb asymmetries can be obtained with a higher between-session reliability during unilateral or bilateral SBJs.

Experimental Methods

Twenty-four amateur basketball players, 12 seniors male (age = 18.9 ± 1.8 years; mass = 80.2 ± 11.0 kg; height = 1.88 ± 0.08 m) and 12 female (age = 21.1 ± 4.2 years; mass = 70.6 ± 7.2 kg; height = 1.75 ± 0.06 m) team that played in a regional-level Spanish basketball club. The subjects completed two identical sessions which consisted of four unilateral SBJs (two with each leg) and two bilateral SBJs. All SBJ tests were performed on two parallel force platforms (Type 9260AA6; Kistler, Switzerland; 0.5 × 0.6 × 0.1 m) embedded in a wooden housing (1.1 ×1.0 × 0.1 m; see Figure 1). The horizontal Ground Reaction Force (GRF) data from each force platform were synchronously acquired with the BioWare® software (Kistler, Winterthur, Switzerland) at 1,000 Hz. Mean and peak values of force, velocity and power, and impulse were obtained separately for each leg using a dual force platform. Inter-limb asymmetries were computed using the standard percentage difference for the unilateral SBJ, and the bilateral asymmetry index-1 for the bilateral SBJ, using the equation proposed by Bishop et., (2018) ([dominant leg – nondominant leg]/[dominant leg + nondominant leg]*100).

Results and Discussion

All performance variables generally presented an acceptable absolute reliability for both SBJs (CV range = 3.65-9.81%) with some exceptions for mean force, mean power, and peak power obtained with both legs (CV range = 10.00-15.46%). Three out of 14 variables (mean force of the left leg and peak force of both legs) were obtained with higher reliability during the unilateral SBJ (CVratio ≥ 1.18), and 5 out of 14 (mean power and peak velocity of the right leg, as well as mean velocity, peak velocity, and impulse of the left leg) during the bilateral SBJ (CVratio ≥ 1.27).
Asymmetry variables always showed unacceptable reliability (ICC range = -0.40 to 0.58), and slight to fair levels of agreement in their direction (Kappa range = -0.12 to 0.40) except for unilateral SBJ peak velocity [Kappa = 0.52] and bilateral SBJ peak power (Kappa = 0.51), that showed moderate agreement for both SBJs. Increasing the sample size would likely result in a more concise results. As others authors aproached many measures of reliability are susceptible to the range of values in the sample, so increasing the sample size may also alter the reliability findings. Because of this lack of reliability, asymmetry measures should not be considered in decision-making performance or preparedness of basketball healthy young senior players.

**Conclusion**

These results highlight that single-leg performance variables can be generally obtained with acceptable reliability regardless of the SBJ variant, but the reliability of the inter-limb asymmetries in the conditions examined in the present study is unacceptable to track individual changes in performance due to the nature variability of asymmetry direction. Practitioners should use caution when considering the results (direction and magnitude) of asymmetry tests as they may not be as reliable. Further studies with a large number of basketball players of different ages and healthy or recovering from lower-limb injuries are needed to confirm asymmetries and to establish clinical guidelines for the assessment of bilateral strength asymmetry using SBJs.

Analysis of reaction force and foot velocity in relation with the dominant leg in soccer kicking

Yecheng Zhang¹, Navandar Archit¹, Rueda Javier², Navarro Enrique¹

¹ Universidad Politécnica de Madrid, salud y rendimiento humano, madrid, ES; ² Universidad Europea de Madrid, Lecturer in Biomechanics, madrid, ES

Introduction
As the most important parameter of the supporting leg in kicking, the ground reaction force (GRF) of the supporting leg occurs in the leg cocking phase and continues until the kicking action ends[1]. After the supporting leg touches the ground, the swing leg transitions from the leg cocking phase to the leg acceleration, followed by ball impact and the follow through phase.[1]. At the end of the backswing phase, the length of the final step in the swing determines acceleration or deceleration of the foot and can significantly impact the ball and foot velocity[2]. This occurs when the hip flexion angular velocity rapidly increases and reaches a similar peak magnitude, after which, the angular velocity decreases until ball impact[3]. As described in previous research, the foot impact velocity is the most important factor affecting ball velocity[4]. There is a deceleration of the proximal segment and an acceleration of the more distal segment, as a result of which the linear speed of the knee was decreases to zero at impact (0.06 – 0.56 m/s) and the foot velocity increases to peak (11.76 – 20.3 m/s)[5].

According to previous studies, most studies on GRF have focused on analysing the differences in GRF between different genders, playing styles, and dominant non-dominant legs. However, the supporting leg and the kicking leg are related to each other, and elite athletes can achieve coordination of their legs. Therefore, the main purpose of this research is to Analysis of reaction force and foot velocity in relation with the dominant leg in soccer kicking.

Experimental Methods
Eighteen soccer players (age = 19.2 ± 0.5 years, height = 179.7 ± 5.3 cm, weight = 71.0 ± 5.9 kg) participated in the study, all of them men, belonging to the youth soccer team of a professional Spanish team. The players trained five days a week and played a match every week. The ground reaction force is collected by the Kistler and the Motivo capture os Vicon is used to collect players' kicking movements.

Results and Discussion
The reaction forces applied in the anteroposterior axis showed a consistent temporal pattern (Figure 1) that means that player is pushing forward with the foot applying maximum forces of 0.7 N/Bw between the 60% and the 70% of the kicking phase.

The lateral reaction forces showed that player applied forces from leg to right during a kick with the right leg due to the inclination of the body maximum forces reaching forces of 0.6 N/Bw between 20% and 30%.

The vertical forces showed that player push down the floor reaching forces around 2.5 N/Bw between 20% and 30% of the kicking phase.

There have not been found (Table 1) differences between dominant and no dominant legs at any of the ten instants analysed. However, the foot speed presented higher (p<0.05) velocities of at the dominant leg at the 50%, 60% And 70% of the kicking phase.

Conclusion
While there are differences on the velocity of the foot of the dominant and no dominant leg during kicking the reaction, forces are similar. It seems that reaction force don’t play a direct role related with the technique of kicking. However, the high forces applied are very huge reaching more than 3 times the body weight which it means the need of an
specific muscle strength training of the lower limbs. More research is needed for improving the knowledge about the behaviour of the support leg during kicking in soccer.

Impulse, Power and Work predictors comparison on standard maximum vertical jump of elite and non-elite performers

Carlos B. Rodrigues1,2, Miguel V. Correia1,2, João Abrantes3, Marco B. Rodrigues4, Jurandir Nadal5

1 University of Porto, Doctoral Program in Biomedical Engineering, Porto, PT; 2 INESC TEC - Institute for Systems and Computer Engineering, Technology and Science, C-BER - Centre for Biomedical Engineering Research, Porto, PT; 3 Lusófona University - CICANT (Centre for Research in Applied Communication, Culture, and New Technologies), MovLab (Laboratory of Technologies for Interactions and Interfaces), Lisbon, PT; 4 Federal University of Pernambuco, Department of Electronic and Systems, Recife, BR; 5 Federal University of Rio de Janeiro, Biomedical Engineering Program, Rio de Janeiro, BR

Introduction

Stretch-shortening cycle (SSC) is a natural form of muscle action with concentric contraction immediately preceded by eccentric stretch to achieve more efficient submaximal actions and powerful maximal efforts [1]. Despite muscle SSC can be observed at lower limbs in gait and running, its higher expression and accessibility corresponds to standard maximum vertical jump (MVJ) with long countermovement (CM) and short CM at drop jump (DJ) for comparison without CM at squat jump (SJ) [2]. Standard MVJ have been increasingly used [3-5] with an open issue on the ability of non-elite performers to exploit long and short CM in relation to elite performers. Elite (E) and non-elite (NE) performers have been compared on standard MVJ based on kinematic and dynamic performance with an open question on impulse, power and work predictors comparison on E and NE.

Experimental Methods

Assessed subjects correspond to a group NE of six male degree sports students with (21.5±1.4) yrs, (76.7±9.3) kg mass and (1.79±0.06) m height without previous injuries, specific train or sport modality, and a group E of sixteen male players of the Portuguese national volleyball team ages (21.4±3.1) yrs, (85.2±5.8) kg mass and (1.93±0.04) m height. Each subject group performed a total of 3 SJ, CMJ and DJ from 40cm step repetitions with 2 to 3 minutes resting and instruction. During MVJ, ground reaction forces (GRF) were acquired with AMTI BP2416-4000CE force plate at 1000 Hz and best execution of each subject SJ, CMJ and DJ was selected according to maximum flight time. Vertical resultant force (RFz) was obtained from GRF and vertical impulse (Iz = \int RFz dt) from time integration of RFz during impulse phase. Vertical velocity (vz = Iz / m) of each subject center of mass was obtained as well as the net mechanical power (P = RFz \cdot vz) and mechanical work (W = \int P dt) developed during vertical impulse phase. Maximum vertical jump height (hi) was obtained from vertical impulse and (ht) from flight time. Selected variables from previous physical quantities were statistically compared at 5% significance with intra-subject paired T-test of mean differences from SJ, CMJ and DJ40 to 40cm step repetitions with 2 to 3 minutes resting and instruction. During MVJ, ground reaction forces (GRF) were acquired with AMTI BP2416-4000CE force plate at 1000 Hz and best execution of each subject SJ, CMJ and DJ was selected according to maximum flight time. Vertical resultant force (RFz) was obtained from GRF and vertical impulse (Iz = \int RFz dt) from time integration of RFz during impulse phase. Vertical velocity (vz = Iz / m) of each subject center of mass was obtained as well as the net mechanical power (P = RFz \cdot vz) and mechanical work (W = \int P dt) developed during vertical impulse phase. Maximum vertical jump height (hi) was obtained from vertical impulse and (ht) from flight time. Selected variables from previous physical quantities were statistically compared at 5% significance with intra-subject paired T-test of mean differences from SJ, CMJ and DJ pairs at each group NE and E, as well as inter-subject mean differences with independent samples T-test on SJ, CMJ and DJ between NE and E groups, Fig. 1-2.

Results and Discussion

NE and E presented higher hi on CMJ than SJ, both higher than DJ40 without statistical significative differences (ssd) between SJ and DJ40. As regards to ht, NE and E presented higher means at CMJ, with higher ht at SJ than DJ40 on NE and higher ht at DJ40 than SJ on E. NE and E presented higher ht than hi at SJ and CMJ, as well as as at DJ40 on E, but lower ht than hi at DJ40 on NE without ssd. On direct comparison between groups hi and ht presented on SJ higher means on NE than E without ssd, and lower means on NE than E at CMJ, with opposite results on DJ40 and higher NE than E on hi without ssd, and higher E than NE on ht.

CMJ presented at NE and E longer duration of the impulse phase (\Delta t imp) and downward subphase (\Delta t down), with longer \Delta t imp at SJ than DJ40 on NE and E, whereas NE presented longer \Delta t down at SJ than DJ40 without ssd and
E longer $\Delta t_{down}$ at DJ40 than SJ. NE and E presented longer upward subphase ($\Delta t_{up}$) than CMJ, both longer than DJ40. NE presented longer $\Delta t_{imp}$ and $\Delta t_{down}$ than E at SJ with shorter $\Delta t_{up}$ on NE than E at SJ and shorter $\Delta t_{imp}$, $\Delta t_{down}$ and $\Delta t_{up}$ at NE for CMJ and DJ40.

Vertical resultant force ($RF_z$) presented dominant higher values at DJ40 than CMJ, both higher than SJ, namely at the downward inversion $RF_z$ start up and the upward subphase $RF_z$ mean up, with higher values at NE than E on SJ and higher values at E than NE on CMJ and DJ40. Nevertheless, due to the balance between the force levels and the duration of the impulse subphases $I(RF_z)$ imp up presents higher values at CMJ on NE, as well as higher value on SJ than DJ40 and higher value at DJ40 than SJ on E, with NE presenting lower value than E on SJ, CMJ and DJ40.

As regards to developed mechanical power during impulse phase, despite $P_{mean imp}$ presents at NE and E higher value on SJ than CMJ and DJ, $P_{mean up}$ presents at NE and E higher value at DJ40 than CMJ, both higher than SJ. Also, NE presented lower $P_{mean imp}$ and $P_{mean up}$ than E.

In relation to developed mechanical work $W_{imp}$ during impulse and the ascending sub-phase $W_{imp}$ up, both NE and E presented lower values than SJ, DJ40, with lower $W_{imp}$ up at NE than E on SJ, CMJ and DJ. Nevertheless, $W_{imp}$ up presents at NE higher value than SJ at DJ40 and $W_{imp}$ up at E higher value on SJ than which can contribute for explaining differences on NE and E performances at SJ and DJ.

Conclusion
Despite vertical impulse has been applied as a dominant variable determining MVJ performance, complementarily developed power and mechanical work need to be considered as an energy transference metrics contributing for explaining differences on NE and E at SJ, CMJ and DJ.

Scientific production in Sports Biomechanics. A vision from the doctoral theses completed in Spain

José Campos¹, Marcos Gutiérrez Dávila², José María Campos Coll³

¹ University of Valencia, Physical Education and Sport Sciences, VALENCIA, ES; ² University of Granada, Physical Education and Sport Sciences, Granada, ES; ³ I.E.E Districte Marítim, Physical Education, Valencia, ES

Introduction
In the literature there are no references of studies oriented in the evolution of doctoral theses in the specific field of Sports Biomechanics. The information available comes from global studies, which have been carried out in the field of Physical Activity and Sports Sciences, such as those carried out by Delgado and Medina (1997), Ponce de León, Gargallo and Loza (1998, and García García (2016). The purpose of this study is to carry out a review of the doctoral theses that have been read in Spain in the field of Sports Biomechanics during the period between the 1980-81 and 2018-19 academic course aimed at knowing the scientific production, the authorship and tutorial data, and the institutional references that give them academic coverage.

Experimental Methods
The sample has been composed of 233 theses, after a selection process with the use of inclusion / exclusion criteria and specific search terms. In order to analyse the data and its evolution over time, four academic periods were distinguished, considering normative issues and specific events that marked the evolution of the centers and doctoral programs in the field of Physical Activity and Sports Sciences in Spain. Descriptive statistics and contingency tables with Chi-Squared test and Haberman Standardized and adjusted residuals were performed.

Results and Discussion
The results have shown that the production of theses on this subject has been progressive and growing throughout the periods analysed, being the last period the one that more theses were read, both in public and private universities. In the second period, the percentage of theses read increased by 16% when compared to the first period. As for the third period, the increment was 10% when compared to the second period. Finally, a 11.5% increase was shown between the third and the fourth periods, which is the largest seen in the series (table 1).

The data collected shows that there is a total of 42 Universities in which Sports Biomechanics theses were read. Among them, 90% were public, whereas 10% were private.

In addition, and regarding the presence of University Departments in the above-mentioned field, it is worth highlighting the leading position of the Department of Physical Education and Sport. Both in the authorship, as in the direction of the theses, there is a majority presence of men. Despite the progressive and growing presence of women as authors of theses (15 theses in the second period, 17 theses in the third period and 39 theses in the fourth period), 69.5% of total are written by men (figure 1).

In the case of thesis tutorial, the presence of women is even more reduced, with a 81.5% of theses directed only by men, 5.2% directed by women only, and 11.6% directed by men and women working together. However, when analyzing its evolution throughout the four academic periods, it has been found that in the last period (2010/11 – 2018/19), 8 theses were directed by women only, and 19 theses were led between men and women. These, when added together, represent the 24.8% of the total theses read, which doubles those registered in the previous periods (11%-12%), resulting in a change of trend (X²: 9.506 y p: .05).

Another area of the study focuses on the evolution in the number of thesis directors. In this regard, the data shows that theses directed by one or two directors represent 89.9% of the total, while those led by three or more directors represent 9.9% of the total. That is, one of each ten theses read. When analysing its evolution in time, there is an increase in the tendency among the number of thesis directors (figure 2).
professors towards sharing the direction of their theses with other colleagues ($X^2: 45,250 \ y \ p: .000$). Specifically, in theses directed by 2, 3, or more directors, there is an increase, from 10 in the second period, to 81 in the fourth period.

**Conclusion**

The production of doctoral theses in Sports Biomechanics has contributed positively to the development and advancement of research in the field of Sports Sciences in Spain. However, its future will depend on the ability to overcome structural problems, such as the difficulty to access and lead projects in the National R+D+i Plans, its level of subsidiarity when compared to other areas of knowledge, and the orientation of research in both the applied field and high-performance sports services.

Introduction

One of the traditional aims of Sports Biomechanics has been analyzing sports technique as training support for athletes. This scientific discipline has, however, expanded its field of action over time, incorporating professionals from different fields to better deal of the systems that command the execution and control of human movement.

In the literature there are no references of studies oriented in the evolution of the contents of doctoral theses in the specific field of Sports Biomechanics. The information available from Spain comes from global studies (Delgado and Medina, 1997; Ponce de León, Gargallo and Loza, 1998; and García García, 2016).

The purpose of this study is to carry out a review of the doctoral theses that have been read in Spain in the field of Sports Biomechanics during the period between the 1980-81 and 2018-19 academic course aimed at knowing the evolution of their contents.

Experimental Methods

The sample has been composed of 233 theses, after a selection process with the use of inclusion / exclusion criteria and 32 specific search terms. In order to analyse the data and its evolution over time, four academic periods were distinguished, as well as four subject fields of study: Basic Biomechanics; Applied Biomechanics; Support Biomechanics; and Biomechanics and Technology. Descriptive statistics and contingency tables with Chi-Squared test and Haberman Standardized and adjusted residuals were performed.

Results and Discussion

The results show that the most common contents of the theses are those of Support Biomechanics and Applied Biomechanics, with a progressive growth that has escalated to a total amount of 107 and 98 theses respectively, followed by the field of Biomechanics and Technologies, with a total of 25 theses read. Finally, there is the field of Basic Biomechanics, which encompasses explanatory theories of human and sports movement and is composed of 3 theses (1.3% of the total). (figure 1).

Regarding the distribution of the established thematic subfields of the theses, in table 1 it can be seen that within the field of Support Biomechanics, the one with the highest representation is the Medical Area, which groups 73 theses (31.3% of the total). Next, the three subfields of Applied Biomechanics are located; (Analysis of sports technique (35 theses), Analysis of human movement (32 theses), and Various Analysis (31 theses), which represent 15%, 13.7% and 13.3% of the total theses respectively. In the last place, we can see the three subfields of Biomechanics-Technologies (Photogrammetry, with 7 theses; Dynamometry, with 8 theses and Other technologies, with 10 theses) that represent 3.1 %, 3.4% and 4.3% respectively of the total.

Nevertheless, it has not been possible to find that there are statistically significant associations between thematic fields and academic periods to justify the number of theses carried out over time.

In addition, the term that appears the most in the titles of the theses is “walking”. Specifically, it appears 61 times. Thus, this term is revealed as a cross-sectional element that is used in the Medical Area, as well as in Engineering, Physical Education and CAFD and also, linked to the three thematic fields considered.

Conclusion

The thematic fields in which theses have been carried out the most in the periods analyzed are Support Biomechanics and Applied Biomechanics. The former is related to studies whose independent variable and specific objective do
not respond to any biomechanical variable, such as specific training, a health program or a sociological, behavioral or psychological variable assessed by using specific techniques of Biomechanics. The latter is linked to studies whose independent variable is from the specific field of Biomechanics, such as the analysis of sports techniques, human movement, strength, or coordination.

This situation has continued to reinforce the applied nature of research over time, and also places Basic Biomechanics as a residual research field, given its orientation towards a more theoretical explanation of human and sports movement.

These trends also show that the field of Support Biomechanics has been growing progressively and expanding its field of action in several areas, such as Health, Occupational Biomechanics and Sports equipment and materials, thanks to a better access to more sophisticated and accurate measurement systems. Moreover, the evolution of the themes and contents of the theses in Sports Biomechanics help to better understand the effect that this scientific perspective may have had on the development of the sports sector in Spain. This evolution has also enhanced the formation of multidisciplinary research teams made up of professionals from various fields related to sports, health and engineering.

**Toward core-shell 3D printed photonic strain sensing medical device**

*David Eglin*¹², Christoph Sprecher², Christophe Marquette³, Edwin J. Courtial³

¹ Mines Saint Etienne, Biomaterials, Saint Etienne, FR; ² AO Research Institute Davos, Davos, CH; ³ University of Lyon, Platform 3D Fab, Villeurbanne, FR

**Introduction**

Medical devices are often required to function in contact with complex organ geometry under mechanical stress. Photonic strain sensing devices are being widely used for their diagnostic and therapeutic functions. In this study, we demonstrate the possibility to endow a 3D printed silicon structure with photonic strain sensing ability [1].

**Experimental Methods**

40, 60 and 63.5 w:w % hydroxylpropylcellulose (HPC, Mw circa 100 kDa): dH₂O solutions were prepared. The HPC solutions were characterized using a rheometer equipped with a camera (DHR, TA instrument). Coaxial 3D printing of a tubular structure was performed with the 63.5 w:w % HPC solution in the inner part and moisture curing silicon in the outer part using a customized Tobeca FDM printer with pressure driven coaxial extrusion head. The strain sensing ability of the printed structure was assessed under an optical microscope (Zeiss AxioVert 200M).

**Results and Discussion**

The viscoelastic properties and thixotropy of the HPC solutions are assessed (Fig 1). Changes of birefringence of HPC 63.5 w:w % under shear is imaged (Fig. 1). Three main regimes are observed in the flow sweep curve of 60 and 63.5 w:w % HPC solution indicatives of birefringent cholesteric liquid-crystalline solutions [2]. A first region, with an increase of viscosity and birefringence, related hypothetically to the setting-up of the formulation, a second region with a progressive extinction of the birefringence together with a decrease of viscosity and a final region with no changes in birefringence and logarithmic decrease of viscosity value. Upon application of high rotational shear, the HPC solutions viscosity drops, with 90% recovery observed after 11 ± 1, 181 ± 1 and 222 seconds for the 40, 60 and 63.5 w:w % HPC, respectively.

Coaxial micro-extrusion 3D printing of HPC (core) and silicon (shell) is performed, and after curing at room temperature in humid atmosphere for 2 days, stable rubbery 3D structure is obtained with conserved liquid crystal properties of the HPC (Fig. 2). Upon application of pressure on the silicon filaments, dark region under cross-polarized light suggests apparition of an isotropic HPC phase (Fig. 2).

**Conclusion**

Core-shell silicon/cholesteric HPC 3D printed structure could be produced with a facile coaxial micro-extrusion approach. The elastomeric structure can be deformed and extinction of the HPC birefringence observed. Further, characterization and fabrication optimization are required to validate potential applications as strain sensitive medical device.

Stereolithography shows potential in additive manufacturing of synthetic trabecular bone structures

Ana Grzeszczak\(^1\), Susanne Lewin\(^1\), Olle Eriksson\(^2\), Johan Kreuger\(^2\), Cecilia Persson\(^1\)

\(^1\) Uppsala University, Department of Materials Science and Engineering, Uppsala, SE; \(^2\) Uppsala University, Department of Medical Biochemistry and Microbiology, Uppsala, SE

**Introduction**

Synthetic bone models are needed to train surgeons but also to test and design medical devices such as screws for fracture fixation. However, currently available models do not accurately mimic the trabecular bone and its complex structure [1]. This study aimed to investigate if stereolithography (SLA) additive manufacturing could produce synthetic trabecular bone models with high accuracy.

**Experimental Methods**

The synthetic bone models were printed by SLA (Formlabs Black resin, Form3 printer). The CAD-model had been generated from micro-computed tomography (micro-CT) synchrotron images of human trabecular bone [2]. The model was printed at the original scale (scale factor 1), and with upscaling factors up to 4.3. Structure replicability was assessed with micro-CT, and the mechanical properties were evaluated by compression and screw pullout tests. Dense cylinders of the printed material were also tested in compression for material characterization.

**Results and Discussion**

The elastic moduli obtained by compression of dense cylinders were approximately ten times lower than average values for human cortical bone. For the trabecular bone models with scaling factors below 1.8, micro-CT image analysis showed major artefacts due to printing and a low accuracy in trabecular thickness distribution (Fig. 1). Analysis of the total printed volume showed a difference to the original model higher than 50% for scale 1.5. However, this difference was less than 10% for scales 1.8 and above, although a refined overlap comparison with the original bone model showed that the scale 1.8 exhibited errors higher than 20%, implying printing inaccuracies of the smaller structures. The pullout strength of SLA-printed parts was higher than for existing synthetic models (Sawbones\(^\text{TM}\)) and cadaveric specimens, but within the same range as FDM-printed parts in poly(lactic acid) [2].

**Conclusion**

In conclusion, trabecular bone models with a scale factor of 1.8 or larger could be printed with acceptable accuracy, but models with smaller scale factors were not well represented. However, for the same 3D model, a higher resolution was achieved by SLA as compared to FDM [2].

Effect of filament orientation and filler density on structural integrity and mechanical property of 3D printed PCL/Laponite construct for bone implants

Hongyi Chen¹, Jia Khong², Jie Huang¹

¹ University College London, Department of Mechanical Engineering, London, GB; ² University College London, Department of Medical Physics and Biomedical Engineering, London, GB

Introduction
3D printing has gained considerable attentions in tissue engineering due to its high efficiency, customizability for personalization of tissue engineered implants. Among the 3D printing techniques, direct ink writing (DIW) stands out as it operates under room temperature and allows the incorporation of biomolecules and cells in the ink. Mechanical property is a crucial aspect of a bone implant for load bearing applications, particularly high stiffness can lead to stress shielding and bone resorption. In this study, Laponite (LP) nanoclay was incorporated into polycaprolactone (PCL), a biodegradable polymer approved by FDA, to improve its bioactivity as well as to match the modulus of bone. Structural accuracy and integrity of the printed implant greatly influences its integration, mechanical properties and function. Micro-CT is an essential tool to analyse 3D structure and guide the manufacturing process of 3D printed products. Therefore, the effect of the 3D printing pattern and particle filling density, which are known to influence mechanical performance, was investigated, from the shape fidelity to modulus and strength of printed constructs.

Experimental Methods
50% m/v PCL was dissolved in DCM solvent with or without LP for making PCL based inks. Loading density of LP is up to 30 wt%. Flow sweep tests with shear rate ranging from 0.01 s⁻¹ to 100 s⁻¹ were conducted on the inks Discovery HR-2 and zero-shear viscosity was calculated. Dumbbell-shaped specimen (ASTM D638 Type IV scaled down 50%) for tensile testing was designed in two printing orientations (0° and 90°) as shown in Figure 1. The surface pattern and fracture morphology of the specimens were examined using SEM and the 3D structure of specimens were assessed using a micro-CT. Tensile tests were performed on the 3D printed specimens with ink and two orientations and their tensile properties were compared with independent t-test with significance level set at p < 0.05.

Results and Discussion
Shear response results show that the incorporation of Laponite has significantly enhanced the viscosity which provides resistance to post-printing deformation and shear-thinning property which facilitates extrusion (Figure 1A). For tensile properties shown in Figure 1BC, the addition of Laponite has improved Young’s modulus, but decreased ultimate tensile strength (UTS) of the structure due to higher porosity within the structure (Table 1) and agglomeration acting as stress concentration causing the formation of holes under tensile loading as shown in Figure 2B. Specimens printed with 90° orientation have higher tensile properties than 0° orientation due to the difference in filament bonding and porosity of the structure (Figure 1). For 0° orientation, nozzle travels longer between adjacent filaments which contributes to bigger exposure area and more solvent evaporation and solidification of filaments before contacting adjacent ones. This affects bonding between the cylindrical filaments. While in 90° orientation, filaments contact sooner leaving less exposure area and more time for post-printing deformation including the flattening and fusing of the deposited cylindrical filaments caused by gravity and capillary force. Although deformation is usually considered undesired for 3D printing, in this case it improves filament bonding. This can be observed in Figure 2(B): the ditches/interfaces between 5 filaments in 0° orientation are prominent while the filaments in 90° orientation are not visible and only shallow horizontal ditches due to uneven drying are observed. The space within Page 998 of 2028
the interfaces of cylindrical filaments and layers become air gaps/voids after deposition of the next layer. In Figure 2, voids in 0° orientation are higher in volume and distributed in parallel to the filaments printing direction in comparison to voids in 90° orientation which are located more to the sides and are likely results from air trapped at the turning points of the filaments. This results in stress concentrate at the interfaces and voids leading to the separation of filaments under tensile loading and lower mechanical properties for specimens printed in 0° orientation.

Conclusion

PCL/LP composites have been 3D printed using DIW. The addition of Laponite in PCL/30LP ink has enhanced viscosity, shear-thinning property and Young’s modulus but decreased UTS. Samples with 0° orientation have lower mechanical properties than 90° orientation due to lesser filament bonding and higher porosity caused by longer nozzle travelling time between adjacent filaments. This study has provided insight into the effects of the filament orientations and filler density on the mechanical properties of 3D printed solid structure for tissue engineering implants.

Figure 1

(A) Shear response comparing pure PCL and PCL/30LP inks. (B) Young’s Modulus and (C) ultimate tensile strength (UTS) of the samples comparing two inks and two orientations. PCL/30LP ink has higher viscosity, Young’s modulus but lower UTS. Specimens of 90° orientation have higher Young’s modulus and UTS with the same ink.
Figure 2
(A) Design of dumbbell shape with two orientations (0° and 90°). (B) SEM images (top view) on midsection of the dumbbell samples printed by PCL/30LP comparing the two orientations before and after tensile testing. (C) 3D visualization from micro-CT results of the surface and inner voids of the midsection comparing two orientations (scale bar is 1mm). Interface between filaments and layers are distinctive in 0° orientation. Voids in 0° are higher in volume and roughly distributed horizontally. Voids in 90° orientation are located more to the sides.

Bioprinting of a cell-laden hydrogel onto a titanium alloy Ti6-Al4-V ELI surface to mimic the bone tissue-implant interface

Marcin Kotlarz, Ana Ferreira-Duarte, Piergiorgio Gentile, Kenneth Dalgarno

Newcastle University, School of Engineering, Newcastle upon Tyne, GB

Introduction
After implantation of a metal implant, a cascade of cellular and extracellular biological events occurs at the bone-metal interface\(^1\). The surface of metallic implants serves as a powerful signaling cue for cells, facilitating early osseointegration by encouraging bone deposition on the surface and stabilising the interface. Here, we investigated the application of a bioprinting process called Reactive Jet Impingement (ReJI)\(^2\) to fabricate high cell density hydrogels onto metallic implants, with the ultimate aim of accelerating osseointegration by enhancing bioactivity at the bone-implant interface.

Experimental Methods
Additively manufactured titanium alloy Ti6Al4V ELI samples produced using the Electron Beam Melting process (Arcam Q10) were used as substrates for bioprinting. Three types of Ti6Al4V ELI samples that varied in surface roughness and surface morphology were investigated: as-fabricated (\(R_a = 14.5 \, \mu m\)), ground (\(R_a = 0.7 \, \mu m\)), and polished (\(R_a = 0.5 \, \mu m\)). Human TERT immortalised bone marrow stromal cells (at a nominal print cell density of 4 x 10\(^7\) cells/ml) were delivered to the metal surface in a collagen-alginate-fibrin hydrogel matrix. Cell-hydrogel-metal implant interactions were assessed using immunofluorescence and SEM. DNA content per construct was quantified with Picogreen assay. Cell mineralisation was demonstrated using Alizarin Red.

Results and Discussion
Cell viability was not affected by the bioprinting process. All three levels of surface finish supported the attachment of the cell-laden hydrogel. Topographical features of the Ti6Al4V ELI surface influenced cell organisation and cell-metal surface communication. Cellular migration from the hydrogel and interactions with the metal surface were visible from day 1. Cell proliferation rate remained stable over 21 days regardless of the Ti6Al4V ELI surface type. SEM observations and Alizarin Red revealed significant mineral deposition on the metal surface, confirming stem cell differentiation into osteoblasts and osteoblast mineralisation.

Conclusion
We showed the ReJI system application for developing cell-hydrogel-metal surface systems to mimic the bone-metal implant interface. The bioprinted cell-laden hydrogels supported the formation of a layer of functional bone-like tissue on the surface of the Ti6Al4V ELI implants.

3D printing of bio-synthetic based Nerve conduit: Fabrication and characterization

Thanusha Av, Maurice N Collins

UNIVERSITY OF LIMERICK, STOKES LAB, BERNAL INSTITUTE, LIMERICK, IE

Introduction
The utmost challenge in the field of neural tissue engineering is the development of peripheral nerve based conduits to treat the damaged nerves. Even though damage to peripheral nerves are not life threatening, it leads to loss of sensory and/or motor functions making daily activities uncomfortable and difficult. These afflicts > one million patients worldwide annually.

Experimental Methods
The overall purpose of this research work is to develop a three dimensional nerve conduit up to definite length utilising 3D printing technology. The nerve conduit has been printed using PCL and gelatine with bioactive components such as hyaluronic acid incorporated. Conducting polymer nanoparticles based on PEDOT and Polypyrrole have been applied via a layer-by-layer coating technique. The fabricated 3D nerve conduit has been physico-chemically characterized via swelling studies, degradation profiles, rheological measurements, mechanical testing and thermal analysis. In vitro characterization comprised of cell cytotoxicity and cell proliferation assays.

Results and Discussion
The fabricated nerve conduit was characterized and the outcome of the 3D nerve conduit plays an effective role in the treatment of nerve damage.

Conclusion
The acquired results demonstrate that the fabricated nerve conduit is biocompatible and a promising candidate for neural tissue engineering applications.

Introduction

Bioactive glasses are used in dental and orthopedic surgery thanks to their osteoconductivity, osteostimulatory effect and high degradation rate. Besides that, mesoporous bioactive glasses (MBG) are specific for their highly ordered mesoporous SiO\textsubscript{2} channel structure and high specific surface area, making them suitable for drug, growth factor or bioactive ion delivery. MBG-scaffolds, containing 80, 5 and 15 mol% of silicon (Si), phosphorus (P) and calcium (Ca), respectively, showed good cytocompatibility after seeding of bone-derived cells. Therapeutic activity of MBG can be improved by substitution of Ca\textsuperscript{2+} in the glass network with bioactive metal ions inducing desired therapeutic effect. In order to make MBG particles usable for extrusion-based 3D printing of scaffolds, they could be combined with pasty biomaterial inks. In the present study we aimed to develop a bioink containing MBG, which is suitable for 3D (bio)printing and delivery of therapeutic metal ions for bone tissue engineering applications. Due to its antimicrobial effect and positive impact on osteoblastogenesis and activity of osteoblasts, Zn\textsuperscript{2+} was selected for substitution of Ca\textsuperscript{2+} in MBG. Already established bioink containing 3 wt% of alginate (alg) and 9 wt% of methylcellulose (MC) supporting mesenchymal stem cell viability was chosen for combination with MBG. We investigated various combinations of algMC ink with high content of MBG with different amounts of Zn\textsuperscript{2+} incorporated in the glass network.

Experimental Methods

Four different MBG were synthesized, containing 15 mol% of Ca (0ZnMBG), 5 mol% Zn and 10 mol% Ca (5ZnMBG), 10 mol% Zn and 5 mol% Ca (10ZnMBG) and 15 mol% Zn (15ZnMBG). Pore channel structure of all the MBG was evaluated by transmission electron microscopy and measuring their size with ImageJ. Composite inks were prepared by mixing MBG particles into algMC blends containing 3 wt% alg and 6 (3-6 ink) or 9 (3-9 ink) wt% of MC. Composites containing up to 10 wt% of the respective MBG in both blends were tested for rheological and printing properties and the amount of 7 wt% MBG was selected for mass flow rate measurement, bioprinting and ion release experiments. Vybrant DiD prelabelled immortalized human mesenchymal stem cells (MSC) were used for bioprinting of composite constructs, which underwent fluorescent microscopy observations and DNA quantification to determine cell number development over time. Bioprinted constructs were also used for the ion release examination using inductively coupled plasma-optical emission spectroscopy.

Results and Discussion

MBG containing 0, 5, 10 and 15 mol% of Zn (15, 10, 5 and 0 mol% Ca respectively) were successfully synthesized, keeping mesoporous structure of the glass and the same channel size. Since Ca\textsuperscript{2+} and Zn\textsuperscript{2+} are crosslinkers of alginate, adding of MBG into 3-6 and 3-9 algMC bioinks induced a pre-crosslinking effect, followed by an increased viscosity of resulting composites. Increasing amount of Zn in MBG (decreasing amount of Ca) resulted in lower viscosity of composites and significantly decreased shape fidelity of printed scaffolds, confirming that Zn\textsuperscript{2+} is weaker crosslinker of alg [3]. Addition of 7 wt% of MBG allowed the most appropriate mixing, rheological and printing properties of composites. When cell suspension was added, a drop in viscosity of inks negatively affected print fidelity of 3-6 bioink. Therefore, 3-9 composites were used for bioprinting of MSC. At the beginning of cultivation, Zn-modified
MBG induced significantly lower cell number than 0ZnMBG, but this effect was not observed from day 7 and as shown in Figure 1, 0ZnMBG and 15ZnMBG did not have a negative effect on cell number development. This is in contrary to observed cytotoxicity of Zn$^{2+}$ [5]. The reason for this is probably the presence of other bioactive ions (silicates, phosphates and Ca$^{2+}$) released from MBG-containing composites, having a beneficial effect on cells. After one day of culturing, Ca$^{2+}$ was released from both types of composites, but an uptake was observed from day 7 (Figure 2A). It is possible that the alginate was taking up Ca$^{2+}$ because of continuous crosslinking. Another reason might be the formation of hydroxyapatite layer, which would explain a constant uptake of P (phosphates) observed with both types of composites (Figure 2B). An uptake of phosphate could be also explained by precipitation of hopeite-like structure, highly depending on pH and Zn$^{2+}$ concentration. A release of Si from composites, corresponding to the degradation of MBG, was stable over time and slightly lower in the case of 3-9 composites. Release of Zn$^{2+}$ was constant over time as well, with higher released concentrations corresponding to its higher initial amount in the samples (Figure 2C).

**Conclusion**

This study shows a successful development of composite bio(ink) for bone tissue engineering with tailorabile release of bioactive ions.

Introduction
Electrospun nanofibers have great potential in soft tissue engineering applications due to their great similarity with the extracellular matrix, promoting accelerated tissue healing and fewer infection risks. Recently, extracts and essential oils of plants have been associated with these nanofibers to promote specific properties. Tea Tree Oil (TTO, Melaleuca Oil), for example, is an antimicrobial and anti-inflammatory essential oil able to optimize wound healing [1]. PHBV (Poly(3-hydroxybutyrate-co-3-hydroxyvalerate)) is an easily spinnable, biocompatible, and biodegradable natural biopolymer [2], being a great candidate for incorporate the TTO. The main objective of this work was to prepare different concentrations of TTO loaded PHBV electrospun nanofibers and to characterize their morphology, physical properties, and antibacterial activity.

Experimental Methods
PHBV pellets (Nature Plast, 2% HV) were dissolved in 1,1,1,3,3,3-Hexafluoro-2-propanol (HFP, Sigma-Aldrich) to obtain an 8 wt.% solution. After complete dissolution, TTO (PHYTOTERÁPICA) was added at 0, 5, 10 and 15% v/v, named of PHBV/0TTO, PHBV/5TTO, PHBV/10TTO and PHBV/15TTO, respectively. The solution was electrospinning at 14 kV with a 27G needle at 1.5 mL/h and 3.000 rpm.

Results and Discussion
SEM images (Figure 1) indicated smooth, uniform, and bead-free mats with an average diameter that decreased according to the increasing of TTO content, from 0,750 ± 0,030 nm (PHBV/0TTO) to 0,430 ± 0,027 nm (PHBV/15TTO). Also, PHBV nanofibers exhibited the plasticizing effect typically induced by essential oil [3]. XRD (Figure 2.a) patterns indicated typical peaks of PHBV, not showing any influence of TTO. DSC curves (Figure 2.b) indicated one peak and one shoulder commonly obtained for PHBV, indicating two crystal conformations (α orthorhombic cell and β planar zigzag)[4]. It was also observed the smoothness of the shoulder according to TTO increase, although the major peak remained between 173°C (PHBV/15TTO) and 175°C (PHBV/0TTO). Antimicrobial assays with E.coli, S. aureus, and C. albicans are in progress.

Conclusion
TTO loaded PHBV nanofibers were successfully prepared and presented great potential to be used in wound healing applications.

Acknowledgement
The authors would like to thank FAPESP (2019/10877-3) for the financial support of this work.

A Design of Experiment methodology to study the influence of production conditions in the behaviour of PCL/gelatin electrospun skin wound dressings

Sara Guerreiro, Joana Valente, Juliana Dias, Nuno Alves

Centre for Rapid and Sustainable Product Development, Polytechnic of Leiria, Leiria, PT

Introduction

Skin wounds associated with chronic diseases that compromise the healing process of tissues have been studied during the last years. Electrospun membranes can be used as wound dressing to enhance the regeneration of damaged tissues due to their intrinsic characteristics (e.g. porosity). Furthermore, they have been explored in drug-delivery systems given the ability of some materials for attaching therapeutic agents. Electrospinning uses electrical fields to stretch the drop of a solution that is continuously pumped to obtain fibers with diameter ranging from micrometres to few nanometres. This process can be used to obtain a physical barrier against infectious agents. The ability of this barrier in transmitting gas molecules depends on the structural arrangement of the nanofibres, and on appropriate hydrophobicity and degradation rate of the materials used. These are the requirements for the membrane to promote and enhance the healing process. At the same time, the versatility offered by electrospinning allows to set specific a drug-release profile for a given therapy. This can be accomplished by manipulating nature and concentration of the materials used. Gelatin and polycaprolactone (PCL) are examples of traditional polymers used to produce electrospun nanofibers given their attributes of biocompatibility and biodegradability, respectively.

Additionally, the high area-to-volume ratio and the low cost associated with the fabrication process of these membranes make electrospinning a cost effective and competitive technology. However, the high number of factors to consider during membrane production accounts for low reproducibility and high heterogeneity of the obtained electrospun membranes.

Experimental Methods

In this work, a statistical approach based on a Design of Experiments (DoE) methodology is proposed to optimize the production of electrospun membranes through a prediction model. The fiber diameter, the permeability of the membrane and its thickness were modelled using a Box-Behnken design where the applied voltage, the flow-rate, the needle’s working distance and the ratio of PCL/gelatin in the solution were defined as independent variables. In order to quantify their influence in the main membrane attributes, a time-domain analysis was performed. The diameter of the fibers was measured using ImageJ after scanning electron microscopy image acquisition. The permeability was calculated based on the mass of water lost in flasks sealed with the electrospun membranes and placed at 37°C for 24 hours. Finally, thickness of electrospun membranes was measured using a digital micrometre. In order to test the suitability of the electrospun membranes in working as controlled released systems, a release study using standard bovine serum albumin was implemented.

Results and Discussion

Statistical significance (p<0.05) was observed for the model accuracy in predicting the main electrospun membrane attributes (diameter, permeability and thickness) for more than 75% of the samples. Permeability showed to be the most reliable measure with R² of 83%. Additionally, the ratio of PCL/gelatin, the needle’s working distance and the flow rate showed to be the most relevant factors for explaining diameter, permeability and thickness, respectively. The developed models were used to guide the experimental methodology to obtain fibers with diameters up to 300 nm, subjected to the maximization of both, permeability and thickness. The membranes were produced under...
predicted conditions (50.10%; 0.82ml/h; 11.91cm and 14.11kV) and the release study was performed using this setup. The results suggest that the devised electrospun membranes successfully act as protein delivery systems, with a constant release rate of 1mg/h for the first 4 hours of contact.

**Conclusion**
Overall DoE showed to be a useful tool to optimize the electrospinning-based production process by allowing to reduce time and cost associated, with positive impact in research and industrial settings.

Biomimetic and bioactive nanofibrous interfaces to modulate cell response

Gianluca Ciardelli$^{1,2}$, Michela Licciardello$^{1,2}$, Chiara Tonda-Turo$^{1,2}$

$^1$ Politecnico di Torino, Department of Mechanical and Aerospace Engineering, Turin, IT; $^2$ Politecnico di Torino, POLITO BIOMedLAB, Turin, IT

Introduction
Electrospun polymer mats have emerged for their great potential as biomimetic and bioactive interfaces thanks to their close structural resemblance to the extracellular matrix-ECM (which enhances the tissue growth), their high porosity that allows gas permeation, and the large surface to volume ratio which provides an open structure for cell adhesion. Nanofibrous mats are widely applied in tissue engineering application showing a high potential to facilitate the formation of artificial functional tissues. To date, biodegradable polymer nanofibres with different chemical and physical properties using both synthetic polymers and natural polymers have been applied in several tissue engineering approaches. In this work, the fabrication and characterization of natural-based nanofibers is discussed highlighting the role of biomimetic and bioactive cues in directing cell growth and fate.

Experimental Methods
Gelatin (GL, type A from porcine skin), chitosan (CS, molecular weight 100 – 200 kDa, deacetylation degree ≥ 95%) and collagen (CL, bovine type I) were used for nanofibers fabrication. Electrospinning protocols were optimized to achieve homogenous fibres with nanoscale size by using a “green electrospinning” method which avoids the use of environmental and cellular unfriendly solvents. Both randomly-oriented and aligned nanofibers were obtained mimicking the ECM architecture of different tissues. Developed nanofibrous matrices were loaded with active compounds such as antioxidant, piezoelectric, conductive and antibacterial agents to induce specific biological effects [1–5]. Complete morphological and physical-chemical characterisation was performed as well as biological in vitro tests.

Results and Discussion
The design of efficient scaffolds to sustain the cell outgrowth and its guidance towards appropriate targets is of paramount importance in reproducing the physiological environment to achieve tissue regeneration. Topographical stimuli can modulate cell organization as shown comparing cell morphology on random and aligned nanofibrous mats (fig. 1). The beneficial effect of morphological cues was combined with active agents such as antioxidant nanoparticles (nanoceria), piezoelectric particles (barium titanate), antibacterial agents (gentamicin sulphate, manuka honey, silver nanoparticles) and conductive polymers to evaluate the role of those cues in directing cell growth and fate [1–5]. Results confirmed the high versatility of the electrospinning technique to process different materials (fig. 2). Furthermore, a cell-specific response was observed when nanofibrous were doped with tissue-like cues [1–5]. The developed electrospun scaffolds allows to create a platform of interfaces able to modulate cell adhesion and growth in a physiological-like manner towards the creation of functional tissues.

Conclusion
Electrospun nanofibres are promising interfaces to enhance and modulate cell behaviour in the attempt to regenerate tissue in vivo as well as to reproduce organ in vitro to create in vitro organ models.

Spatiotemporally functionalizable and mechanically tunable biomaterial for embedded bioprinting of tubular structures

Malin L. Becker, Maik R. Schot, Jeroen Leijten

University of Twente, Department of Developmental BioEngineering, TechMed Centre, Enschede, NL

Introduction

Embedded 3D bioprinting holds great potential as a versatile tool for the engineering of tissue replacements. Conventionally, the embedding bath has mostly acted as a removable support bath with its main function being to mechanically support the printed structure until solidification is achieved and the printed construct can be removed from the bath. Additionally, the use of sacrificial inks in combination with crosslinkable baths has been reported in order to create pre-vascularized perfusable tissue engineered structures. However, resulting tissue constructs featuring perfusable channel networks lack distinct mechanical and chemical properties and thus do not resemble their natural counterparts, which has limited their functional performance. Here, we tested our hypothesis that a dual crosslinking strategy could enable the embedded bioprinting of complex, integrated, and perfusable vascular networks that are mechanically and chemically distinct from the engineered tissues they are embedded within.

Experimental Methods

A dually crosslinkable polymer was created by functionalization of a dextran backbone with tyramine and biotin moieties. Physically crosslinked embedding baths were realized by exploiting the strong protein/ligand interaction between biotin and avidin. For the creation of tubular structures the bath was loaded with horseradish peroxidase (HRP) and a hydrogen peroxide (H₂O₂) containing gelatin based sacrificial ink was extruded into the bath. Local covalent crosslinking could be combined with bulk photocrosslinking to yield free standing or embedded tubular structures, respectively. Subsequently to crosslinking, the tissue’s biotin moieties can be utilized for on-demand biochemical functionalization, either of the bulk and/or the channel surfaces.

Results and Discussion

Rheological characterization of the physically crosslinked bath revealed shear-thinning and self-healing properties that were highly suitable for embedded bioprinting (Figure 1). Covalent crosslinking resulted in a three-fold increase of the storage modulus of the hydrogel constructs, which enabled the stabilization of printed channel networks. The wall thickness of the printed tubular structures could be adapted with varying H₂O₂ concentrations. The inside-out crosslinking resulted in a mechanical gradient with decreasing stiffness with increasing distance from the channel wall. The printing setup allowed for the creation of more complex vascular designs such as perfusable bifurcating tubular structures (Figure 1). Furthermore, the channel walls were demonstrated to be on-demand functionalizable with biotin-coupled moieties in a functional manner.

Conclusion

We report on a novel and dually crosslinkable hydrogel suitable for embedded bioprinting, in combination with an inside-out crosslinking approach resulting in perfusable structures that offer spatially distinct and modifiable mechanical properties, which resembles natural tissue designs. The resulting structures offer for on-demand functionalization with bioinstructive moieties to further guide tissue fate and function in a spatially controlled manner.

Highly Oriented Electrospun Conductive Nanofibers of Biodegradable Polymers—Revealing the Electrical Percolation Thresholds

Muhammad A. Munawar¹,², Dirk W. Schubert¹,²

¹ Friedrich-Alexander-University Erlangen-Nuremberg, Department of Materials Science, Institute of Polymer Materials, Erlangen, DE; ² Bavarian Polymer Institute, Key Lab Advanced Fiber Technology, Fürth, DE

Introduction
The main goal of this study is to fabricate highly oriented electrospun conductive fiber composites (ECFCs) by using a special rotating collector electrode and allow an accurate determination of electrical conductivity. The determination of critical volume filler concentration/percolation threshold ($\varphi_c$) by using McLachlan and Kirkpatrick’s models for experimental conductivities of conductive fibers is another important objective. Since at percolation threshold, the conductivity of conductive fibers boost to several orders of magnitude, so it is very important to know for scientific community to have better understanding about conductivity behavior of conductive electrospun nanofibers for their right applications.

Experimental Methods
An electrospinning process with a special rotating collector electrode [1] is used to generate highly oriented electrospun conductive fiber composites (ECFCs) of biodegradable polymers and demonstrated in schematic Figure 1.. Polyethylene oxide (PEO), polycaprolactone (PCL) and polyactic acid (PLA) are blended with intrinsically conductive polymers (ICPs)—fillers of Poly 3,4 ethylenedioxythiophene (PEDOT) and polyaniline (PANI) [2]. The PEDOT doped with polystyrene sulfonate (PSS) anions and PANi doped with (+)-camphor-10-sulfonic acid (CSA) in their appropriate solvents, respectively. The processing parameters were varied from case to case and their ranges were; voltage (5-20 kV), flow-rate (0.1-2 mL/h), tip-collector distance (5-25 cm) and collector rotation (50-200 rpm). At the optimized processing parameters, the viscoelastic spinning solution ejected from spinneret and stretched in the form of a charged jet towards the grounded collector. The displacement of jets from spinneret to collector, the complete evaporation of solvent gave solid ECFCs on rotating wheel electrode. A detailed electrospinning theory can be found in the work from DW Schubert [2]. These highly oriented conductive fibers were collected on microscopic glass slide (GS) for the measurement of resistance $R$ using ohmmeter (Keithley 2400).

Results and Discussion
The straining of polymeric chains under mechanical stretching and thermal relaxing is seemed to be a significant factor for dynamic of percolation threshold in electrospun conductive nanofibers, as shown schematically in Figure 2. The ICPs-fillers (PEDOT and PANi) made agglomerations in their solvents (Figure 2a) and this was overcome by incorporating with their respective ionic surfactants (PSS & CSA) also called dopants or stabilizers, which can easily stabilize the ICPs particles against coagulation and precipitation (Figure 2b). The attraction between the positively charged ICPs and the negatively charged dopants or vice versa in the solvent systems led to coiled ICPs (Figure 2b). The ionic surfactants (dopants) which surrounded the coiled ICPs can create a barrier that block the charge transport within the ICPs. Therefore, blending with high molar mass polymer matrices (PEO, PCL and PLA) weakened the electrostatic interaction between ICPs and dopants, and hence helped in phase separation development (Figure 2c). The mechanical viscoelastic stretching of chains of ICPs, dopants and host polymers (matrices) disrupted the static charge interactions under high electrostatic forces during electrospinning process (Figure 2d & 2e). Therefore, the molecular chains started to reorganize themselves into more stretched structures, which essentially are responsible for high inter-chain conductivity in electrospun fibers (Figure 2f, 2g & 2h). During annealing process, the molecular chains of host polymers became more relaxed (expanded) and ICPs (filler particles)
acquired a certain degree of freedom to interconnect/reorganise themselves. This reorganising (intermingling) of ICPs created more paths and additional conductive channels, which essentially responsible for intra-chain conductivity in annealed ECFCs (Figure 2i, 2j, 2k, 2l & 2m) [3].

Conclusion
The existence of different interactions/compatibilities between polymer matrices and conductive fillers causes a dynamic $\phi_c$. The mechanical viscoelastic stretching under high electrostatic forces in electrospinning process introduces high inter-chain conductivity to electrospun fibers. The higher the inherent conductivity of intrinsically conductive polymers (ICPs) produce the higher conductive ECFCs and vice versa. The annealing process in electrospun fibers enhances the built up of additional conductive channels, which lead to superior electrical performance and lowering the percolation threshold and a hint is evident of a potential time-temperature superposition. Moreover, the conductivities of our fabricated ECFCs are suitable for a wide range of biomedical applications.

Anisotropic Conductive Melt Electrowritten Patches Combined with Electrical Stimulation for Cardiac Tissue Engineering

Yanping Zhang¹, Menglin Chen¹⁄²

¹ Aarhus university, Interdisciplinary Nanoscience Center (iNANO), Aarhus C, DK; ² Aarhus university, Department of Engineering, Aarhus C, DK

Introduction
Cardiac patches, three-dimensional (3D) tissue constructs of polymer scaffold embedded with cardiac muscle cells, represents a promising approach for the treatment of myocardial infarction (MI). However, recapitulation of the fibrillar structural organization, anisotropic mechanical behavior, and electrophysiology of native-like myocardial muscle remains a major challenge for engineering cardiac patches. Herein, we present an anisotropic conductive patch that conforms to the mechanical and bioelectrical properties of human myocardium.

Experimental Methods
Melt electrowritten (MEW) as an emerging technology combining electrospinning with 3D-printing, can realize tailored micro-architectures manufacturing. This unique capability of MEW was exploited to fabricate patches with controlled fibrous microstructures that can accommodate the strains and stresses exhibited by the human myocardium. Furthermore, a nanolayer of gold coating endowed the patch with electrical conductivity similar to that of human myocardium, and this patch served as an electroactive path to electrically stimulate cardiac muscle cells under exogenous electrical fields.

Results and Discussion
The results showed that the patches exhibit large biaxial deformations, and the structure of the patches can be fine-tuned to reflect anisotropic mechanical properties. Moreover, the patches guided HL-1 cardiac cells growth, proliferation, and alignment along the microfibers. Calcium imaging indicated that HL-1 cardiac cells appear synchronous contraction within 2 days after seeding on the patches. Coating gold on the patches led to the increased expression of cardiac-specific genes of HL-1 cells involved in muscle contraction and electrical coupling. In the following work, we will apply the electrical stimulation to promote the maturation of cardiac cells.

Conclusion
Overall, our anisotropic conductive patch holds great potential for cardiac tissue engineering.

Design of hybrid peptide / polymer nanofibers for soft tissues regeneration

Coline Pinese, Karima Belabbes, Audrey Bethry, Gilles Suba, Xavier Garric

University of Montpellier, IBMM, Montpellier, FR

Introduction
Nanofibers are excellent supports for tissue regeneration thanks to their topography that reproduces the architecture of the extracellular matrix. Very commonly, nanofibers are made of PCL, PLA or PLGA and in these cases have a guiding role essentially.[1–3] Our objective is to create nanofibers which, in addition to this guiding role, could modulate the cellular behavior, in particular by introducing bioactive peptides in the intrinsic composition of the nanofibers biomaterial. We are considering sol-gel chemistry for this purpose, the goal being to assemble polymers and peptides like Legos® to create a bioactive tri-dimensional network constituting the nanofibers. For that purpose, we set up an original synthesis based on star-PLA bearing triethoxysilyl propyl groups (PLA-PTES) and bifunctional silylated peptides that react together via sol-gel process to create a bioactive network. [4,5]

Experimental Methods
We synthesized and functionalized the polymers and peptides according to protocols previously developed by our team. [4] Electrospinning was performed under fixed hydrolysis conditions by varying the molar mass of the polymers, the shape of the polymers and their ratio. The formation of the network was evaluated by FTIR and by quantifying the gel fraction of the network. The percentage of peptide incorporation (peptide-FITC) within the networks was performed by GPC double detection IR and fluorescence. The biological properties of the hybrid materials were then evaluated by deposition of HDFs on the nanofiber mats and by investigating their proliferation capacity according to the percentage of incorporated peptides.

Results and Discussion
First, we synthesized and characterized star-shaped PLAs functionalized with IPTES (StarPLA-PTES) and bifunctional silylated peptides that react together via a sol-gel process to create a bioactive network. Subsequently, we produced functional nanofibers by activating the sol-gel reaction during the electrospinning process. We studied the impact of different parameters on 1/ the formation of the three-dimensional polymer network composing the nanofibers and 2/ the rate of incorporation of the peptide into this network. During the fabrication of the nanofibers, the molecular weight of the polymer and the hydrolysis kinetics of the PTES functions had the most impact on the cross-linking between the polymers and on the incorporation rate of the peptide. The improvement of the peptide grafting rate to the polymeric network by using low molecular weight polymers is explained by the increase in the content of cross-linking groups (PTES). Finally, the potential of this new type of hybrid biomaterials created for soft tissue engineering was demonstrated by cells adhesion assays that showed a significant improvement of fibroblast adhesion on the peptide-containing nanofibers.

Conclusion
In conclusion, we demonstrated that poly(lactide), a degradable polymer wildly used for biomedical application could be crosslinked using sol-gel siloxane chemistry during electrospinning process, producing nanofibers composed by a bioactive three-dimensional network. This reaction takes place during the electrospinning process and offers the possibility to functionalize the nanofibers with peptides, bearing a siloxane function, with various properties and therefore adaptable to many applications.
Production of bioactive and degradable nanofibers by electrospinning of bifunctionalized star-shaped materials.

Development of chitosan / natural gums based bioinks for extrusion-based 3D bioprinting

Aurelia Poerio¹, Jean-Philippe Jehl¹, Sandrine Hoppe², Philippe Marchal², Joao Mano³, Franck Cleymand¹

¹ University of Lorraine, Institut Jean Lamour, Nancy, FR; ² Université de Lorraine, Laboratoire Réactions et Génie des Procédés, Nancy, FR; ³ University of Aveiro, Department of chemistry, CICECO, Aveiro, PT

Introduction
Due to its biocompatibility, nontoxicity and biodegradability, chitosan has become of great interest for medical and pharmaceutical applications in the form of films or hydrogels [1]. Nevertheless, its application as bioink for 3D bioprinting is limited due to the soft stiffness, which usually significantly reduces shape fidelity and resolution of the printed scaffolds. Different strategies can be adopted to improve the printability of bioinks through the increase of their viscosity such as the inclusion of additional molecules. Recently, natural gums have been extensively investigated as biomaterials for tissue engineering applications thanks to their similarity with the native extracellular matrix (ECM) and their capability of increasing solution viscosities even at small concentrations [2].

Experimental Methods
The aim of this work is the development and characterization of new bioinks based on chitosan and natural gums, such as guar gum (GG) and tamarind gum (TG) and the evaluation of their printability using an extrusion-based bioprinting process. The viscoelastic properties of the bioinks were evaluated and the bioprinted scaffolds were characterized by their morphology, swelling ratio, degradation in lysozyme and ability to release bovine serum albumin (BSA) as model protein.

Results and Discussion
The results show that the inclusion of GG and TG increases the viscosity of the bioink forming solutions improving their printability. The morphological characterization of the bioprinted scaffolds shows an highly porous internal structure that could provide a suitable and interconnected network essential for cell nutrition, proliferation, and migration. Furthermore, while constructs with no gums were completely degraded after 3 weeks, the inclusion of GG and TG slowed down the degradation process up to two months, in absence of crosslinkers. The construct containing TG also reduced the amount of BSA released suggesting their potential to be used for a more sustained release of the encapsulated factors. Furthermore, cellular studies to investigate the biocompatibility of the bioinks are in progress.

Conclusion
Taken together, these data show that these two natural gums have the potential to be successfully used for 3D bioprinting applications.

3D printed carboxymethyl cellulose scaffolds enriched with autologous growth factors for diabetic wound regeneration

Luis A. Diaz-Gomez¹, Iago Gonzalez Prada¹, Rosendo Millan², Angel Concheiro¹, Carmen Alvarez-Lorenzo¹

¹ Universidade de Santiago de Compostela, Departamento de Farmacología, Farmacia y Tecnología Farmacéutica, I+D Farma (GI-1645), Facultad de Farmacia and Health Research Institute of Santiago de Compostela (IDIS), Santiago de Compostela, ES; ² Universidade de Santiago de Compostela, CEBEGA, Santiago de Compostela, ES; ³ Universidade de Santiago de Compostela, Pharmacology, Pharmacy and Pharmaceutical Technology, SANTIAGO DE COMPOSTELA, ES

Introduction
Wound regeneration in diabetic patients remains a clinical challenge. The delivery of autologous growth factors, such as platelet-rich plasma (PRP), is a promising strategy to enhance the regeneration ability in diabetic ulcers by increasing the deposition of collagen and promoting angiogenesis [1]. However, the direct administration of platelet concentrates in the wounded tissue might not ensure the adequate availability to local cell population [2]. Therefore, encapsulation strategies aiming to provide a controlled release of growth factors (GFs) are needed. In this work, we developed a strategy to prepare 3D printed personalized carboxymethyl cellulose (CMC) skin scaffolds loaded with autologous PRP to promote diabetic ulcer regeneration.

Experimental Methods
CMC (15 w/v%) hydrogels were autoclaved and then citric acid (15% w/w of CMC) was added to the dispersions. The obtained inks were printed using a commercial 3D printer to fabricate cylindric skin scaffolds (8 mm in diameter; 600 μm pore size). The scaffolds were freeze-dried for 24 h, crosslinked at 120 °C for 7 min, and then, immersed in a PRP solution previously activated by freeze-thaw cycles. The structure, mechanical properties, and GFs release of the obtained wound dressings were evaluated. In vitro cell proliferation and migration were also assessed. Finally, the ability of the dressings to promote wound regeneration was evaluated in a full-thickness cutaneous wound in a streptozotocin-induced diabetic rat model.

Results and Discussion
The rheological, morphological, and mechanical testing demonstrated that the developed CMC inks showed excellent printability and shape fidelity. Crosslinked dressings presented a remarkable swelling behavior able to promote the moist microenvironment necessary during the wound healing process, and GFs were released from the dressings over 7 days in a controlled manner. Migration assays confirmed that CMC and CMC-PRP dressings promoted mesenchymal stem cell (MSC) migration, while released PRP significantly enhanced cell proliferation. Compared with control treatment, CMC and CMC-PRP dressings resulted in a significantly accelerated wound closure rate in vivo, increased vascularization, and enhanced regeneration of granulation tissue.

Conclusion
CMC-PRP 3D scaffolds were successfully prepared using a straightforward procedure. The developed skin scaffolds may act as wound dressings to sustainably release autologous GFs and significantly enhance cell migration and proliferation. In vivo studies confirmed the ability of the CMC-PRP dressings to significantly enhance wound healing in a diabetic rat wound model. In summary, personalized CMC-PRP wound dressings may represent a promising therapeutic approach for the treatment of diabetic ulcers.

Synthetic 3D fibrous scaffolds as animal free and low cost basis in 3D cellular applications

**Tobias Weigel**, Christoph Malkmus, Verena Schneider, Bastian Christ, Maximiliane Wußmann, Jörn Probst, Florian Gröber-Becker, Jan Hansmann

1 Fraunhofer Institute for Silicate Research (ISC), Translational Center for Regenerative Therapies (TLZ-RT), Würzburg, DE; 2 University Hospital of Würzburg, Dept. Tissue Engineering & Regenerative Medicine, Würzburg, DE; 3 University for Applied Sciences Würzburg/Schweinfurt, Department Electrical Engineering, Schweinfurt, DE

**Introduction**

Besides organoid/spheroid culture, 3D cellular constructs always require scaffolds as a fundamental building block. One example are hydrogel matrices, either isolated from organisms (animal or plants) or specifically designed as synthetic variants. Other possibilities are submicrometer sized fibrous tissues, mainly produced by decellularization of animal derived organs. Apart from ethical reasons, the mentioned scaffold possibilities have high batch-to-batch variations or are expensive to produce. Electrospun fibers, covering the diameter range between nano and micro, can be applied as a serious alternative achieving the mandatory three-dimensionality for cells. To gain the 3D structure of electrospun scaffolds with a sufficient cellular accessibility, we combine a high numbers of pores with large mesh openings. By incorporating high amounts of porogens in the scaffold during the spinning process, the required 3D properties can be generated with focus on stromal tissue applications.

**Experimental Methods**

Materials for the synthesis of electrospun 3D submicrometer fibrous scaffolds were polycaprolacton (PCL), polyamide 6 (PA6), polyacrylonitrile and silica. Applied water-soluble porogens were NaCl particles as well as microfibers of polyvinylalcohol or titanium-oxo-carboxo-complexes. Porogens were incorporated in the scaffolds by an alternating process. Porogen placement was performed by particle strewing or placing micro-fibrous mats during the paused spinning process or by unwinding microfibers during a continuous spinning process. The structural properties of the resulting 3D scaffolds were characterized by SEM, LM and CLSM. The suitability for 3D cell culture was tested with human primary cells (hdFs, hMSCs, heKs and different cellular organoids).

**Results and Discussion**

The removement of the porogens resulted in a highly porous scaffold with porosities higher 98.5 %. Depending on the porogen size and the collector speed, the pores demonstrated an elliptical morphology or were extended to form a kind of laminar scaffold composition. The fiber layers around the pores showed a loose network of single fibers with low numbers of contact points as well as mesh openings up to several 100 µm². Thereby, the pores separated the fiber layers and prevented the structural collapse resulting in spatial consolidation.

When seeding stromal cells on the scaffolds, the cell were able to migrate and populate the scaffolds with a population speed of around 100 µm per week. By suitable supplementation, the stromal cells were able to synthesize ECM and transform the synthetic structure to a biological tissue. Besides matrix expression, cells were also able to differentiate inside the fibrous scaffold.

By combination of several cell types in different scaffolds, more complex tissue models were generated. Starting with a synthetic scaffold based skin model with a dermis and epidermis layer, the model was extended with a subcutis layer.

Concerning further applications, additional cell types and co-cultures are tested on the extended electrospun matrices to classify the application range of potential tissue models.

**Conclusion**

Page 1025 of 2028
The incorporation of high amounts of porogens into electrospun scaffolds resulted in highly porous and for cells accessible scaffolds. First 3D cell experiments showed promising results towards the application of biological tissue generation.
Nano-engineered naturally-derived inks for bone tissue regeneration

Andreea I. Dinu¹, Alexandra I. Cernencu¹, Adriana Lungu¹, Horia Iovu¹, Sorina Dinescu²

¹ University Politehnica of Bucharest, Advanced Polymer Materials Group, Bucharest, RO; ² University of Bucharest, Department of Biochemistry and Molecular Biology, Bucharest, RO

Introduction
The popularity of additive manufacturing techniques in bone tissue engineering lies at an upward path, as more polymer formulations for extrusion based methodologies are developed to aid the effective regeneration of bone-tissue by printing a structure with the desirable shape, structural, chemical and biological characteristics. Taking advantage of both naturally derived polymers and nanostructured materials, we propose an innovative bio-inspired nano-engineered printing material that combines two types of nano-fillers, polyhedral oligomeric silsesquioxanes nanoparticles (POSS) and cellulose nanofibrils (CNF) with a proteinaceous-polysaccharidic matrix composed of methacrylated gelatin and amidated pectin by means of which we aim to fabricate a scaffold with applications in bone tissue engineering.

Experimental Methods
Ink formulations were synthesized and assessed herein by taking advantage of the fast-crosslinking potential of gelatin methacrylate and amidated pectin and the remarkable shear-thinning properties of oxidized nanocellulose. Prior to 3D printing, the polymeric formulations were studied closely to determine the suitable concentration for each component, as well as the best methods for blending the organic-inorganic POSS cages in the polymeric network. In this regard, physical mixing techniques were combined with dissolution in organic solvents while availing the surface chemistry of functionalized POSS compounds. The performance of the 3D printed structures after photo-cross-linking followed by enzymatic crosslinking was evaluated in terms of mechanical properties and swelling behavior. FTIR spectroscopy served as a tool for determining the compositional characteristics of the constructs before and after crosslinking. The morphology of the 3D-scaffolds was investigated focusing on the dispersion of POSS, the porosity and the geometrical features of constructs. Pre-osteoblasts were used to perform preliminary in vitro biological tests onto freeze-dried hydrogels.

Results and Discussion
The structural, chemical and biological properties were considered within a comprehensive study on the influence of polymer and nanoparticle concentration in relation with the chosen synthesis methods. By testing POSS with different functionalities we were able to determine the best approach and ensure that the designed formulation is highly homogeneous. Our results showed that the use of POSS did not hinder the swelling capacities of the freeze-dried scaffold and all samples maintained their hydrophilic character. The mechanical properties proved the great potential of the designed scaffold for bone tissue engineering and the preliminary in vitro biological tests performed using pre-osteoblasts showed an optimum biocompatibility. Accordingly, the resulted 3D scaffolds offer essential support for stem cell adhesion, differentiation and proliferation through the synergic roles of each wisely chosen component that ultimately emulate the natural extracellular matrix.

Conclusion
Novel bio-based ink formulations were designed as suitable for 3D printing inks by using POSS and CNFs as reinforcing agents in a hydrogel network. Therefore, by means of using different POSS compounds and a controlled polysaccharide:protein ratio, materials with enhanced biomechanical properties could be obtained. The composition of the bio-inspired formulations along with quick and efficient crosslinking properties imply that these inks are...
candidate biomaterials for extrusion based 3D printing. The 3D printable materials grant 3D networks with a high porosity that exhibits a good structural and functional resemblance with native (living) tissue.

Mechanically reinforced tri-layered composite scaffolds with a biomimetic composition for restoration of articular joint function following traumaticinjury

Mark Lemoine\textsuperscript{1,2,3}, John O’Byrne\textsuperscript{1,4}, Daniel Kelly\textsuperscript{2,3}, Fergal O’Brien\textsuperscript{1,2,3}

Introduction

Articular cartilage has limited self-healing capacity and damaged cartilage can lead to osteoarthritis, and to the need for joint replacement surgery. Regeneration of joint tissue presents a clinical challenge as the layered structure of the osteochondral tissue has depth varying composition, mechanical properties, and biomechanical functions. Our lab has developed multi-layered collagen based matrices that can regenerate both bone and cartilage \cite{1, 2} which have shown potential in a number of animal models and in human patients but their mechanical properties restrict their use to small joint defects. To overcome this limitation, this study focussed on developing a biomimetic multi-layered scaffold with both mechanical and biochemical properties tailored to the specific requirements of the complex native tissue. It achieved this by initially developing a process to produce a tri-layered 3D printed polycaprolactone (PCL) scaffold which was then combined with a layered collagen matrix containing ECM components known to direct bone and cartilage formation respectively. The aim of the study was thus to assess the mechanical properties of the scaffolds to ensure their efficacy as implants to restore function in large joint defects and the capability of the biochemical composition to direct bone and cartilage formation in the distinct layers.

Experimental Methods

By 3D printing PCL struts with varying alignment and size, innovative scaffolds that mimic the mechanical properties of the osteo and chondral layers of native tissue were developed and used to reinforce a biomimetic collagen matrix with a cartilage layer of collagen type I and II (0.25%w/v of both) and hyaluronic acid (0.05%w/v) (CI/II-HyA), an intermediate layer of collagen type I (0.5%w/v) and hyaluronic acid (0.05%w/v) (CI-HyA), and a bone layer of collagen type I (0.5%w/v) and nano-hydroxyapatite particles (0.5%w/v) (CI-nHA) (Fig. 1A). The mechanical abilities of the composite scaffolds to resist compression, shearing and delamination, and dislodgement from osteochondral tissue were tested to ensure implant safety in load bearing joints. The capacity of the tri-layered composite scaffolds to support layer-specific deposition by bone marrow stem cells of sulphated glycosaminoglycans (sGAG) for cartilage formation and calcium for bone formation, was assessed by histological staining and biochemical analysis.

Results and Discussion

Increased mechanical properties over culture time proved that functional restoration of osteochondral tissue is possible with this composite scaffold (Fig 1B). The high fixation strength (47.4kPa) and shear strength (0.93MPa) of the composite scaffold ensures that it can be securely anchored in a joint defect and withstand the shear forces in a moving joint. The tri-layered composite scaffolds supported layer-specific stem cell differentiation, with cell infiltration and cartilage matrix formation to a depth of 3mm, with mineralization in the bone layer (Fig. 1C). Quantitative analysis of deposited sGAG and calcium showed that differentiating cells in the bone and cartilage layers produced requisite matrix components specific for each layer (Fig. 1D).

Conclusion

This novel tri-layered composite scaffold was shown to support support layer-specific stem cell differentiation \textit{in vitro}, which is crucial for regeneration of osteochondral tissue. The mechanical properties of the composite scaffolds are
optimized to be suitable for load bearing joints to regenerate large defects to alleviate the need for joint replacement surgeries. In vivo assessment of the composite scaffold in an osteochondral defect model in goats is currently ongoing.

Introduction
After blood, bone remains the most transplanted organ, used in cases of bone trauma and resection. Currently, surgeons are still faced with major hurdles: i) complexity, availability and morbidity associated with vascular fibula grafts, ii) insufficient vascularization/innervation and osteointegration for implanted biomaterials in the absence of autologous cells, iii) complexity/regulatory hurdles in the use of growth factors (i.e BMPs). Furthermore, tissue engineering cell-based approaches have also shown limitations: i) limited ability of autologous cells from non-healthy patients to proliferate and integrate with biomaterial systems, ii) tissue-engineered constructs are labor intensive to produce, low throughput and difficult to form into complex 3D geometries, iii) advanced cell therapies are associated with stringent regulatory hurdles. Also, for many years, bone tissue-engineering strategies were mainly focused on osteogenesis and shown limited clinical success. Only recently, focus has been drawn on the importance of neurovascular modulation to attain fully functional tissues [1]. Here, we explore the 3D fabrication of a cell-free scaffold, designed to support the intricate orchestration between vascularization, innervation and bone healing, in a regeneration scenario. We focused on a hyaluronan-based matrix functionalized with laminin derived peptides, characterized by rheology, able to be bioprinted [mstoddar2] and support endothelial and neuronal cell adherence and maturation. We present the main optimization steps for its development towards improved bone vascularization and innervation, and its impact on bone regeneration.

Experimental Methods
The tyramine-modified hyaluronan-based matrix (HA-Tyr) was serially crosslinked with a first step involving an enzymatic oxidation with H₂O₂ and horseradish peroxidase, and a second step consisting in visible light-mediated cross-linking (505 nm) with Eosin Y [2]. The first cross-linking was used to pre-jellify, and enable microextrusion bioprinting, and the second to set the bioprinted structure for final shape fixation. HA-Tyr was added to increasing peptide concentrations (i.e. 0, 0.5, 1 and 2 mg/mL), and the rheological properties evaluated before and after light cross-linking. The viscoelasticity properties and the tan δ value (G’/G”) were analyzed in the linear domain. The peptide is derived from laminin, an assembly of IKVAV-YIGSR with Tyr at each end, allowing covalent crosslinking with HA Tyr.

In vitro evaluation was performed on gels following both polymerization approaches by seeding Human Umbilical Vein Endothelial Cells (HUVECs), human bone Marrow Mesenchymal Stem cells (MSCs) or human Induced-Pluripotent Stem cell-derived sensory neurons (iPS-SN) on the top of the matrix. To evaluate the cellular metabolic activity and indirect cell viability, alamar Blue™ assay was performed, up to 7 days of culture. Phenotypical characterization was performed using cell-specific immunolabelling. Finally, the printability of the matrix (with different peptide concentrations) was evaluated for microextrusion on a 3D Discovery (RegenHU) bioprinting system.

Results and Discussion
The first crosslinking of HA-Tyr brought to the formation of a weak gel as expected, with an average G’=58 Pa and G”= 27 Pa. The addition of peptides showed to decrease the viscoelastic properties of the composite hydrogel, with...
decreased G’ and G” values. For the highest peptide formulation, 2 mg/mL, a loss of cohesion is observed. Nonetheless, all formulations with lower peptide concentrations, or without peptide, showed a tan δ (G”/G’) value between 0.4 and 0.6, in the optimal range for extrudability in terms of microextrusion bioprinting [3,4]. Following the second polymerization of HA-Tyr without peptide, we observed a higher crosslinking efficacy, with an average G’=576 Pa and G”=23 Pa. Again, we observed a lower elastic modulus when peptides were associated within the matrix. These results suggest that optimal peptide concentration will be established at concentrations lower than 1 mg/mL.

In terms of in vitro results, the addition of peptide enhances HUVEC and MSCs cell adhesion, metabolic activity and phenotype. Current studies are underway to establish the capacity of the developed matrices to support axonal growth of iPS-SN.

Conclusion
We showed the grafting of laminin-derived peptides supports cellular adhesion and phenotype. Further studies are ongoing and will improve the capacity of this biomaterial to sustain the interplay between angio/neurogenesis for bone regeneration.

Effect of calcium sulphate pre-crosslinking of alginate based bio-inks on humal limbal stromal fibroblast survival in 3D bio-printed constructs.

Anastassia Kostenko, Che Connon, Stephen Swioklo

Newcastle University, Newcastle Upon Tyne, GB

Introduction
Over the last decade, progress in three dimensional (3D) bioprinting has advanced considerably. The principle of 3D bio-printing involves integration of biomaterials, live cells and controlled motor systems for creating complex biomimetic constructs. Bio-ink is one of the most important components in the process of 3D bio-printing. Hydrogels are the bio-inks of choice for extrusion-based 3D bio-printing due to their ability to absorb large amounts of water, low cytotoxicity whilst creating structures similar to the native extracellular matrix. Bio-inks need to be sufficiently viscous to be dispensed as a free-standing filament and have appropriate strength and stiffness to maintain structural integrity after printing. Alginate has been used widely for 3D bio-printing due to its biocompatibility, tuneable properties, rapid gelation, low cost, and ability to be functionalized to direct cell behaviour. By tuning the physiochemical parameters of alginate-based bio-inks, improvements in print resolution, fidelity and growth characteristics of encapsulated cells can be achieved. Thus further optimizing the extrusion based bio-printing technique for therapeutic and drug discovery applications.

In this study, the viscosity of alginate-based bio-inks was increased compared to the control by pre-crosslinking with calcium sulphate (CaSO₄) to improve their suitability for the bioprinting process. Mechanical and structural properties of alginate-based bio-inks were characterized with the aim of mitigating the resolution problems associated with existing bio-inks used in extrusion based bioprinting. Subsequently, the survival of human limbal stromal fibroblasts (hLSFs) under standard cell culture conditions was compared between pre-crosslinked and control alginate-based bio-inks.

Experimental Methods
Medium viscosity, high β-D-mannuronic acid (MVM) alginate stock in ddH₂O was made up to 2.4%. Stock solution was then mixed in a 1:1 ratio with 0.01 M CaSO₄ in ddH₂O producing the final concentration of 1.2% pre-crosslinked alginate. The alginate CaSO₄ mixtures were mixed 50 times using two syringes and left to cure at room temperature for 3 hours prior to rheological analysis and later use as cell-laden bio-inks. Bio-inks were assessed using bio-printing and wet spinning. Wet spinning allows for standard quantification of the amount of cell-laden bio-ink extruded. Fibers can be produced with both the pre-crosslinked alginate and the liquid 1.2% control alginate. Wet spinning was performed at the rate of 1mL/minute dispensing 0.25mL of bio-ink into a 0.1M calcium chloride (CaCl₂) bath. Human limbal stromal fibroblasts (hLSFs) grown in standard serum containing medium were detached, mixed with either 1.2% alginate alone or 1.2% pre-crosslinked alginate (10% cell suspension, 90% bio-ink) and bio-printed in a lattice shape through a 30G polytetrafluoroethylene (PTFE) lined needle. CaCl₂ (0.1M) was added to the bio-printed constructs to post-crosslink the lattice and prevent the bio-ink from spreading. CellTiterGlo assay was used to assess hLSF viability over time.

Results and Discussion
CaSO₄ pre-crosslinking of alginate significantly increases the viscosity of the bio-ink, thus making it suitable for 3D bio-printing compared to the 1.2% MVM alginate control (p = < 0.0001; n = 3). Viability of encapsulated bio-printed
hLSF remained above 90% over 7 days in CaSO₄ pre-crosslinked alginate-based bio-inks in standard cell culture conditions. These results are consistent with hLSF viability assessed using the wet spinning model.

Conclusion
Pre-crosslinking of alginate-based bio-inks with CaSO₄ has a significant effect on the viscosity of the biomaterial influencing the final resolution of the printed structure. Encapsulation of hLSFs in pre-crosslinked alginate-based bio-inks does not have a detrimental effect (92% of encapsulated hLSFs are viable at day 7) on hLSF viability over 7 days in standard culture conditions.
Additive manufacturing of patient-specific prosthetic medical devices

Helda Pahlavani, Mohammad J. Mirzaali, Jie Zhou, Amir A. Zadpoor

Delft University of Technology (TU Delft), Department of Biomechanical Engineering, Faculty of Mechanical, Maritime, and Materials, Delft, NL

Introduction
Limb amputation has severe physical and psychological implications for the patients. Restoring normal function, comfort, and appearance are the main characteristics that should be taken into account when developing prosthetic devices. Patient-specific (PS) design offers many advantages with regard to satisfying the design requirements of such prosthetic medical devices (e.g., transtibial sockets).

Experimental Methods
These PS designs are based on the patient's anatomy obtained from various medical imaging modalities (e.g., computed tomography (CT) or optical scanning), thus, allowing for better fixation and improving the patient's comfort while enabling successful recovery. To aid in the PS design, computational models may be used to assess the functionality of these medical devices subjected to various physiological loading scenarios. These computational models can also provide further insight into the structural optimization and efficient material distribution of PS medical devices. Such an approach will lead to an optimized design with complex internal micro-architecture. The emergence of additive manufacturing (AM) techniques makes the high-quality manufacturing of these complex PS medical devices feasible. Due to the form-freedom offered by the AM technology and the availability of a wide variety of materials, it is now possible to design and fabricate various medical devices at a fast production speed and with minimized specialized manual labour.

Results and Discussion
Here, we developed a methodology connecting different steps (i.e., geometrical design, AM fabrication, and computational models) for the design of PS transtibial sockets. Towards this aim, the accurate geometries of the residual limb and internal bones were extracted from CT images. Next, the geometry of the socket was designed based on the geometry of the residual limb through computer-aided design (CAD) and all constructed 3D parts (i.e., bone, tissue, and designed socket) were imported into a finite element (FE) software for further analysis and structural optimization.

Conclusion
We showed that high-quality PS prosthetic devices are achievable through a combination of imaging, computer-aided design, computational modelling, and rapid prototyping using AM.

Effect of hydrophobicity on the tumorigenesis of triple-negative breast cancer

David Angelats Lobo¹,²,³, Sònia Palomeras¹, Joaquim Ciurana², Paola Ginestra³, Elisabetta Ceretti³, Teresa Puig Miquel¹

¹ University of Girona, Department of Medical Sciences / New Therapeutic Targets Laboratory (TargetsLab) Oncology Unit, Girona, ES; ² University of Girona, Department of Mechanical Engineering and Industrial Construction / Product, Process and Production Engineering Research Group (GREP), Girona, ES; ³ University of Brescia, Department of Mechanical and Industrial Engineering, Brescia, IT

Introduction
Breast cancer is the second cause of death in both sexes, being triple-negative breast cancer the most aggressive, with a tendency to relapse between 2 to 3 years after the initial treatment. Cancer stem cells, a small subpopulation of cancer cells within the tumors, have been proposed as responsible for the growth, proliferation, and spread of the tumors within the body. Recently, the combination between engineering and biology allowed the fabrication of three-dimensional platforms, known as scaffolds, that helped to mimic the natural microenvironment of those cancer stem cells. Nowadays, the main research is focused on the study of those cancer stem cells, but there is still a lack of understanding of the tumorigenesis process in vivo.

Experimental Methods
In recent times, in 2013, a group of research produced a scaffold capable of mimicking the in vivo microenvironment where the tumors are found. Briefly, a polymeric solution containing methoxy-polyethylene glycol (mPEG), polylactic acid (PLA), and poly lactic-co-glycolic (PLGA) combined with the electrospinning technique, provided an interesting platform for the study of tumorigenesis.

Results and Discussion
This protocol has been reproduced in our group, showing a relationship between hydrophobicity and attachment to the tumoral samples.

Conclusion
This model may provide an interesting platform to study the aggressiveness of triple-negative breast cancer, and possible mechanisms to interrupt it.
Enzymatic Freeform 3D Biofabrication of Cell-laden Tubular structures

Marta A. Rocha, Maria V. Monteiro, Vítor M. Gaspar, João F. Mano

Aveiro University, Department of Chemistry, CICECO – Aveiro Institute of Materials, Aveiro, PT

Introduction
Reproducing human tissues composition, structure and architecture has gained a widespread interest in the tissue bioengineering and regenerative medicine field.[1] Due to monolayers incapacity to resemble human tissue features, three-dimensional (3D) human organ/tissue models have emerged as a promising alternative to better recapitulate the complexity of human tissues at cellular and organ level. To reproduce human tissue native components cells are commonly embedded in relevant biomaterials similar to that found in human microenvironment and assembled as bulk 3D in vitro models. Although such approach enables to reproduce important in vivo aspects, they cannot emulate complex tissues architecture. Recently, 3D bioprinting technique emerged as valuable tool to produce high-content 3D in vitro models assuming complex 3D structures. In this technique, cells are commonly embedded in relevant hydrogels to form a bioink and then printed according to the desired and pre-established arrangement following a computer assisted design software. Despite 3D bioprinting offers the ability to obtain complex 3D human-sized models, the establishment of printable bioinks that maintain the structure fidelity and resolution after the printing process remains a challenge. In order to improve the printability of hydrogel-based bioinks, researchers commonly modulate their rheological properties and crosslinking densities aiming to obtain more robust inks, which could affect cell viability, proliferation and differentiation. To face this issue, an emerging strategy is the use of supporting baths to provide a physical support during the 3D printing process, ensuring the shape fidelity maintenance of the printed structures with the desired spatial control. Such freeform bioprinting approach offers the possibility to print highly complex architectures such as hollow tubular constructs with high resolution without the demand of find or optimize fully printable hydrogels.[2] Commonly used supporting materials reside on microparticle systems, however such strategy is time-consuming, labor-intensive and influence cell maintenance and structure recovery. Alternatively polymeric-based baths are recently emerging as a more efficient approach to circumvent the drawbacks offered by traditional techniques ensuring the easily fabrication of high-resolution constructs.[2] Particularly, Xanthan gum-based baths already demonstrated be efficient in tubular constructs bioprinting with potential application for the assembly vascularized and/or ductal tissue/organ models.[2]

In this work, we exploit freeform bioprinting techniques to obtain highly complex and cell laden hollow tubular constructs crosslinked via enzymatic approaches. Complex freeform tubular models were obtained by direct 3D bioprinting of an ECM-mimetic ink comprising hydroxyphenyl propionic acid-modified gelatin (Gelatin-HPA) at different concentrations, in a xanthan gum supporting bath containing the crosslinking mushroom tyrosinase enzyme (MST).

Experimental Methods
Gelatin-HPA synthesis followed a carbodiimide/active ester-mediated coupling reaction. The chemical modification was performed overnight with HPA, DMF, NHS and EDC.HCl. Then, the obtained solution was dialyzed and freeze-dried. Gelatin-HPA conjugates crosslinking occurred by an enzymatic oxidative reaction mediated by MST, a naturally derived copper-containing enzyme [3,4]. The design of a representative 3D model of hollow-vessel like tubes was created in a CAD software. The 3D bioprinted constructs were manufactured by extrusion 3D bioprinting using a Cellink INKREDIBLE + Bioprinter (Cellink, Germany).

Results and Discussion
Prior to the 3D bioprinting process, the bioink concentration and 3D bioprinting conditions (i.e., temperature, pressure). In the case of gelatin-HPA bioink, which is a thermosensitive biomaterial, the highest resolution was obtained at $T = 30^\circ$C and a pressure between 30-40 kPa. A supporting bath comprising xanthan gum, cell culture medium and MST was used not only to achieve maximum printing fidelity, but also for gravitational support of the tubular structure during enzyme-mediated crosslinking (Figure 1, A). The structure was then easily retrieved and set to culture (Figure 1, B). Gelatin-HPA based-bioink has shown to be an appropriate formulation for freeform 3D bioprinting of hollow-vessel like tubes. Also, MST was revealed to be a successful crosslinking approach for obtaining 3D scaffolds with high resolution and structural stability.

**Conclusion**

Overall, the use of the support bath provided the ideal conditions for printing and crosslinking, while enabling constructs retrieval in a non-destructive manner. The bioactivity and processability of the enzymatic crosslinked bioink combined with the spatial manufacturing freedom and ease of scalability obtained from polymer supporting baths render this a promising approach for fabricating anatomic size living constructs for a myriad of biomedical applications.

3D printed scaffold containing drug-loaded PLGA microspheres for bone tissue engineering
Habib Belaid¹², Catherine Teyssier², David Cornu¹, Vincent Cavailles², Mikhael Bechelany¹

Introduction
Breast cancer is the most common invasive cancer in women, and the second main cause of cancer death in women. Metastatic breast cancer, most frequently localized in bone, is causing considerable pain and high patient morbidity. The treatment of bone is challenging due to bone repair, and patients are often treated by implanting a passive artificial junction in addition to a systemic chemotherapy treatment.

3D printing is a powerful tool providing the ability to print bone substitute materials or “scaffolds” designed to mimic the extracellular matrix. The scaffolds need to be biocompatible and biodegradable with a highly porous and interconnected pore network. The mechanical properties have to match those of the tissues at the site of implantation. For patients with bone metastasis, the scaffold may also allow the controlled and local release of anticancer drugs.

One of the strategies to deliver these drugs by the scaffolds is to encapsulate them in microspheres such as Poly(lactic-co-glycolide) or PLGA.

The aim of this work is the development and characterization of novel biomimetic biodegradable 3D printing scaffolds allowing both bone regeneration and inhibition of breast cancer cell proliferation. To this aim, PLGA microspheres have been loaded with Raloxifene Hydrochloride (RH) and Alendronate (AL). These microspheres have been incorporated into a 3D scaffold fabricated using a Stereolithography 3D printer system with a Poly(propylene fumarate) (PPF) photopolymer.

Experimental Methods
To prepare drugs-loaded PLGA-microspheres of around 1 μm in diameter, a single or double-emulsion-solvent-evaporation method was used. PPF/DEF scaffold was fabricated using a Formlabs Form 2 printer equipped with a Class 1, 405 nm violet laser with a power of 250 mW and laser spot size of 140 μm. Axis resolution (i.e., layer thickness) used for printing was 50 μm.

Results and Discussion
The physicochemical properties of the nanocomposites scaffold have been fully characterized. Biological testing has been carried out in order to confirm the effects of encapsulated drugs on MCF7 cells proliferation. A cell viability test using MG63 cells has been conducted to determine the scaffold biocompatibility and its effects on cell proliferation. The successful cell adhesion was revealed by fluorescent microscopy, and MG63 bone differentiation was monitored by Alizarin red staining and semi-quantitative RT-PCR.

Conclusion
Altogether, our data showed that PLGA microspheres incorporated in PPF scaffolds could be suitable for the treatment of bone metastasis in breast cancer.

Introduction
Recently bone grafts have been increasingly used around the world. Bone grafting frequency is indeed the second most frequent tissue transplantation worldwide, coming right after blood transfusion [1]. Over two million surgical surgeries are performed per year to treat bone tissue defects [1-2]. Bone tissue defects larger than 4-6 cm are critical and should be treated with bone grafts [2]. Critical-sized defects can be congenital or formed due to trauma, tumours, infections, and diseases such as osteoporosis, necrosis, or bone atrophy [1]. Four main types of bone grafting are used to treat bone tissue defects: autologous, allogeneic, xenogeneic, alloplastic. Autologous bone is currently considered the “gold” standard for treating bone tissue defects [1,3]. However, more and more attention is paid to alloplastic bone graft materials, as the use of these bone grafts could simplify operations and avoid the most common complications [1,3]. The major advantages of alloplastic materials include their high abundance relative to natural materials, no risk of disease transmission and the very low antigenicity. They can be made available in both resorbable and non-resorbable forms, and can be customized with varying levels of porosity and pore sizes [4].

Experimental Methods
The main objective of this study was to print hydroxyapatite (HA) scaffolds of complex geometry that could potentially be used to fill bone defects. One of the world’s latest 3D ceramic printing technologies LMC (Lithography-based ceramic manufacture) was used for printing hydroxyapatite scaffold. Using this technology, the production of printed hydroxyapatite scaffold essentially consists of two main parts: 3D printing and heat treatment. The geometry of the printed HA experimental specimens (see Fig. 1), scaffold porosity, scaffold pore size, and material density fluctuations were analysed using industrial computed tomography (µCT). In order to analyse the structural properties of HA samples, studies were performed using X-ray diffraction (XRD) analysis and Fourier transform infrared spectroscopy (FT-IR) analysis. The surface topography and roughness of HA samples were analysed using optical profilometry and scanning electron microscopy (SEM). The mechanical properties of HA scaffolds were evaluated by mechanical compression test.

Results and Discussion
The scaffold was designed using special software. The geometry of the scaffold used in the study was 10 x 10 x 10 mm with diamond-shaped lattice (see figure 1 a). The porosity of the designed scaffold was 89.05 ± 0.07%, the scaffolding thickness was 152.20 ± 0.40 µm, and the pore size – 784.80 ± 2.79 µm. Final part can be seen in figure 1 b. Investigations using industrial computed tomography (µCT) were performed to evaluate printing accuracy and other scaffold parameters. Comparing the 3D model with the manufactured scaffold, it was found that the deviations of the geometry of the manufactured scaffold from the 3D model range from -12 µm to 136 µm. These deviations can be explained by the fact that during the heat treatment, the material did not shrink as much as planned. Scaffold analysis showed that the porosity was 84.5 ± 0.42 %, the scaffolding thickness –175.45 ± 4.54 µm, and the pore size – 715.89 ± 7.56 µm. Volumetric analysis of the scaffold revealed that the scaffold did not exhibit any volume fluctuations.

In order to identify the crystalline phases of hydroxyapatite, XRD studies were performed on the printing material
(suspension), 3D printed object (green body) and after heat treatment (final product). XRD results of the performed studies are presented in Figure 2. According to JCPDS no. 00-009-0432 card, all peaks correspond to pure hydroxyapatite. The most intense reflection peaks of all the samples are at 31.8°, 34.1°, 32.2°, 25.9° and 49.5° 2θ angles. There are no significant differences between the suspension, printed and sintered samples. Calculated mean crystallite sizes of the suspension, printed, and sintered samples are 27.5 nm, 28.1 nm, and 30.6 nm respectively. In this work, the analyzes and results of FT-IR, SEM and optical profilometer will be further examined in more detail.

**Conclusion**

The study found that LCM ceramic printing technology is suitable for production of complex geometry scaffolds with high geometric accuracy and repeatability. In order to obtain even better results, more attention should be paid to the thermal treatment of hydroxyapatite. After XRD analysis, it was found that the hydroxyapatite scaffold formed by the LCM method has analogous crystalline phase properties as the hydroxyapatite objects produced by conventional methods. Using LMC technology, it is planned to produce more structures of different geometry, lattice and to study them in pre-clinical studies.

Time-Temperature Superposition in Highly Oriented Electrospun Conductive Nanofibers of Biodegradable Polymers

Muhammad A. Munawar\textsuperscript{1,2}, Dirk W. Schubert\textsuperscript{1,2}

\textsuperscript{1} Friedrich-Alexander-University Erlangen-Nuremberg, Department of Materials Science, Institute of Polymer Materials, Erlangen, DE; \textsuperscript{2} Bavarian Polymer Institute, KeyLab Advanced Fiber Technology, Fürth, DE

Introduction
An electrospinning process with a special rotating collector electrode is used to generate highly oriented electrospun conductive fiber composites (ECFCs) of biodegradable polymers. Polylactic acid (PLA) are blended with intrinsically conductive polymers (ICPs)-filler of polyaniline (PANi). As the proportion of filler increases, the number of “conductive pathways” grows, and consequently the conductivity of the ECFCs also increases. A procedure is developed for calculating the volume fraction ($\phi$) of filler, density and conductivity of electrospun nanofibers. The conductivity as a function of filler fraction is shown and described by using a McLachlan equation for the first time to reveal the electrical percolation thresholds ($\phi_c$) of nanofibers. During the annealing process, a build up of additional conductive channels within ECFCs is responsible for increasing inter and intra-chain conductivities among fillers and matrices. Therefore, annealed ECFCs transport charge more efficiently due to an increase in continuous pathways, which lead to superior electrical conductivity and lowering the percolation threshold. Moreover, a time-temperature effect on percolation thresholds of ECFCs is evident.

Experimental Methods
The highly oriented electrospun conductive nanofibers of biodegradable polymers were fabricated successfully using a special collector electrode as depicted in Figure 1. The electrical conductivity $\sigma$ of ECFCs can be calculated by using the value of resistance $R$, which was measured using a two-point probe method.

Results and Discussion
We mainly studied the calculation of percolation threshold using the McLachlan equation on experimental conductivities of ECFCs with different annealing temperatures and annealing times. The percolation threshold decreased either with increasing annealing temperature or time. Finally, the contour plot (as shown in Figure 2) shows time-temperature effect on percolation threshold of electrospun nanofibers.

Conclusion
The annealing process in electrospun fibers enhances the buildup of additional conductive channels, which lead to superior electrical performance and lowering the percolation threshold $\phi_c$ and time-temperature superposition exists in electrospun nanofibers.

Introduction
Biofabrication of living cells with a reproducible high cell survival and high special resolution is still a challenge in the biofabrication field. Substantial shear forces during common high-resolution printing processes can negatively impact cell viability, therefore the protection of printed cells against the shear forces during printing is necessary.[1] One conceivable way to enhance cell survival, cell viability and expand the biofabrication window is the encapsulation of living cells in microgels that act as a protective coating. Furthermore, with the application of these encapsulated cells as ink additive, it is possible to engineer multifunctional scaffolds with different cell types and uncouple cell micro- and macrome surrounded.[2] The fabrication of uniform and size controllable microgels can be achieved via microfluidics of in situ cross-linking polymers, which form mechanically stable hydrogels.[3] In this study, we prepared POx/GelPA-based microgels of controllable size using a custom-built microfluidic setup and crosslinked them via a visible light mediated thiol-ene reaction. The microgels were used and printed as additive in a GelPA/sPEG-based ink.

Experimental Methods
To synthesize the POx-based hydrogel precursor, 2-ethyl-2-oxazoline (EtOx) was randomly copolymerized with 2-(3-butenyl)oxazoline (ButEnOx) to yield polymers with a double bond to allow a subsequent functionalization. Afterwards the polymer was modified at the double bonds with free thiol groups for hydrogel formation according to an already published procedure.[4] For the bioactive component GelPA, the free amines of a gelatin with a low molecular weight were functionalized with free vinyl groups via NHS chemistry. The modified gelatin was further dialyzed against ultrapure water and freeze dried. The dissolved polymers were subsequently combined in a custom-designed microfluidic chip, which allowed the production of droplets of varying sizes with high uniformity. To crosslink the hydrogel precursor solution via thiol-ene reaction, a low concentration (0.5 wt%) of a UV/visible light sensitive photo initiator (LAP) was added. The droplets were stable crosslinked directly after their formation in the microfluidic chip. NIH/3T3 cells were used to demonstrate the successful encapsulation of cells in the aforementioned microgels.

Results and Discussion
For this application Poly(2-oxazoline)s are the ideal synthetic polymers, due to their excellent biocompatibility and synthetic availability. Moreover, the polymers provide an easy possibility for a side chain functionalization to control cross-linking degree of the obtained microgels.[4,5] Modified gelatin with its bioactivity and degradability can act here as cell-friendly component for a better viability of encapsulated cells. Both polymers were mixed and droplets were produced via microfluidics. It was possible to crosslink the hydrogel precursor solution droplets via visible light directly after the production to avoid coalescence of the droplets. The 3D-printing of the cell free microgels, after washing and purification, as additive in an ink could be shown in this study. Furthermore, the encapsulation of cells was already possible using this microfluidic approach. NIH/3T3 cells were mixed into the polymer precursor solution and cells were encapsulated during the microfluidic process.

Conclusion
We could successfully generate stable crosslinked POx/GelPA-based microgels via microfluidics and encapsulate living NIH/3T3 cells in these microgels. Additionally, it could be shown, that the printing of the cell free microgels as particulate additive in bioinks was still possible. In future studies the POx/GelPA-based microgels will be a used as protective coating of encapsulated cells during 3D printing process and subsequently provide a cell friendly microenvironment for the encapsulated cells. The ultimate applications for the bioactive microgel droplets are particulate bioinks for extrusion-based 3D-printing or as protective additive in conventional bioinks to ensure sufficient cellular protection and eventually the coextrusion of two or more different cell types.

Development of a 3D in vitro hierarchized vascular model under active perfusion: a new model for the study of prostate cancer intravasation.

Lise Chagot, Chantal Medina, Leo Comperat, Nathalie Dusserre, Marie-Laure Stachowicz, Jean-Christophe Fricain, Hugo Oliveira

INSERM, U1026 ART BioPrint, Bordeaux Cedex, FR

Introduction
Prostate cancer is the third most frequent cancer diagnosed in men, with high incidence rates in Europe and North America [1]. Metastasis is the leading cause of prostate cancer-associated deaths and bone metastases can be found in most patients with castration-resistant prostate cancer [2]. The metastasis process of solid tumors starts with the migration of invasive cancer cells into the local microenvironment. Then, cancer cells intravasate into the vasculature or lymphatic system, disseminate through the circulatory system and extravasate into a secondary tissue and colonize it. The precise driving mechanisms responsible for each metastasis step remains relatively unclear [3]. Biofabrication, based on the precise deposition and assembly of materials and cells, can enable to mimic the structure and function of the desired tissue [4]. These complex 3D in vitro cancer models can provide new research tools to further decrypt complex mechanisms and open new therapeutic approaches. Here we have developed a new model to study prostate cancer intravasation, in flow conditions, through a hierarchized vascular model.

Experimental Methods

Cells models
Human umbilical vein endothelial cells (HUVECs) were isolated from fresh human umbilical cords and human skin fibroblasts (HSF) from human skin explants, using established protocols. Both were cultured under standard conditions, until passage 10.

PC3 cells, a human prostate cancer cell line, were obtained from ATCC and cultured under standard conditions, between passages 35 – 40. HUVECs and PC3 were transduced with lentiviral vectors coding for red and green fluorescent proteins, RFP or GFP, respectively. After printing, all cells were cultured in complete EGM2 MV medium.

Bio-inks

Pluronic was prepared from Pluronic F127 powder dissolved in milliQ water at a final concentration of 37%. Methacrylated gelatin (GelMA) was prepared from gelatin type A, obtained from porcine skin, and anhydride methacrylate at 140 μL/g gelatin was added for a methacrylation degree of 61.8 % (Average ±SD, n=9). GelMA was then used at a final concentration of 120 mg/mL in DMEM HG.

Methacrylated collagen (CollMA) was prepared from type 1 bovine collagen and anhydride methacrylate at 95 μL/g collagen. CollMA showed a methacrylation degree of 57.15 % (Average ±SD, n=3). The CollMA bio-ink was formulated at 4 mg/mL, by adding 10X DPBS, 1M NaOH, DMEM HG and LAP (0.1% w/v final) as a photoinitiator.

Bioprinting platforms

A multimodal commercial printer (Discovery 3D, RegenHU), equipped with two microvalve printerheads, two pneumatic microextrusion printheads, and a 365 nm UV curing source, was used.

Perfusion chambers

A personalized PDMS chamber was printed by microextrusion (Fig.1 A). This chamber was then sealed between two layers of Plexiglass and mechanically enclosed in a PETG 3D-printed system with screws. Culture medium active perfusion was ensured by a peristaltic pump (Ismatec) with a flow rate from 1 to 20 μL/min (Fig 1.C).

Bioprinting process

Page 1048 of 2028
The computer assisted design was created using the BioCAD software (RegenHU) (Fig1.B). Then, HUVEC and HSF (in coculture) and PC3 cells were bioprinted using two independent microvalve printheads. Following UV curing, Pluronic was deposited by microextrusion, as a negative mold for a perfusable tube. A second layer of GelMA was poured to cover all the printing and a final UV curing was performed to polymerize the whole structure. The sacrificial bioink, Pluronic, was removed by reducing the temperature and perfusing with cold DPBS. After poly-D-lysine coating, a suspension of HUVECs was added and let to adhere and to endothelialize the hollow tube. The system was then placed under active perfusion in standard culture conditions.

**Results and Discussion**

Gel rheology, bioprinting parameters and cell survival were optimized and evaluated. We could show that in optimal conditions a cell survival of 99.02% (Average ±SD, n=3) was obtained for HUVECs. HUVEC+ HSF bioprinting, tested at 10+10, 20+20, or 30+30 million/mL, showed optimal endothelial network maturation for 30+30 mio/mL, following 14 days of maturation.

Efficient macro to microvasculature connection was asserted by perfusing with Dextran-FITC 500kDa. PC3 cell association is ongoing, and the design of PC3 inkjet spots alongside HUVEC + HSF spots is being pursued. Maturation of the complex system is currently being evaluated using time lapse and confocal microscopy. Future studies will consider the validation of this biofabricated model in response to anticancer and anti-angiogenic drugs (e.g. Sunitinib treatment).

**Conclusion**

Here, we show the application of this modular hierarchized vascular system to model intravasation of prostate metastasis. Nonetheless, due to its inherent modularity it can easily be applied to other cancer models or to find use for the study of circulatory cancer cell extravasation. Also, active flow conditions allow to attain further physiological relevance, particularly important when modeling the metastasis mechanism.

Kolff Research Institute, Groningen, NL; ³ University of Groningen, University Medical Center Groningen, Groningen Research Institute for Asthma and COPD, Groningen, NL; ⁴ University of Groningen, University Medical Center Groningen, Department of Biomedical Engineering, Groningen, NL

Introduction
The extracellular matrix (ECM) is a non-cellular, heterogeneous mixture of macromolecules that provides cells with structural support. The ECM mechanics are commonly modelled using hydrophilic polymeric networks (i.e. hydrogels); with most studies focused solely on its elastic properties. Now it is recognised, that ECM mechanics are driven by a combination of elastic and viscous response, rendering the ECM viscoelastic. In this work, we compared the viscoelastic properties of organ-derived ECM hydrogels and mathematically modelled the data with a generalised Maxwell model of viscoelasticity

Experimental Methods
Adipose, cardiac left ventricle (LV) and lung tissue were decellularised and lyophilised. The resulting ECM was ground to a fine powder and 2% w/v hydrogels were produced by proteolysis with 10 % w/v porcine pepsin 0.01M HCL for 6 h (adipose), 8 h (LV) and 48 h (lung) [1 - 3]. The digested ECM was brought to 1x PBS, pH neutralized to 7.4 and gelated at 37°C. After 24 h of swelling at 37°C, ECM hydrogels underwent low-load compression testing (LLCT) at a 20%/s strain rate. The elastic modulus was determined during the first second of compression on the LLCT, while the viscoelastic properties were derived from the 100 s of stress relaxation at a constant strain of 20% [4].

Results and Discussion
The elastic modulus of Adipose-ECM (1.7 ± 0.6 kPa) differed from both Lung-ECM (4.98 ± 1.8 kPa) and LV-ECM (4.38 ± 1.73 kPa) (Fig. 1a). The time to reach 50% stress relaxation was fastest in Adipose-ECM (13.2 ± 15.68 s), followed by Lung-ECM (46.1 ± 10.37 s) and lastly LV-ECM (53.14 ± 8.23 s) (Fig 1b, 1c). Maxwell analysis showed that Adipose-ECM had two Maxwell elements, while Lung-ECM and LV-ECM had three, with differences in their relaxation time constants and their relative importance (Fig. 1d).

Conclusion
These data illustrate that irrespective of gel percentage, not only the stiffness of the ECM hydrogels was organ-dependent but also their viscoelasticity. Comparison of the molecular composition, such as polysaccharide and protein content, of the three ECM hydrogels may explain their respective physical properties.

Loco-regional skin toxicity of *in situ* forming depot administered subcutaneously at different flow rates in minipig

**Charlotte Peloso, Adolfo Lopez-Noriega**

*MedinCell, Research Applied to Development Unit, Jacou, FR*

**Introduction**

Despite the increasing interest of the scientific community for *in situ* forming depots (ISFD), little has been published regarding their loco-regional toxicity [1], which is one of the key parameters when developing an injectable drug product. MedinCell’s proprietary ISFD technology, trademarked as BEPO®, is based on bioresorbable PEG-PLA copolymers, mixed with an API into a biocompatible solvent [2]. Upon administration, the solvent will diffuse from the system and the copolymers will precipitate, forming a solid depot that will physically entrap the drug to be progressively delivered. To secure its proper administration and future compliance in clinic, local tolerability of BEPO® technology was investigated on top of the biocompatibility of the components themselves. In particular, injection flow rate was evaluated for both depot formation concerns and tissue tolerability. The aim of the present study was to assess the loco-regional skin tolerability of a model BEPO® vehicle (copolymers blend dissolved into solvent, without drug) when subcutaneously (SC) administered at different flow rates and volumes into Göttingen minipigs.

**Experimental Methods**

Two groups of four female Göttingen minipigs were injected either with 0.2 mL or 1 mL BEPO® vehicle. The tested vehicle had a high viscosity (> 600 mPa.s) and a particular polymeric composition with a slow degradation kinetics. Each animal received two manual injections of test item in SC in the *plica inguinalis*: one targeted at 1 mL/min and one targeted at 10 mL/min. Injection sites were systematically observed for macroscopic loco-regional skin reactions as well as ultrasound scanning, enabling longitudinal *in vivo* imaging of the depot. Observations were complemented by histopathological examinations (haematoxylin and eosin stain) at 72 h and 240 h post-injection.

**Results and Discussion**

On a macroscopic level, no skin local intolerance was observed at both injection flow rates and volumes. However, an induration was recorded over the 10 days. Because of the very thin skin and hypodermis present at the *plica inguinalis*, these inductions were visually evident, allowing their measurement with a caliper. At palpation, a firm mass was clearly identified and suggested as the implant itself. To confirm that this induration was mainly due to a mechanical swelling from the depot and not a loco-regional skin reaction, ultrasound imaging was performed. Implants were clearly detected and measured along the study. These measurements were comparable to macroscopic induration measurements, confirming it was mainly due to the mechanics of the implant and not a local reaction.

At the microscopic level, histopathological examinations were performed at both 72 h and 240 h post-injection. From 72 h, a pseudocyst with a well circumscribed empty space and thin fibrous capsule was highlighted. Over time, the pseudocyst developed into a well-defined encapsulated nodule, often multilocular. At 240 h, the observed nodule was composed of empty spaces limited by fibrous cords combined with mixed inflammatory cells, among which numerous multinucleated giant macrophages were noted. At both time points, the cavities most probably represent the location of the polymeric depots which dissolved during tissue processing, hence their empty appearance. Such reaction from pseudocysts to nodules represents a continuum characteristic of a Foreign Body Reaction (FBR). This innate biological response was expected, especially for this particular polymeric composition of the vehicle, as it was...
designed to degrade slowly (prolonged FBR). Again, the volume and/or rate of administration had no influence on the nature and severity of the induced local changes.

**Conclusion**

Local tolerability of the depot was highlighted by macroscopic observations and histopathological examinations of the injection sites. Ultrasound imaging helped to complete the observation, allowing to follow the morphological evolution of the depots during the course of the study. Taken together, these experiments showed an acceptable loco-regional response to the injected polymeric test item, designed to be an extreme case study (*i.e.* a vehicle of high viscosity and slow degradation kinetics), following low as well as high injection flow rates. The formation of a well-circumscribed subcutaneous nodule was observed along with a typical foreign body reaction (FBR) for all injections. The scoring of the injection site reactions was volume dependent, and no cases of treatment-emergent adverse events were reported, ruling out any matter of concern from a histopathological perspective. It can thus be considered that the ISFD PEG-PLA based-product is well tolerated locally, when injected subcutaneously at volumes ranging from 0.2 mL to 1 mL, and high injection flow rate.

Based on the loco-regional tolerance data noted in the Göttingen minipig, a human-relevant animal model for subcutaneous administration, we consider the ISFD BEPO® technology likely to be safe in human patients.

2D/3D imaging of osteogenesis and macrophage polarization in magnesium-based alloys

Maryam Rahmati1, Sabine Stötzel2, Thaqif El Khassawna2,3, Kamila Iskhahova4, Florian Wieland4, Berit Z. Plumhoff4, Håvard J. Haugen1

1 University of Oslo, Clinical Dental Faculty, Biomaterials department, OSLO, NO; 2 Justus-Liebig University Giessen, Experimental Trauma Surgery, Giessen, DE; 3 University of Applied Sciences, Faculty of Health Sciences, Giessen, DE; 4 Helmholtz Zentrum Geesthacht, Institute for Materials Research, Division of Metallic Biomaterials, Geesthacht, DE

Introduction

Immune system responses are vital for tissue healing after injuries (1). The ability of a biomaterial to induce angiogenesis and macrophage polarization is a key element in defining its success (2). Magnesium (Mg)-based degradable alloys have attracted significant attention for orthopedic bone regeneration due to their biodegradability and potential for avoiding secondary removal surgeries (3). However, information regarding early inflammatory responses and osteogenesis to these alloys in vivo.

Experimental Methods

In this study, we investigated the early body responses to Mg 0.45 wt%Zn-0.45 wt%Ca pin-shaped alloy (known as ZX00 alloy) in juvenile rat femora 2, 5 and 10 days after implantation. We used 3D µCT and histological analyses to study new bone formation and early inflammatory responses at the implant-bone interface.

Results and Discussion

Our results suggested the potential of ZX00 alloy to stimulate the polarization of type 2 macrophages, 5 and 10 days after implantation, compared to the sham group. In addition, we observed an increased newly bone matrix formation at day 10, compared to day 5 and sham group in all time points, suggesting better bone formation in the ZX00 alloy group.

Conclusion

To sum up, our results supported the early osteoimmunomodulatory potential of the ZX00 alloy toward inducing the expression of anti-inflammatory type 2 macrophages and osteogenesis.

Introduction

From ancient times it is known that silver is effective against a wide range of microorganisms. Today, silver ions are used to prevent bacterial growth (sometimes controlled) in a variety of medical applications, including dental work, catheters, and wound healing. It is clear that we are exposed to a wide range of largely unknown uses of silver-containing products that are intended to function as antimicrobial biocides. Therefore, it is necessary to elucidate the antimicrobial activity of silver ions, which are widely used in these products [1]. Despite the prominent benefits of using silver in such applications, the possible effects on health as well as on the environment have raised concerns about their use and production, without a clear understanding of their behavior in biological systems. The release of silver into an environment, such as air or water, in experimental environments or in biological fluids, can produce transformations that alter its properties, influencing transport, bioactivity, and possible toxicity [2, 3]. A challenge in the field of bioactive glass with Ag content is the elimination of AgCl formation after immersion in simulated biological fluid (SBF). It is known that in aqueous media, the release of Ag\textsuperscript{+} ions takes place in the glass matrix, which interacts with chlorides, sulfides, or thiol groups and leads to the formation of AgCl. The literature does not specify a maximum permissible limit after which the composite is toxic, but certainly, large amounts of AgCl can have a negative influence on bioactivity, especially due to the fact that the release of this amount in the body cannot be controlled.

The purpose of this study is to identify the chemical transformations of silver, which was used to the obtaining of bioactive samples in two forms, as silver iodide and silver oxide, and their effect on bioactivity and antibacterial activity.

Experimental Methods

The bioactive glasses (60SiO\textsubscript{2}·32CaO·8P\textsubscript{2}O\textsubscript{5}) with AgI and Ag\textsubscript{2}O content were obtained by sol-gel process. AgI microcrystals were prepared by the addition of silver nitrate, sodium iodide, and PVP by the solvothermal method. Silver nitrate was used as silver oxide precursor.

Structural, morphological and optical investigations were performed using a Shimadzu XRD 6000 diffractometer, JASCO-V650 spectrophotometer with an integration sphere (ILV-724), Hitachi S-4700 Type II cold field emission scanning electron microscope, and X-ray photoelectron spectroscopy, SPEC PHOIBOS 150 MCD system. \textit{In vitro} bioactivity was evaluated seven days after the introduction of the samples into the SBF. The Gram-negative strain of \textit{Pseudomonas aeruginosa} was used to test the antibacterial activity of Ag-based composites.

Results and Discussion

After immersion in SBF the X-ray diffraction patterns indicated the existence of a self-assembled apatite layer in both systems, the difference being noticed by the presence of a signal associated with silver chloride for the Ag\textsubscript{2}O addition system. To provide information about these transformations, UV-Vis and XPS spectra were recorded. Both UV-Vis spectra show a maximum at about 370 and 420 nm, respectively, that can be attributed to the presence of silver nanoparticles with different size [4]. In the case of bioactive glasses with Ag\textsubscript{2}O appear a maximum at about 256 nm
that indicates the presence of AgCl. By adding the AgI microcrystals in the glass system can be eliminated the formation of AgCl, but the antibacterial effect remains moderate. In contrast, for the bioactive glasses with Ag₂O it was obtained good antibacterial activity against *Pseudomonas aeruginosa*, but in all samples the AgCl was present after immersion in SBF.

**Conclusion**

The sol-gel method has been successfully used to obtain bioactive glass composites with silver content using different silver sources. The result shows that the silver sources affect the samples’ in vitro bioactivity and bactericide effect.

Porcine Abattoir Blood as a Valid Model for In-vitro Hemocompatibility Investigations

Johanna C. Clauser¹, Judith Maas¹, Ilona Mager¹, Frank R. Halfwerk²,³, Jutta Arens¹,²

¹ RWTH Aachen University, Department of Cardiovascular Engineering, Institute of Applied Medical Engineering, Aachen, DE; ² University of Twente, Chair of Engineering Organ Support Technologies, Department of Biomechanical Engineering, Faculty of Engineering Technology, Enschede, NL; ³ Medisch Spectrum Twente, Thorax Centrum Twente, Enschede, NL

Introduction
The major challenge of cardiovascular and cardiopulmonary medical devices lies in their hemocompatibility, such as hemolysis, thrombogenicity and platelet activation. Consequently, extensive in-vitro and in-vivo blood testing is mandatory to ensure the application of safe devices. Device thrombogenicity can be evaluated by in-vitro human blood tests; however, they are often restricted by the availability and required blood volume. Instead, animal blood use is allowed by the current standards and thus common practice for in-vitro investigations.

In order to reduce the necessity of donation animals and avoid limited availability, the use of abattoir blood provides a possible alternative. However, abattoir blood might present elevated blood values and pre-activated platelets due to stressed and frightened animals as well as non-standardized and potentially blood-damaging collection methods, which possibly affect the test results.

To this end, we investigated the pre-activation state and the remaining activation potential of porcine abattoir blood in comparison to human donor blood.

Experimental Methods
Light transmission aggregometry (LTA) was used to evaluate the pre-activation state of human donor and porcine abattoir blood.

Human blood (n=30) was collected from healthy donors from the cubital vein without stowing (Ethical Committee reference number EK 033/18) and immediately anticoagulated with 3.2 % citrate. Porcine blood (n = 30) was collected at the abattoir from the jugular vein of the animals into a bottle prepared with 3.18 % sodium citrate in a ratio of 1:9. Platelet poor and platelet rich plasma (PPP and PRP, respectively) were obtained from the blood samples by centrifugation and PRP.

Light transmission aggregometry (LTA) was adjusted to a platelet concentration of 200 000 PLTs/µL – 250 000 PLTs/µL by mixing of PRP and PPP.

Light transmission aggregometry (LTA) was performed according to the Born method. Collagen I and adenosine diphosphate (ADP) were used as activators with three different concentrations each (ADP: 5 µM, 10 µM, 20 µM; collagen: 2.5 µg/mL, 5 µg/mL, 10 µg/mL).

Results and Discussion
The stimulation of porcine abattoir blood with either ADP or collagen showed considerable activation of platelets. This disproves the general expectation that abattoir blood is already maximally pre-activated and therefore gives evidence to our hypothesis that this type of blood is suitable for in-vitro thrombogenicity testing. However, there are some differences to human donor blood.

Especially after ADP activation, porcine platelets show a different activation profile than human platelets, particularly a lower maximum aggregation (Fig. 1) and a significantly higher disaggregation. The reduced maximum aggregation might be due to the pre-activation of the abattoir platelets. Disaggregation in the range of 59 % – 84 % shows that the platelet activation is not stable and thus reversible. The reversible ADP-activation is a porcine platelet

Page 1060 of 2028
characteristic, which is present in abattoir blood as well, indicating a normal platelet behavior in that special type of blood [1].

Collagen-induced platelet activation reveals more similarities of human and porcine blood and generally presents a higher degree of activation of porcine platelets compared to ADP stimulation. In terms of maximum aggregation (Figure 2), slope and lag phase, only single pairs present significant differences between the species, whereas the majority does not present significances. Only the disaggregation presents significantly higher values for the porcine blood than for human blood; however, values vary around 5 % in contrast to < 2 % in the human data. Collagen stimulation thus seems to trigger an irreversible platelet activation also for porcine abattoir blood that is stronger compared to the activation with ADP.

Drawing a general comparison between the platelet activation properties of human blood and porcine abattoir blood, our data proves that the abattoir blood still bears an activation potential between 60 % - 90 %, depending on the activator. Accordingly, abattoir blood seems to be suitable for in-vitro thrombogenicity and particularly platelet activation evaluation. Porcine characteristics, which particularly differ from the human blood behavior, are preserved and activation kinetics remain in a reasonable range.

**Conclusion**

Light transmission aggregometry was performed with human donor and porcine abattoir blood. ADP activation of porcine abattoir platelets revealed a reversible platelet activation that is typical for pig, whereas collagen activation resulted in a stable and irreversible platelet activation. Despite generally lower values of maximum aggregation in the abattoir blood, no severe differences or malfunctions were obvious for the abattoir blood, thus verifying the use of abattoir blood for in-vitro investigations. This result is an important finding, allowing for a wide range of in-vitro testing with an ethically acceptable and easily available blood type and still valid outcomes.

Introduction
In order to guarantee long-term success of percutaneous components like dental implants, abutments and their superstructure, a stable attachment of the soft tissue to the material interface is of great relevance for the prevention of peri-implant diseases and tissue regression. To date, titanium and its alloys as well as high-performance oxide ceramics -like zirconia- representing clinically relevant materials for the mentioned application because of their advantageous biological, physical and esthetic properties. In dentistry, a major factor for the success of an implant-supported restoration apart from the osseointegration of the implant is the gingival adhesion on the abutment surface. A tight adhesion acts as a sealing and hinders bacteria and other pathogens from penetrating into the implant/bone interface. However, the mucosa around the implant abutment shows numerous differences from that around natural teeth, which result in a reduced sealing capacity of the gingiva against bacterial invasion. To overcome these limitations, here we propose a novel method to effectively bioactivate abutment materials surfaces through the covalent conjugation of ECM proteins in order to enable a stable soft tissue adhesion.

Experimental Methods
A silane monolayer was applied on relevant implant materials (Y-TZP and Ti6Al4V) to present various functional groups on the material interfaces. The successful application was verified via XPS, FTIR-ATR and AFM. Laminin and fibronectin were covalently bound to the silanized surfaces via specific crosslinkers. Successful coupling was proven by AuNP-antibody staining. Retained function of the ECM-proteins after surface coupling was shown in a centrifugation-assay. Mechanical exposure, acid and heat resistance on the modified specimens was verified via XPS, AFM and SEM.

Results and Discussion
Human gingival fibroblasts (HGFs) seeded onto the ECM-protein-coupled surface exhibited significantly higher adhesion (at 50xg) in comparison to non-functionalized controls. Confocal microscopy and SEM analysis revealed a much higher cell area and enhanced expression of pFAK-Y397 on ECM protein coated surfaces compared to those seeded on native Y-TZP and Ti6Al4V. The influence of saliva in terms of pFAK-Y397 expression was investigated additionally. Moreover, HGFs on ECM-protein coated surfaces showed a higher proliferation rate and exhibited an enhanced integrin expression.

Conclusion
We showed that the covalent conjugation of ECM proteins via crosslinking on the dental abutment materials Y-TZP and Ti6Al4V enables a strong adhesion of gingival fibroblasts. Therefore, the novel approach could improve the...
'sealing' against bacteria at this interface and thus holds promise to potentially reduce or prevent peri-implant diseases in clinical application.

Liquid flow chambers for biomaterial degradation analysis - Flow simulation and in vitro testing of various liquids and flow velocities

Benjamin Kruppke, Hans-Peter Wiesmann

Technische Universität Dresden, Institute of Materials Science, Dresden, DE

Introduction
The application of degradable biomaterials, e.g. for hard tissue replacement, requires a precise knowledge of their degradation behavior in order to adapt them to the time course of the healing process by material selection, processing or scaffold geometry. The limited investigation possibilities with cell cultures and animal experiments make it of great interest to analyze the high number of biomaterials in advance with regard to their degradation. It would be desirable, obviously, to know the influences such as the exchange rate of the surrounding fluid (as a trigger for increased material dissolution), the effect of aggressive media (e.g. as a simulation of osteoclastic resorption) and the ion concentrations in the liquid (as an indication of the bioactivity of the materials).

Experimental Methods
To analyze the aforementioned parameters, three versions of a flow chamber were designed and manufactured consecutively. For this purpose, the CAD models were tested with a liquid flow simulation and two new design load factors were established for the materials. The utilization of liquid (UOL) and the shear homogeneity index (SHI) provide information about the effectiveness of the chamber designs.

To test the chamber designs in vitro, suitable degradable biomaterials were fabricated after the chambers were manufactured and tested in different fluids in the flow chambers. The materials are based on gelatin-modified calcium strontium phosphates, which have previously shown their different degradation rates in static and quasi-static regimes [1,2]. The liquids chosen were phosphate-buffered saline (PBS) and simulated body fluid as reference media and citric acid solution (pH 3) and PBS with lowered pH (pH 6.0) to mimic osteoclast resorption and wound acidification, respectively.

Results and Discussion
As a result of the flow chamber design with respect to simulation, an adaptation to an increasingly efficient utilization of the fluid can be seen. It was crucial not to design a perfusion reactor with high pressure differences, but to allow the specimens to be passed around by the liquid with priority. This is similar to a biomaterial used in a bone defect, since this is also the path with the supposedly lowest resistance for the tissue fluids in vivo. In addition, this approach can be used to get closer to the fact that the fluids, through their continuous exchange, always cause a refreshed concentration gradient for the degradation products of the substitute materials.

The adaptation of the chamber to the non-destructive monitoring of the degradation process with a µCT allows a detailed observation of the degradation process. It was shown, that even for different fluids, increased degradation occurs at higher previously calculated UOL and SHI. Furthermore, the use of aggressive fluids induced a degradation of up to >90% within only 7 days, while <20% occurred for the reference liquids. Despite this, the material influences can be clearly distinguished, making the degradation results much more meaningful for a late stage of material resorption. This corresponds to previously obtained findings of the material variants in animal experiments [3].

Conclusion
The study showed, that bone substitute material degradation can be analyzed very efficiently with in vitro flow chambers to reduce time-consuming and costly experiments with cell cultures or ethically questionable material testing in vivo. Testing of biomaterials in large numbers could thus initially be simplified by this type of analysis, in...
order to complete further material characterization in vitro and in vivo with a small pre-selected set of materials with precisely known degradation behavior.

Aging effects on shape memory and tensile properties of high toughness polylactide composites for resorbable devices

Xabier Larrañaga, Jose-Ramon Sarasua, Ester Zuza

University of the Basque Country (EHU) and Polymat, Engineering faculty of Bilbao - Department of Metalurgy and Materials Science, Bilbao, ES

Introduction
Poly lactides are biodegradable polyesters obtained from renewable resources, widely investigated and used in the medical field. Due to their bioabsorbiability, tuneable mechanical properties and biodegradation rates, polylactides are exceptional materials for resorbable devices such as stents or orthopedic fixation anchorages [1]. Moreover, an additional property of the poly(L-lactide) (PLLA) is the shape memory effect (SME), a key feature for minimal invasive surgery [2].

However, PLLA particularly is featured by its mechanical brittleness. To overcome this drawback, previous works have been reported adding 10 wt.% of barium sulphate (BaSO₄) particles to the polylactide matrix in order to obtain a radiopaque composite with high toughness and ductility [3]. Nonetheless, the physical aging in PLLA takes an important role in the properties because they may vary along the time, due to its value of $T_g$ close to the room temperature. The effect of aging in the before mentioned composites has not been stated yet [4]. Consequently, this work consists in the analysis of physico-chemical properties, SME and mechanical behaviour of these high toughness composites within progressive aging times, paying attention in the effect of particle amount in the composites.

Experimental Methods
Commercial PLLA of molecular weight of 150,000 g/mol and BaSO₄ with a mean size of 1.45 µm was used.

Samples were prepared by melt blending using a Vertical DSM and injected in a dumbbell-shape mould. PLLA neat samples and PLLA composite samples with selected ascending particle quantities of 0.5, 1, 5 and 10 wt.% have been aged at 21 ± 2 ºC and 50 ± 5% relative humidity.

Tensile tests and SME were performed on 1 mm thick specimens in an Instron 5565 with a thermal chamber. Thermal transitions and aging were determined by means of differential scanning calorimetry on a DSC 200 (TA instruments).

Results and Discussion
DSC results depict aging effects, a glass transition temperature rise and an enthalpy relaxation signal. The presence of particles modifies the cold crystallization behaviour.

Figure 1 shows the stress-strain curves from which two set of values are obtained: toughness values and yielding energy values. Both are analysed as indicators of the aging effect on the mechanical behaviour.

Regarding the evolution of toughness with aging, the initial high toughness of composite specimens is affected. Samples with 0.5 and 1 wt.% of particles show a brittle behaviour after 10 aging days, while, those with 5 and 10 wt.% of particles remain tough for longer times. Therefore, high toughness PLLA composites are found to be sensitive to the enthalpy relaxation of chains, conditioned by the added particle proportion.

Concerning to the energy values measured, yielding energy values are higher for composite samples than those obtained for neat PLLA. With aging, energy absorption values rise and specimens with 0.5 and 1 wt.% load tend to reach higher absorption values unlike composites with 5 and 10 wt.% of particles, which retain lower yielding energy absorption values over time.

Page 1067 of 2028
Shape memory tests indicate how the addition of BaSO₄ particles and segmental relaxation during physical aging affects on the measurable parameters of programming and recovery stages. Therefore, properties can be tuned by adjusting the particle content in the matrix; yet, storage time of the material is a conditioning factor that must be taken into account.

**Conclusion**

Summarizing, this study comprehends PLLA and the PLLA/BaSO₄ composite as an evolving system over time. Based on the evidence of early aging of the neat polymer, this work focuses on the importance of the durability of the mechanical behaviour and SME of such high toughness composite materials oriented to design reliable bioresorbable devices.

Evaluation of \textit{In-situ} Intrahepatic Strain Distribution under Micro Deformation by Using Multiphoton Microscopy

\textbf{Yuna Nakano\textsuperscript{1}, Yusuke Morita\textsuperscript{2}, Koji Yamamoto\textsuperscript{2}}

\textsuperscript{1} Doshisha University, Graduate School of Life and Medical Sciences, Kyoto, JP; \textsuperscript{2} Doshisha University, Department of Biomedical Engineering, Kyoto, JP

\textbf{Introduction}

It is known that the mechanical properties of cell adhesion substrates can also affect the following cellular events, such as molecular synthesis, phenotypic expression and motility. For instance, changes in the elastic modulus of the artificial cell adhesion materials have an influence on the albumin production of liver cells\cite{1}. It is considered, however, that the mechanical properties of the micro-environment around the liver cell are uneven and anisotropic due to the collagen structure and density in the liver tissue, and those effects on cell activities have not been clarified yet. In this study, we focused on the micro-area mechanical property of liver tissue and evaluated the \textit{in-situ} strain distribution on the basis of the collagen image obtained by a multiphoton microscope (MPM).

\textbf{Experimental Methods}

\textbf{Materials} : In order to acquire the strain distribution generated in liver tissue, we used a chicken liver processed to a cylindrical shape (diameter:4 mm) with a biopsy punch, and the tissue with a 2\% agarose gel mold was installed in a lab-made apparatus capable of loading a micro deformation to the specimen. Before installing, the composite material was immersed in physiological saline for 2 hours, and to avoid the effect of Glisson’s capsule, 0.5-mm thickness of the liver specimen from the surface layer was removed with a medical blade.

\textbf{Analysis and evaluation of liver strain distribution} : Since the second harmonic generation signals can visualize the collagen fibers in living tissue without any fixing and staining, stacking images of the collagen before and after deformation were acquired by using MPM. A displacement of 0.2 mm was applied to the specimen by compressing both sides using stepping motors and the images taken at the center of the liver specimen (picture size: 442 μm × 442 μm) were analyzed using GOM Correlate (GOM), which is one of the strain analysis software using the digital image correlation method. After the equivalent strain distribution generated at the surface of the liver tissue was visualized using a color contour map, the mean collagen amount within each strain region was measured using gray scale value.

\textbf{Results and Discussion}

Figure 1 shows an image of strain distribution overlayed on the collagen image depicted with grayscale. It was found that the strain in the micro area changed with the collagen distribution (maximum magnification: 50 times). From this result, it was found that the various strains were widely distributed in liver tissue depending on the collagen distribution at the peripheral part of the cell and the strain gradient expressed in the tissue could vary within micro distance. Figure 2 shows the histogram of the mean gray value of each contour region calculated from the strain distribution image. It was found that small strain regions tended to show relatively high accumulations of collagen fibers even in micro area of liver tissue.

\textbf{Conclusion}

The intrahepatic strain distribution in the micro region was successfully obtained by using the collagen images before and after deformation. From the results of the strain distribution, it was suggested that the micro-area mechanical properties of live tissue can be affected by the collagen distribution.
Figure 1: Image of strain distribution overlayed on the collagen image, (Bar : 100 μm).

Figure 2: The histogram of the mean collagen amount in each strain using gray scale value.

**Introduction**

The aim of this study is to verify the interactions of different laser wavelengths on the titanium grade 4 and grade 5 surfaces commonly used in dentistry for the creation of implant screws for the replacement of dental missed elements; focusing attention on a new Q-Switch Nd:YAG laser device. To date, dental prosthesis on implants is considered the best solution for the rehabilitation of edentulous areas; this is demonstrated by the fact that around 5,000,000 dental implants are placed every year around the world. Hand in hand with the spread of implantology, there has also been a significant increase in cases of peri-implant disease, a multifactorial disease mainly of bacterial origin which, in the long run, can lead to implant loss. (1).

However, nowadays, it has not yet been possible to identify a truly predictable therapy for the treatment of these pathologies. Among the innovative technologies most used in the treatment of peri-implant mucositis and peri-implant disease, one of the most promising is certainly laser light. (2).

In fact, as already shown by publications in the literature, the use of laser devices is able not only to decontaminate the implant surface and the surrounding areas, but also to stimulate tissue repair, thus speeding up healing times. (3).

**Experimental Methods**

The research was carried out at the DICCA Department at University of Genoa. The two titanium metal surfaces were divided into 5 parts. (fig1). Of these, four were treated with different laser wavelengths and one was used as a control group. The samples were placed inside a bioreactor that faithfully reproduces the oral conditions specifically with the exact oral PH, temperature and humidity, in which they would be found during the interaction maneuvers with the laser lights. The wavelengths examined were: 810nm laser diode with 320um 1.5 w 50hz gated mode 20 sec optical fiber; Nd-yag 1064nm laser with 320um optical fiber 1 W 50Hz 20 sec 5 ms pulse; Erbium-Yag laser 2940 nm optical fiber 320um 1,2 W 30mj 40Hz 20 sec; Q-Switch Nd:YAG Laser 1064 nm with optical fiber 320um 1.2 W 50Hz 20 sec 3 ns pulse. Each of the four sections was treated by coming into contact with the surfaces, to best simulate situations of clinical management. This process was also recorded by a thermal-camera that made it possible to track the temperature variations that occurred on the titanium during exposure to laser light. To verify any damage and their extent on the surfaces, the samples were then analyzed by means of a scanning electron microscope (SEM).

**Results and Discussion**

The microscopic analyzes carried out have shown that the diode laser does not alter the surface of the titanium in the slightest, but during its use it causes an excessive temperature increase of about 25 °C.

Conversely, the Nd: YAG laser, although it causes a lower temperature increase than the previous laser (about 19 °C), greatly damages on the surfaces, creating craters and melting areas. The Er: YAG laser, on the other hand, being used under a constant water jet, does not cause any variation in the temperature of the titanium and only micro morphological alterations, however, not able to make the surface more subject to accumulation of bacterial biofilm. Finally, the Q-Switch Nd:YAG laser, in addition to not causing a rise in temperature above 5 °C, like the previous laser, does not cause surface alterations such as to be able to host bacterial cells.

**Conclusion**
Based on the results obtained, we can state that the most promising device to be used in laser-assisted peri-implant therapy may be the latest generation Q-Switch Nd:YAG laser. The latter, always having a wavelength of 1064 nm, has the same decontaminating and biostimulating properties of the other devices, but, being used with pulse emission mode in nano seconds, it never reaches high temperatures and consequently does not cause superficial alterations of the titanium structure. Nevertheless, these technologies require an excellent learning time on the part of the professional to be properly used in order to significantly improve the oral health of patients.

Introduction

Along with the development of innovative bone substitute materials, an appropriate animal model is essential to investigate in vivo biocompatibility, mechanical properties, degradation, and interaction with host tissue. Most existing preclinical models for evaluating the safety and bone-regeneration efficacy of the tested biomaterial are single-site defect model and vary drastically with anatomical locations. While the mechanism of bone healing often differs by anatomical location, owing to developmental, structural, and functional difference, which is particularly true for maxillofacial wounds (1-2). Taking this into account, the bone healing efficiency of a bone substitute shown at one anatomical defect location cannot ensure that at another. The novelty of this study was to develop a reproducible preclinical model of bilateral critical-sized defects (CSD) at two distinctly different anatomical locations (non-load bearing calvaria and load-bearing mandibular) in one rabbit. It makes each animal served as its own control subject, therefore, maximizing its statistical power for comparative testing by pairwise comparison. This bilateral double-site CSD model was validated by comparing the “gold standard” autograft to the sham (no graft) group. Subsequently, a newly developed 3D-Implant composite mesh material was implanted to assess the utility of this model for demonstrating the potential translational success of new bone substitute materials or tissue engineering constructs.

Experimental Methods

Twenty healthy adult male New Zealand rabbits, weighing 3.5–4 kg was randomly assigned to a sham or an autograft group (n=10 in each group), which were evenly subdivided into two observation periods (4-, and 12-week). The full-thickness cylindrical calvaria (10 mm diameter) defect on frontoparietal region and full-thickness mandibular (11 mm diameter, comprising removal of buccal cortex, tooth roots, and lingual cortex) defect on the body of the mandible were created bilaterally using low speed drilling with saline irrigation. The defect on one side was filled with autograft debris, and the other side was left empty. For further assessing its utility, a multilayer-stacked polycaprolactone/nano-hydroxyapatite composite (PCL/nHA) 3D-implant, fabricated by melt electrowriting was implanted on one side of the rabbits, and the other side was filled by autograft or left empty alternatively. At time points 4- and 12-week, the mandible and calvaria bone defect specimens were harvested and fixed in 10% neutral formalin buffer. Bone regeneration was assessed by microcomputed tomography (micro-CT) imaging and histological evaluation.

Results and Discussion

No clinical concerns were noted during the study, and no animals were euthanized before the experimental endpoints. All animals recovered within 5-6 days after surgery. Animals were euthanized at predetermined time points 4- and 12-week, no macroscopical sign of infection or necrosis was observed in any of the group: in the autograft group, the fragments of bone graft remained stable and integrated well with adjacent bone, and partial healing at 4w and almost complete healing at 12w were observed in both calvaria and mandible defect; while there was only a fibrous cap (associated with scattered ossified areas) at both 4w and 12w in the empty group.

Page 1074 of 2028
The percentage of bone volume ratio (BV/TV) by micro-CT showed that, in calvaria defect, BV/TV of the autograft group (39.52% ± 5.2% and 47.41% ± 5.4% at 4w and 12w, respectively) was statistically higher ($p<0.05$) than that of the empty group (15.20% ± 2.3% and 21.24% ± 3.17% at 4w and 12w, respectively) and 3D-implant group (15.7% ± 1.44% and 19.46 ± 2.5% at 4w and 12w, respectively); similarly in mandible defect, BV/TV of the autograft group (49.57% ± 6.6% and 41.72% ± 1.2% at 4w and 12w, respectively) was statistically higher ($p<0.05$) than the empty group (33.84% ± 2.3% and 26.24% ± 3.81% at 4w and 12w, respectively) and 3D-implant group (14.66% ± 1.7% and 30.42 ± 5.2% at 4w and 12w, respectively). Histological results were concordant with the micro-CT results. Thus, the untreated mandibular and calvaria defects did not heal without intervention (autograft) makes this model a well-defined and standardized CSD model, which is useful for evaluating the experimental 3D implants.

Conclusion
Based on the histological and micro-CT findings of the response of bilateral double site calvaria and mandible defects to autograft and sham, the developed model was validated as the CSD till 12w. For the first time, this study showed that the rabbit has a high tolerance for the studied bilateral double-site CSD model. The encouraging results of 3D-implant imply, though the results of animal models may not perfectly extrapolate to humans, this comparative rabbit model may be a useful tool for reliably assessing and comparing the efficacy of new tissue engineering constructs at two different anatomical locations in one rabbit.

Alginate di-Aldehyde-Induced Oxidative Stress in Endothelial Cells and Fibroblasts: Cell-specific Responses

Hatice Genc1, Jonas Hazur2, Emine Karakaya2, Barbara Dietel3, Faina Bider2, Jürgen Groll4, Christoph Alexiou1, Aldo R. Boccaccini2, Rainer Detsch2, Iwona Cicha1

1 University Hospital Erlangen, Section of Experimental Oncology and Nanomedicine (SEON), Else Kröner-Fresenius-Stiftung-Endowed Professorship for Nanomedicine, Department of Otorhinolaryngology, Head and Neck Surgery, Erlangen, DE; 2 Friedrich-Alexander-Universität Erlangen-Nürnberg, Institute of Biomaterials, Erlangen, DE; 3 University Hospital Erlangen, Department of Cardiology and Angiology, Erlangen, DE; 4 University Hospital Würzburg, Department of Functional Materials in Medicine and Dentistry, Würzburg, DE

Introduction
A hydrogel system based on oxidized alginate covalently crosslinked with gelatin has been utilized for different biofabrication approaches to design constructs, in which cell growth, proliferation and migration have been observed. However, cell–bioink interactions are not completely understood and the potential effects of free aldehyde groups on the living cells have not been investigated. In this study, alginate, alginate di-aldehyde (ADA) and ADA crosslinked with gelatin (ADA-GEL) were characterized via FTIR and NMR, and their effect on cell viability and cellular responses regarding on oxidative stress that caused by hydrogels were investigated in vitro.

Experimental Methods
Fourier-transform infrared spectroscopy (FTIR) and Solid state 13 C NMR spectroscopy were used for the characterization of hydrogels. Suitable oxidation degree was chose by live/dead cell viability assay that performed on NIH/3T3 and EA.hy926 cell lines. Oxidative stress caused by hydrogel systems was analyzed via Flow cytometry on primary endothelial and fibroblast cells. Proliferative state of cells determined with immunofluorescent staining of Ki67 protein.

Results and Discussion
With increasing oxidation degree of ADA, cell viability in NIH/3T3-fibroblasts and endothelial cell line EA.hy926 was reduced, with the strongest cytotoxicity observed after 72 h of culture in ADA with 26% degree of oxidation. This cytotoxicity was related to the presence of free aldehyde groups in ADA system and further investigations were performed to address this question (Fig. 1). Primary human cells, namely fibroblasts and endothelial cells (ECs) were grown in ADA and ADA-GEL hydrogels for 6h, 24h and 72h to investigate the molecular effects of oxidized hydrogels. Cell viability, mechanisms of cell death, intracellular reactive oxygen (ROS) and thiol level were measured using flow cytometry and proliferative state of cells was determined by immunofluorescent staining of Ki67 protein.

Conclusion
Taken together, we were able to show for the first time that two different cell types in contact with an oxidized alginate hydrogel respond with strikingly different reaction paths. We demonstrated that the free aldehyde groups of ADA trigger pathways of intracellular oxidative stress, which ultimately result in either necrotic cell death in cells with low antioxidant capacity, or recovery and renewed proliferation in cells with high antioxidant capacity. The interactions between this sensitive system of chemically active groups in ADA-GEL hydrogels and the cellular responses must be considered in order to design cell-friendly biofabrication approaches.\(^1\)

**Figure 1**

Schematic summary of the study: alginate-di aldehyde hydrogel was prepared by NaIO4 treatment of pristine aldehyde and crosslinked with Ca2 solution. Free aldehyde groups of alginate-di aldehyde hydrogel induce intracellular reactive oxygen species production. Cell types with lower antioxidant capacity react with sudden necrotic death. Cell types with higher antioxidant capacity overcome the oxidative stress and regain their proliferative state.

Different Effects of Grid Blasting on Mechanical Properties of Ceramic Coated Co-Cr Alloys

Christina Mouchtaridi¹, Marta Muñoz Hernández², Marta Multigner Domínguez², Maria D. Escalera Rodríguez², Juaquin Rams², Triantafyllos Papadopoulos¹, Ioannis Eleftheriadis¹

¹ National and Kapodistrian University of Athens, Dental Biomaterials, Athens, GR; ² Rey Juan Carlos University, Mechanical Engineering, Madrid, ES

Introduction
The purpose of this in vitro study was to determine the influence of grit blasting on microstructure and mechanical properties of cobalt chromium alloys coated with porcelain layer.

Experimental Methods
Thirty Co-Cr metal substrates were fabricated according to ISO 9693-1, by Direct Melting Laser Sintering. Ten of them were sandblasted with 50μm Zinc oxide nanopowder and another group of ten substrates were treated with 250μm. The third group of ten substrates were left as received. A commercially available feldspathic porcelain was placed on the 50μm and 250μm sandblasted substrates, and then the specimens were tested for metal-ceramic bond strength with the 3-point bend test, according to ISO 9693-1. The fractured specimens were observed with optical and scanning electron microscopy using electron dispersive spectroscopy to define the mode of failure. X-ray diffraction spectroscopy was conducted to determine changes in crystalline phases after fabrication and the 3-point bend test. Also, profilometry observations were conducted.

Results and Discussion
The differences in modulus of elasticity showed that the bigger the particles of the sandblasting are, the more elasticity the substrate reveals. The metal-ceramic bond strength for both of the groups was cohesive. The metallographic analysis of the as-received, the after porcelain firing, and the after 3-point bend test specimens revealed changes in microstructure. The crystallographic microstructure revealed that the patterns had minor changes among the groups. The profilometry, also indicated that the bigger the sandblasting particles were used, the smoother the surface was.

Conclusion
Sandblasting does not affect to the adhesion between the metal substrate and the ceramic layer. The study revealed that all of the techniques showed similar results. The modulus of elasticity and metal-ceramic bond strengths revealed that the bigger the particles of the sandblasting is the higher the mechanical properties are. The mode of failure was cohesive. The profilometry revealed differences among the three groups.

Introduction
Biofabrication is a disruptive manufacturing paradigm that utilises the metabolism of bio-organisms to produce complex living and non-living structures with advanced functionalities.

The use of fungal micro-organisms as cell factories in biofabrication is opening great possibilities for converting residues of agroindustrial value chains into renewable and compostable mycelium-based materials (myco-materials).

Such materials represent alternatives to a range of traditional materials/products, such as petroleum-based foams and plastics, textiles, and others [1]. Despite the number of publications on biofabricated myco-materials, in the literature there are few studies about their mechanical properties.

This work aims to experimental investigate the behavior of several categories of such materials.

Experimental Methods
Different types of chitin-based myco-materials produced by MOGU S.r.L are investigated (Figure 1). In particular, we perform a mechanical characterization through tensile and tear tests (Figure 2). Three standards referring to leathers are selected to conduct these tests. In particular, EN ISO 3376 is used for the determination of tensile strength and elongation at break, while EN ISO 3377-1 (single-edge tear) and EN ISO 3377-2 (double-edge tear) are used for the determination of tear load.

Results and Discussion
Tensile strength, elongation at break, Young's modulus, and tear loads are obtained from the performed tests. Results demonstrate that the properties of the analyzed myco-materials vary according to the production procedure, plastification, and post-treatments. The mechanical results obtained are satisfactory and promise a future full of possibilities for the use of chitin-based myco-materials in different applications. The examined materials are also pleasing to the eye and to the touch, similar to traditional petroleum-based leather-like materials. The color range obtainable in a natural way is varied and similar to the classic leather colors. This, combined with the mechanical properties found, makes, among other applications, the use of these materials in the textile industry of alternative leather very close.

Conclusion
All the achieved experimental results enrich the knowledge in the literature about the mechanical responses of myco-materials and are fundamental for providing guidelines on how to proceed in the design of targeted industrial products. Further investigations are essential to enable the full potential of mycelia to be used for a revolution in the world of alternative materials. The potential field of interest are multiple including automotive, packaging, insulation, wearable, building/construction, aerospace, and biomedical applications such as wound healing, bio-sensing, and drug delivery.

Thin silica microsheets as a new biomaterial concept for Tissue Engineering applications

Marta M. Maciel1,2, João Borges2, Pavel A. Levkin3, Sónia G. Patrício2, Tiago R. Correia2, João F. Mano2

1 University of Minho, CEB- Centre of Biological Engineering, Braga, PT; 2 University of Aveiro, CICECO- Aveiro Institute of Materials, Aveiro, PT; 3 Karlsruhe Institute of Technology (KIT), Institute of Biological and Chemical Systems-Functional Molecular Systems(IBCS-FMS), Eggenstein-Leopoldshafen, DE

Introduction
In Tissue Engineering (TE), the engineering of highly bioactive materials with specific shape is extremely challenging when incorporating mammalian cells. Limiting factors such as materials processability, scaffold design and implantation into the host can result in functionality and survival restrictions for mammalian cells. To overcome these scenarios, efforts have been made, especially, using encapsulation-based systems to maintain cell integrity and functionality. Yet, most of them do not present adequate stiffness or specific cell binding domains. Microfabrication have been pointed out as a valuable method used to produce highly complex architectures with increased precision. For instance, inorganic materials have become an interesting source for developing new platforms due to properties like inertness, stiffness, easy functionalization and processability to produce materials with specific features and sizes. This work reports the high throughput fabrication of thin silica-based microsheets as a new concept of biomaterial platform to potentially guide cell fate in TE applications. Different geometries will be fabricated and compared to achieve the best shape for TE purposes.

Experimental Methods
The microarrays used on silica microsheets production were obtained by a protocol described by Feng and colleagues. (1) Silica-based microstructures were fabricated under acidic conditions as previously described (Figure 1). (2) Briefly, a gelatin (gel strength 300 g Bloom) solution was used to create a sacrificial layer to avoid silica interaction with the microarray surface. After gelation, a sol-gel method was performed by using a previously hydrolysed tetramethylorthosilicate (TMOS) (Sigma-Aldrich) solution that was applied under the gelatin layer and dried for 5 min at 37 ºC. To recover silica microstructures from the arrays, the glass slides were incubated at 60 ºC in a water bath until their detachment. The resulting microstructures were collected and characterized through different techniques (FTIR, XRD, SEM). A simulated body fluid assay was also carried out to investigate the mineralization capacity of the produced silica-based microsheets.

Results and Discussion
The results revealed the successfully manufacture of porous silica microstructures with defined shape and a thickness of 7mm (Figure 2). Moreover, microsheets bioactivity potential was confirmed by carrying out a simulated body fluid assay (Figure 2). Flower-like shape hydroxyapatite crystals were formed at the surface of the microsheets. In a near future, a Janus-like design (Figure 1) using different cell types is intended by functionalizing microsheets surfaces with suitable bioinstructive cues (e.g., antibodies, ions, peptides), providing the biochemical and biophysical cues to recruit the different living units in a controlled manner.

Conclusion
A novel and simple strategy for fabricating free-standing thin silica microstructures with well-defined geometry was reported. This enabling technology has a widespread potential not only due to silica properties but also due to the simplicity of processing. The possibility to control the sol-gel reaction allows the manufacture of other type of geometries or even use of other type of inorganic materials and hybrid systems. We envision that future studies will
enable to produce microparticles with high control over the microstructure, including mesopores with fixed geometries and sizes, and surface post-functionalization, that could find new applications in bottom-up Tissue Engineering area.

Strut spreading measurements as shape fidelity prediction tool

Stefan Schruefer, Dirk W. Schubert

Friedrich Alexander University Erlangen Nuremberg, Material Science / Polymer Physics and Processing, Erlangen, DE

Introduction
Shape fidelity is a key property, besides biological compatibility, for newly developed bioinks. Therefore, shape fidelity characterization methods evolved from comparative or binary (good/bad) methods towards more analytical approaches. Various researchers have tried more reliable and comparable data generation to reveal relevant correlations between material properties and the results of printing experiments. Common printability assets still rely on “one-picture” approaches and do not consider sufficient data to capture the visco-elastic nature of hydrogels during printing. Rheological properties of bioinks are often in the focus for predicting the printability of such materials. However, the key parameters for reliable predictions are yet to be revealed, which results from two main issues of classic rheological characterizations. First, many characterizations in the literature are not closely related to the real process conditions, which especially limits the information value for thermal responsive materials such as gelatin or collagen. A short guideline to improve the data quality is given in the scope of this presentation. Furthermore, the vast variety of potential information given by rheological measurements can mislead scientists during the evaluation process.

Experimental Methods
Therefore, we developed a novel approach to reveal rheological model parameters from commonly performed frequency sweeps. The evaluated traditional rheological equivalent circuits, consisting of springs and dashpots, can reduce the frequency dependent material properties to only two to four parameters, which include all necessary information to describe the viscoelastic nature of hydrogels and bioinks. During first evaluations, another major challenge did become evident. Many hydrogels and bioinks do show spreading behavior, which is not covered by common printability evaluation assets. Therefore, a novel set-up to evaluate the time-dependent strut diameter was developed. Fiber-filled alginate composites are used as model systems for tunable hydrogels. Therefore, we blended PH176 Alginate solutions of various concentrations (3 and 4 wt.%) with different degrees of fiber fillers. For this study, low aspect ratio poly-ε-caprolactone (PCL) fiber fragments and cellulose nanofibers are investigated. Furthermore, silicon oils of different viscosities (Wacker AK50 – AK5000) are analyzed in order to reveal artifact free correlations of rheological properties and spreading kinetics.

Results and Discussion
Rheological modelling revealed an augmented form of the burgers model as most suitable model system for all composite. Subsequent analysis of fiber-filled alginites revealed a clear correlation between process properties, namely material throughput and printing speed, rheological model parameters and the observed time-dependent strut spreading. The evaluation of silicon oil enabled detailed and artifact free modeling. The rheological properties of alginate composites altered by increasing the fiber infill of alginate composites, which also influenced the resulting rheological model parameters. The spreading behavior of composites can be drastically reduced by adding only 2 wt.% of cellulose nanofibers. Low amounts of PCL fiber fragments did not show a significant influence on the rheological and printing properties. Increasing fiber infill (>5 wt.%) also did reduce the spreading of the investigated hydrogel composites.

For further correlations between rheological properties and spreading characteristics Statistica, a statistical data evaluation software, is used. Here, a variety of possible parameters, ranging from the revealed model parameters to
traditional rheological parameters, such as the zero shear viscosity, and process characteristics are evaluated. The subsequent elimination of statistical non-relevant parameters did lead to two main influencing factors. Here, the ratio of material throughput and print speed as well as the viscosity of the Maxwell-dashpot (of the Burgers system) did emerge as key criteria for describing the spreading behavior of all composite systems. Those key criteria can potentially be used to predict the shape fidelity of bioinks from rheological measurements.

**Conclusion**
The here presented data did reveal a two distinct diameter-time-dependencies for hydrogel composites, that is not considered in conventional evaluations of printability. Therefore, an improved method for robust and analytical printability evaluations is established. Furthermore, a clear correlation of rheological measurements and printing results is revealed. The generalization of our findings is in progress.

The biocompatibility of novel citric acid-based biomaterials modified with D-panthenol for vascular tissue engineering

Agata Flis¹, Martina Trávníčková², Filip Koper³, Lucie Bačáková², Tomasz Świergosz³, Wiktor Kasprzyk³, Elżbieta Pamuła¹

¹ AGH University of Science and Technology, Department of Biomaterials and Composites, Cracow, PL; ² Institute of Physiology of the Czech Academy of Sciences, Department of Biomaterials and Tissue Engineering, Prague, CZ; ³ Cracow University of Technology, Department of Physical Chemistry and Biotechnology, Cracow, PL

Introduction
Poly(alkylene citrates) (PACs) are novel biodegradable elastomers with potential application as substitutes of small blood vessels or as surface modifiers of the commercial Dacron® and ePTFE vascular prostheses. The advantages of PACs are non-toxic monomers and simple synthesis, which can be performed under mild conditions, as well as controllable mechanical properties and biodegradation kinetics. In addition, the PDC structure can be easily modified with D-panthenol to provide it with anti-oxidant properties. In this study, we report the results of two experiments on PACs modified with D-panthenol. In the first one, we used L929 cells to test cytocompatibility of 6-oxo-3,4-dihydro-2H,6H-pyrido[2,1-b][1,3]oxazine-8-carboxylic acid (ODPC), i.e. a product created during reaction of D-panthenol [AH1] with citric acid during polymerization, which is expected to be present in the modified PACs. In the second experiment, we tested PACs modified with D-panthenol in contact with human umbilical vein endothelial cells (HUVEC).

Experimental Methods
For isolation of pure ODPC, citric acid and D-panthenol at molar ratio of 1:1 were reacted (1 h, 180°C, 100 rpm), dissolved in methanol, separated by preparative liquid chromatography and freeze-dried. To test the potential cytotoxicity of ODPC, this compound was diluted in a DMEM medium in the concentrations of 1, 0.1, 0.01 and 0.001 mg/ml, and sterilized by filtration (0.22 μm syringe filter). L929 cells were seeded in 96-multiwell culture dishes at a concentration 5x10³ cells in 200 μl DMEM, and cultured for 24 h at 5% CO₂, 37°C. Next, the culture medium was aspirated and replaced by an ODPC solution with defined concentration or with a fresh medium (control sample). The viability of the cells was evaluated using live-dead staining (calcein-AM/propidium iodide based). The cell metabolic activity was measured using Alamar Blue assay (10% w/v resazurin sodium salt solution in phosphate-buffered saline). PACs were synthesised through polycondensation of citric acid with 1,6-hexamethylenediol or 1,8-octamethylenediol at molar ratio of 2:3. In brief, reagents were melted at 140°C for 40 min under stirring and subsequently purified, resulting in liquid prepolymers, in which D-panthenol at 0.4% or 0.8% concentration was added. Afterwards, the prepolymers aliquots were poured in 96-well plates and left for cross-linking for 8 days in a vacuum oven at 80°C, 200 mbar. Non-modified poly(1,6-hexamethylene citrate) (cPHC) and poly(1,8-octamethylene citrate) (cPOC) and those modified with D-panthenol (cPHC_P) and (cPOC_P) were sterilized with 70% ethanol and exposed to the UV light for 30 min. HUVEC in early passage, cultured in EGM-2 medium, were seeded on materials at a density of 5x10³ cells into 96-multiwell plates. After 24 h and 72 h, the cells were stained with hematoxylin/eosin and their morphology was assessed. The number of adhered cells, the cell spreading area and the cell aspect ratio were calculated.

Results and Discussion
In the first experiment involving L929 cells, the live-dead staining revealed almost all cells alive irrespectively of the ODPC concentration; the cell morphology was the same as in control conditions. Cells were distributed evenly and formed a monolayer after 72 h. The metabolic activity of cells in medium supplemented with ODPC in all studied concentrations was the same as in control conditions, what confirmed non-toxicity of ODPC. Higher D-panthenol
concentrations (4 and 8%) in PACs were found to impede the HUVEC adhesion and growth. Low concentrations of D-panthenol (0.4 and 0.8%) in cPHC_P and cPOC_P materials did not have a negative influence on the HUVEC morphology. The cells were less spread in comparison with their culture on TCPS, although they maintained their characteristic shape. Moreover, the cell viability and growth on cPOC were lower as compared to cPHC.

**Conclusion**
Tests with L929 cells showed that ODPC is non-toxic irrespectively of the concentration used. cPHC and cPOC were successfully synthesised and modified with D-panthenol. According to in vitro tests, cPHCs containing 0.4% and 0.8% of D-panthenol were found to be more compatible with HUVEC than cPOC. Thus cPHC seems to be prospective for vascular tissue engineering purposes. It will be further examined in terms of ability to support endothelial, smooth muscle and mesenchymal stem cell adhesion, proliferation and differentiation with the final goal to reconstruct small blood vessels.

Improving osteogenic response of electrical discharge machined Ti6Al4V by plasma treatment

Deepak Rajendra Unune¹, Russell Goodall¹, Frederik Claeyssens¹, Gwendolen C. Reilly¹

¹ University of Sheffield, Material Science and Engineering, Sheffield, GB; ² University of Sheffield, Insigneo Institute of in silico Medicine, Sheffield, GB; ³ The LNM Institute of Information Technology, Department of Mechanical-Mechatronics Engineering, Jaipur, IN

Introduction
Ti6Al4V alloy usually need to undergo surface treatment to enable good bone growth and implant integration. Electrical discharge machining (EDM), owing to its simultaneous machining and surface modification ability, has emerged as a new trend for processing of biomaterials [1]. However, EDM treated surfaces are hydrophobic in nature which affect the osseointegration capabilities of the treated metal for implant applications. In this work, air plasma treatment is proposed to improve the hydrophilicity of EDM processed Ti6Al4V and to promote bone regeneration by supporting cell proliferation and differentiation.

Experimental Methods
Ti6Al4V plate was cut to prepare samples of 8mm X 8mm X 2mm size. Prepared sample were polished using Silicon Carbide papers from #400 to #1200 on a grinding machine and used for further treatments. Polished samples were used as control group. Two types of EDM treatments were performed including plain dielectric and hydroxyapatite mixed dielectric and samples were labelled as ‘EDM’ and ‘H-EDM’, respectively. EDM processing performed at a pulse current of 5 A and pulse-on-time of 15 µs. Air plasma was applied on EDM treated surfaces of with a power of 50 W and a pressure of 0.8 mbar for 60 s to improve cell attachment to the hydrophobic surfaces. The water contact angles were analysed using a drop shaper analyser with a 5 µL water droplet on all surfaces. The average surface roughness (Rₐ) of samples was evaluated using an optical focus variation microscope. Prepared samples were cultured using the immortalized bone marrow stromal cell line (Y201) [2]. To induce osteoblastic differentiation, osteogenesis induction media was added 24 h after seeding and changed over every 2-3 days. Resazurin reduction assays were performed to determine the appropriateness of treated samples for cell growth. Calcium deposition was evaluated through Alizarin Red S (ARS) staining analysis performed and the collagen deposition was evaluated using Sirius Red Stain Assay (SRS) assay on day 21 of cell culture.

Results and Discussion
Figure 1 (a) revealed generation of porous surface coating on Ti6Al4V, known to enable bone “ingrowth” into the implant and promoting a better bone-material connection. Plasma treatment significantly reduced the water contact angle of both EDM and H-EDM processed surfaces, thus inducing hydrophilicity post EDM processing (Fig.1(b)). H-EDM supported better Y201 cell growth and differentiation, as compared to EDM treatment, probably due to the coating containing Calcium and Phosphorous. Furthermore, plasma treated samples (EDMPT and H-EDMPT) supported enhanced metabolic activity of Y201 cells, in terms of Resazurin fluorescence (Fig. 1(c)), indicating a net increase in the viable cell number. Similarly, increased extracellular calcium deposition and collagen deposition was found for both EDMPT and H-EDMPT samples, as compared to EDM and h-EDM samples, respectively (Fig. 1(d,e)).

Conclusion
EDM is a promising technique for concurrent synthesis of an accurate shape of a biomaterial and provision of a favourable cell compatible surface for orthopaedic and dental applications. Hydroxyapatite containing dielectric EDM processing has shown better capacity for cell growth and osteogenic differentiation than that of pure dielectric based EDM. The proposed plasma treatment induced hydrophilicity and surface free energy to the implant surface post
EDM processing. Furthermore, plasma treatment has contributed to improved growth and osteogenesis of Y201 cells. Thus, plasma treatment can be exploited as an effective way to promote the formation of bone-like material on EDM treated implant surfaces.

Influence of copper-substitution in calcium phosphate ceramics on endothelial cells

Arthur Brunel, Esther Pagès, Amandine Magnaudeix, Eric Champion

Université de Limoges, CNRS, Institut de Recherche sur Les Céramiques, UMR 7315, Limoges, FR

Introduction

Hydroxyapatite (HA) possesses a high biocompatibility making it an interesting candidate for bone graft substitutes. However, the use of HA scaffolds for the repair of large bone defects is hindered because of their inability to promote vascularization and blood vessel invasion within the porous network. Copper in its Cu(II) form is known to significantly stimulate endothelial cell (EC) proliferation with concentration as low as $10^{-5}$M (1). However, it can also induce cytotoxicity. The objectives of this study are to assess the biocompatibility of a novel copper-substituted hydroxyapatite (2) and to evaluate whether it promotes EC proliferation and/or activation.

Experimental Methods

Dense copper-substituted hydroxyapatite ceramics pellets containing 0.8 and 3.8 wt% of copper (Cu0.1HA: Ca$_{9.9}$Cu$_{0.1}$(PO$_4$)$_6$(OH)$_{1.9}$O$_{0.1}$ & Cu0.5HA: Ca$_{9.5}$Cu$_{0.5}$(PO$_4$)$_6$(OH)$_{1.5}$O$_{0.5}$, respectively) are seeded with C166 murine EC and cultured for up to 96h. EC viability is assayed using MTT metabolic assay or in situ calcein staining. Apoptotic cells are detected in immunofluorescence targeting cleaved-caspase 3. Proliferation is tested by incorporation and in situ detection of EdU. Proteins whose shift in expression is linked to EC function and activation such as MMP-9, VEGFR-2 or vWF are monitored by Western Blot. Wound healing assay is performed to evaluate migration and activation of EC. Finally, the release of ionic species in culture medium is characterized chemically by inductively coupled plasma.

Results and Discussion

Metabolic activity results indicate a good biocompatibility from the Cu0.1HA material with values comparable to the HA standard. On the other hand increased copper concentration in the Cu0.5HA material induces a loss of metabolic activity over time. Nonetheless, early results show similar cellular viability and no excess of mortality through apoptosis between the different materials. However, no adverse or positive effect on proliferation is found. Similarly MMP-9 enzyme levels are comparable between the tested materials. Further characterization are on the way to thoroughly assess their biological effects.

Conclusion

This novel copper-doped material shows comparable biocompatibility to the gold standard hydroxyapatite with the C166 EC.

Mechanical modeling of the porcine abdominal wall through a hyperelastic model.

Javier Ortiz-Ortiz, Georgina Carbajal-de-La-Torre, Marco A. Espinosa-Medina, Hilda Aguilar-Rodriguez, Ma. Lourdes Ballesteros-Almanza

Introduction
The abdominal muscles are responsible for biological functions such as breathing, containment, and protection of organs and tissues. The knowledge of the mechanical behavior of the abdominal wall is essential for the development of prostheses and techniques that generate favorable results for patients suffering from abdominal wall hernias. In the present work, an animal model of mechanical behavior in the transverse and perpendicular directions is proposed based on experimental data collected from porcine abdominal tissue due to the similarity concerning the human.

Experimental Methods
Abdominal wall muscle tissue samples were collected from pigs between 4 and 6 months of age. The samples were cut in the longitudinal and transverse directions to be analyzed in the CellScale® brand Univert® test machine. While the tests were being carried out, the samples were immersed in a saline solution to prevent dehydration. The data obtained were treated to obtain the stress-strain curves in each direction and in a next step to adjust the curves in the COMSOL Multiphysics® software using its optimization tool through the Levenberg-Marquardt least-squares algorithm. Various hyperelastic models were tested until the material model that best fits the experimental data is obtained.

Results and Discussion
The parameters of a hyperelastic model were obtained from experimental data for the longitudinal and transverse directions of the abdominal muscles of the pig, to obtain an animal model that is representative of the mechanical behavior of the human abdominal wall. Different mechanical behavior is observed in each direction, depending on the direction of the collagen fibers.

Conclusion
The generated model helps to describe the mechanical behavior of the abdominal wall in pigs, due to the similarity of the pig tissue concerning the human tissue, this model can be used in finite element analysis that generates results closer to the real behavior concerning to traditional mechanical behavior models.

3D printing strategy to design anisotropic and macroporous dense collagen hydrogels for tissue engineering applications

Marie Camman\textsuperscript{12}, Onnik Agbulut\textsuperscript{2}, Christophe Hélary\textsuperscript{1}

\textsuperscript{1} Sorbonne Université, CNRS, UMR 7574, Laboratoire de Chimie de la Matière Condensée de Paris, Paris, FR; \textsuperscript{2} Sorbonne Université, Institut de Biologie Paris-Seine (IBPS), CNRS UMR 8256, Inserm ERL U1164, Paris, FR

Introduction
Thanks to its biocompatibility and its biodegradability, collagen I is broadly used in tissue engineering to develop biomaterials such as dermal substitutes, scaffolds for neurons guidance or cardiac patches\cite{1}. Collagen based hydrogels, usually fabricated from low concentrated collagen solutions, are characterized by poor mechanical properties and low physical stability with a significant shrinkage by encapsulated cells\cite{2}. To circumvent these drawbacks, the addition of synthetic polymers or cross-linking are required to improve collagen hydrogel physicochemical properties\cite{3}. An original approach is to increase collagen concentration. Dense collagen hydrogels concentrated at 30 mg.mL\textsuperscript{-1} exhibit high mechanical properties, do not shrink and are stable over several weeks after in vivo implantation\cite{4}. However, their high collagen concentration limits cell infiltration and neovascularization from the host. In this study, dense macroporous collagen hydrogels have been shaped by 3D printing to better mimic extracellular matrix physical properties while promoting cell migration. In addition, intrinsic anisotropy of collagen fibrils has been generated by extrusion through the needle during printing within hydrogels to favor cell alignment, property required for axon growth or cardiomyocyte organotypic growth.

Experimental Methods
The 3D printing of dense collagen solutions (30 mg.mL\textsuperscript{-1}) allowed an easy hydrogel shaping and the alignment of collagen triple helices to form an anisotropic scaffold. The printing process by extrusion was performed within a gelation bath to set the collagen anisotropy quasi instantaneously and form fibrils. Besides, macropores were created using needles or a sacrificial matrix. This step created large macropores, appropriate for cell culture which will favor better cellular infiltration. The anisotropy of the final hydrogel was examined by polarized light and second harmonic generation microscopies. MicroCT was also performed to control and measure porosity. Finally, fluorescent light microscopy was performed to observe cells and their alignment on top of anisotropic collagen.

Results and Discussion
The first goal was to obtain anisotropic collagen gels. Combining a flat bottom extrusion needle and the suitable extrusion speed, collagen molecules aligned during the 3D printing process along the needle axis. However, the viscosity was too low to prevent relaxation. To tackle this issue, the collagen solution was printed within a buffer bath to trigger a rapid gelling. After the end of the 3D printing process, the gelling time was extended (from 24h to 7 days) using different gelling conditions. Ammonia vapors (30\% in aqueous solution) enabled the formation of collagen hydrogels with high mechanical properties (E=10 kPa) but without anisotropy. On the opposite, phosphate buffer 5X generated a gel with lower mechanical properties (E=3 kPa) but preserved collagen anisotropy. The anisotropy occurrence was observed by polarized light (Figure 1- A and B) and SHG microscopy (Figure 1- C). Gelling in a PBS 5X bath for two days followed by an incubation under ammonia vapors for one day was the optimal condition to generate anisotropy and high mechanical properties. To assess the impact of anisotropy on cells, fibroblasts were seeded on top of the printed hydrogels. Fibroblasts aligned along the collagen fibrils of anisotropic hydrogels following the axis of printing whereas they exhibited a random orientation on isotropic hydrogels only gelled by ammonia vapors (Figure 1- D and E). Beside anisotropy, the 3D construct requires a high porosity to allow cell colonization. Without 3D printing, there is no porosity within collagen hydrogels (Figure 2- A). Our novel 3D printing process generated an
intrinsic porosity of 20-40 µm in diameter between the different layers (Figure 2 - B). This porosity is suitable for vascularization or neuronal guidance. However, some tissues require a larger porosity to induce 3D organotypic cell growth. To increase the scaffold porosity, the addition of macroporous channels with sacrificial matrix printing or needles molding created larger channels ranging from 100 to 500 µm (Figure 2- C). These bigger channels were adequate for a 3D organotypic organization of cardiomyocytes. The porosity of the gels was controlled by microCT imaging and revealed well defined 300 µm pores with the needles process. In a heart tissue model, combining anisotropy and macroporosity is required to ensure a good conduction of the contraction and cell survival inside the gel.

**Conclusion**

These results demonstrate the performance of 3D printing of dense collagen solutions to generate elaborated biomaterials with macropores and anisotropy. Their characteristics can be tuned to suit for a specific field of applications. Small pores will be useful for neuronal guidance whereas larger pores will adequate to model bundles of muscle fibers.

Introduction

Brain modelling is mostly based on 2D in vitro or animal models but none offer the best solution to understand this organ and its related diseases. Recently, 3D in vitro models have been explored as they resemble more accurately physiological conditions. However, neuronal cultures face a challenge due to their high sensitivity to changes in their surroundings.

Experimental Methods

In this work we present a hydrogel composed of methacrylated gelatine and alginate for neural progenitor cell culture. Hyaluronic acid was added to this hydrogel composition to better mimic the native tissue. This material was characterized in terms of its Young Modulus and swelling capacity. Compatibility with neuronal cell culture and differentiation was also tested during 8 or 28 days in vitro.

Results and Discussion

Results showed that hydrogels with and without hyaluronic acid have good porosity, allowing nutrient and oxygen diffusion. They also present low Young Modulus, especially for hyaluronic acid formulation, rendering values similar to brain tissue. Comparing these new materials with Matrigel for 8 days, our formulations allowed neuronal proliferation and differentiation with high viability rates. After 28 days, the hydrogels in culture presented minimal degradation and cells showed projection growth, increased connectivity and expression of neuronal markers.

Conclusion

Overall, these results make these hydrogels a promising scaffold for induced pluripotent stem cells long-term culture and differentiation.

Maximum projection of immunostaining confocal images.

C17.2 cells after 28 days of differentiation embedded in (A) methacrylated gelatin and alginate or (B) methacrylated gelatin, alginate and hyaluronic acid.

Tailoring the physicochemical properties of tricalcium phosphate-based porous scaffolds

Joanna Czechowska, Szymon Skibiński, Ewelina Cichoń, Anna Ślósarczyk, Aneta Zima

AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Krakow, PL

Introduction
Implantable 3D scaffolds are widely applied for the restoration and reconstruction of bone defects. Recently, the focus is put towards biodegradable, macroporous templates with similarity to bone architecture. The most promising biomaterials applied for 3D scaffolds are tricalcium phosphates (α-TCP, β-TCP) due to their biodegradability and biocompatibility [1]. The production of scaffolds with favourable microstructure is one of the critical success factors in biomaterials development. The porosity parameters impact inter alia scaffolds permeability, cells infiltration, and angiogenesis [2].

Experimental Methods
In our study, the initial β-TCP powder was synthesized via the wet chemical method. Afterwards, three different methods of powder preparation were applied. Based on results from electrokinetic potential, specific surface area (BET) and grain size measurements by dynamic light scattering (DLS) the most favourable method of β-TCP powder preparation was chosen. Tricalcium phosphate-based scaffolds were prepared by a polymer sponge replication method. In order to tailor their physicochemical properties, different polyurethane matrices and various amounts of a solid phase (powder) per polyurethane sponge were used. Obtained materials were investigated by various techniques including powder X-ray diffraction, X-ray fluorescence, scanning electron microscopy, hydrostatic weighing and compression tests.

Results and Discussion
It was found that both the porosity and the mechanical properties of the scaffold depended on the kind of polymer sponge and the amount of β-TCP powder used. XRD analysis revealed that all materials composed of β-TCP 97 ± 1 wt% and α-TCP 3 ± 1 wt%. The microstructure of bioceramic scaffolds was characterised by a network of interconnected spherical pores with sizes between 100 to 1000 µm (Fig.1). Obtained materials possessed open porosity in the range of 56 to 70 vol% and compressive strength between 2.4 ± 0.7 and 4.8 ± 1.0 MPa. These results correspond to the porosity and compressive strength of spongy bone, which means they might act as potential scaffolds for bone tissue regeneration.

Conclusion
Developed biomaterials are promising candidates for bone tissue engineering. Further biological studies are needed.

Development of the vibration stimulating culture system to evaluate cell activity under microscope

Yuki Masuda\textsuperscript{1}, Koji Yamamoto\textsuperscript{2}, Yusuke Morita\textsuperscript{2}

\textsuperscript{1} Doshisha University, Graduate School of Life and Medical Sciences, Kyoto, JP; \textsuperscript{2} Doshisha University, Department of Biomedical Engineering, Kyoto, JP

Introduction
Bone implants need to attach to bone in a short period after implantation. Mechanical stimulation with daily motion is involved in bone remodeling, and treatment with low-power high-frequency vibration and low-power ultrasonic vibration have been attempted in bone fracture treatment. Therefore, it is expected that vibration stimulation is effective to enhance bone formation at interface for early fixation between living bone and replacement implant. Vibration stimulation using a vibrating generator promoted cell proliferation and ALP activity of osteoblast-like cells \cite{1}. It is considered that vibration stimuli from outside of body propagates and affects to attached cells via surface of bone and implant. It is necessary to evaluate quantitatively evaluate effects of vibration stimulation on cell activity through adhesion surface to clarify the effect of vibration stimulation on bone formation. The purpose of this study was to develop the culture system that has vibration stimulation generated on culture surface and enable to evaluate effects of vibration stimulation on activity of MC3T3-E1 under a microscope.

Experimental Methods
The developed culture dish consisted of polypropylene chamber, PVDF as bottom surface and two ring-shaped electrodes (Fig.1(a)). PVDF was coated with PEDOT / PSS on both sides. Vibration stimuli was generated during cultivation by applying AC voltage to both sides of PVDF through ring-shaped electrodes. The culture area of the culture dish was 10 mm in diameter. MC3T3-E1 cells were cultured for on glass slide coated by PEDOT / PSS of 1.0, 1.5, 2.0 \% coating concentration to determine the concentration without toxicity. The glass slide without PEDOT/PSS was prepared as the control. After 1 and 3 days of cultivation, the number of adherent cells were evaluated by using MTT assay. Generated vibration stimulus with AC voltage were validated by measuring amplitude of vibrated culture surface with a laser doppler vibrometer. Applied frequencies were 3, 4, 5, 10, and 15 kHz and voltages were 2.5, 5, and 10 V\textsubscript{p-p}. Measuring points were center and points 2 mm and 4 mm from center. MC3T3-E1 cells were cultured for 12 hours in the culture dish, and then the cells were cultured for 12 hours under vibration stimulation with AC voltage of 15 kHz and 10 V\textsubscript{p-p}. MC3T3-E1 cells cultured for 24 hours without stimulation were prepared as the control. Expression of actin fibers and nuclei were observed with a fluorescence microscope to evaluate effects of vibration stimulation.

Results and Discussion
PEDOT / PSS showed low toxicity is not toxic, and number of attached cells increased with decreasing coating concentration of PEDOT / PSS. PEDOT / PSS concentration of 1\% was determined to coat both sides of PVDF. Figure 1 (b) shows the results of measurement of amplitude generated in the culture area under AC voltage of 15 Hz and 10 V\textsubscript{p-p}. Amplitudes at all measuring points showed sinusoidal wave form. The amplitude at the center was 0.185 \mu m, and amplitude value decreased toward the outer peripheral side of the culture chamber. Amplitude increased with increasing applied voltage and frequency. These results showed that vibration stimulation on culture surface can be controlled by the voltage and frequency. Figure 2 (a) and (b) show the fluorescence observation images. Development of actin fibers of MC3T3-E1 cells under by vibration stimulation was observed in comparison with the cells without stimulation. Vibration stimulation did not cause cell detaching from culture surface. It is expected that the developed culture system can evaluate effects of vibration stimulation on cell activity under an optical microscope.
Conclusion
We developed the culture system that enable to control vibration stimulation of the culture surface and evaluate cell activity under a microscope.

Introduction
Malignant bone tumors are one of the main non-trauma factors resulting in critical size bone loss/defects. The subsequent regeneration of such defects still represents a clinical challenge [1]. Grafting procedures are considered the standard treatment for such bone defects. However, such implants in most cases result in unsuccessful repair of the defect. Moreover, after tumor extirpation, the local recurrence of the tumor cells is a major concern that requires further treatment as well. Therefore, a polymeric scaffold for bone regeneration that simultaneously kills residual tumor cells is of much benefit. Magnetic hyperthermia using superparamagnetic iron oxide nanoparticles (SPIONs) has emerged as a potential cancer treatment option since it is considered an effective treatment without adverse side effects [2]. On the other hand, mesoporous bioactive glasses (MBGs) dissolution products have demonstrated their effect on osteoblast cell gene expression and the potential effect on angiogenesis and neovascularization, which in turn promotes bone healing. Moreover, these systems can form an interfacial bond with bone tissue. We therefore propose a new concept for the treatment of bone cancer and the regeneration of bone defects: a polymeric scaffold produced by electrospinning containing MBG that combines magnetic hyperthermia therapy through the incorporation of the SPIONs into the scaffold [3].

Experimental Methods
The experimental work to produce the multifunctional scaffolds is divided into 3 parts: 1) production and characterization of SPIONs and MBGs individually; 2) Incorporation of these individual materials into a polyvinylpyrrolidone (PVP) solution; 3) Characterization of such composites. Herein we synthesized a sol-gel-derived MBG by templating with a block copolymer (pluronic F127) that acts as a structure-directing agent through an evaporation-induced self-assembly process [4]. MNPs were synthesized by chemical precipitation with a core diameter of about 10 nm. The electrospinning process was optimized through the design of experiments (DOE) method using the JMP software. Different electrospinning solutions of PVP/SPIONs (2, 5, and 8% of polymer's mass) and PVP/MBG (10, 28, 56, 83, 100% of polymer's mass) were prepared in order to obtain polymeric composites, which were then thermally crosslinked. Polymeric composite with both SPIONS and MBG added to the electrospinning solution was also prepared. The composites are under characterization in terms of heating ability, bioactivity, cytotoxicity, degradation rate, and swelling capability.

Results and Discussion
The produced MBG powder (Fig. 1 A, D) was morphologically characterized by N2 porosimetry (BET specific surface area of 232 m²·g⁻¹; BJH pore volume of 0.25 cm³·g⁻¹). The average pore diameter was about 5.9 nm as it's expected for a mesoporous bioactive glass. The mesoporous structure implies a higher specific surface area compared to non-mesoporous BAG (typically few m²·g⁻¹). Consequently, the mesoporosity implies a greater solubility of sol gel-derived BAG among other advantages such as enhanced protein adsorption [5]. Fig 1B and C represent the MBG after soaking 1 and 5 days in SBF solution, respectively. It's worth pointing out the morphological and chemical changes on the MBG surface less than 24h after soaking in SBF solution. The produced SPIONs (Fig. 1E) were magnetically characterized to assess and confirm their superparamagnetic
behavior. The composites have been produced by adding the MBG and SPIONs to the electrospinning solution. The SPIONs were also incorporated in the polymeric matrix by the adsorption method. In order to assess whether the materials keep their individual properties after blending, the individual materials were fully characterized. The PVP/MBG composites (Fig. 1F, G) were already characterized in terms of degradation ratio, swelling capability (Fig. 2A, B), and their bioactive behavior. Magnetic hyperthermia assays (Fig. 2C) were performed to evaluate the heating ability of SPIONs incorporated into PVP nanofibers (Fig. 1H, I). However, the composites produced by adding both MBG and SPIONs simultaneously to the electrospinning solution are currently under characterization.

**Conclusion**

PVP/SPIONs composites revealed their potential as possible candidates to perform magnetic hyperthermia therapy due to the heating ability of SPIONs within the membrane. Furthermore, more composite characterization is being done, particularly the bioactivity of PVP/MBG composites and the cytotoxic effect of both PVP/SPIONs and PVP/MBG composites. Lastly, the final PVP/MBG/SPIONs composite is being also characterized in order to assess whether the materials keep their individual properties allowing such composite to act as a multifunctional scaffold.

A tubulogenesis assay to characterize the influence of hydroxyapatite-based ceramic properties on endothelial cells

Adeline Dumur¹,², Julie Usseglio¹,², Esther Pagès¹,², Emeline Renaudie¹, Joël Brie¹,², Eric Champion¹, Amandine Magnaudeix¹

¹ Limoges university, IRCER, Limoges, FR; ² Limoges university hospital center, maxillofacial surgery, Limoges, FR

Introduction
Vascularisation is mandatory for bone healing. Thus vascular endothelial cells actively participate in tissue repair through molecular communication with resident cells in the injured tissue. Hydroxyapatite-based ceramics (HA - Ca₁₀(PO₄)₆(OH)₂) are biocompatible and osteoconductive. They have been widely used as porous scaffolds in bone regenerative medicine since the 1980’s but an improvement of their ability to be vascularized is required to extend their applications.

Cells are sensitive to the chemical-physical properties of their environment modulating their activities. This influence depends on the cell type and may differ for endothelial and bone cells. A strategy to improve endothelial cell growth at the ceramics surface is to act on chemical and microarchitectural design of the scaffolds. Silicon has been described as acting positively on endothelial and bone cell activity¹. Microporosity, by increasing surface area and modulating its topography has an influence on the quality of bone cell colonization².

The first objective, was to investigate colonization of HA-based ceramics surface by endothelial cells, and their ability to form tubules, as a function of the composition (pure HA or silicon doped HA: SiHA) and microstructure (dense or microporous ceramics). This needed 3D conditions that were achieved by the set up of an expedient and efficient experimental protocol using fibrin-gels. With the aim of modelling the interaction between cells in bone tissue and taking account cell communication, coculture of pre-osteoblast and endothelial cells will be investigated in the same conditions, which required first to select an accurate ratio of the different cell types that constituted the second objective of this study.

Experimental Methods
Pellets of sintered HA and SiHA (Ca₁₀(PO₄)₅.₆(SiO₄)₀.₄(OH)₁.₆) were manufactured from well characterized powders³,⁴. Sintering temperature and duration allowed to obtain 2 different microstructures: dense and 25% microporous. An experimental method based on the use of a fibrin-based gel was developed to study the ability of cells to form vessels on the surface of materials: C166 endothelial cells were seeded either on top of a fibrin gel poured on HA ceramics or directly on ceramics surface before the addition of the fibrin gel, and cultured for 7 and 14 days. For the co-culture assays, pre-osteoblastic MC3T3-E1 cells and C166 endothelial cells were seeded on a fibrin-based gel at variable ratios: 2/1, 1/2, 1/1 for the same culture duration. After cell fixation and immunofluorescence staining, cells on ceramics were imaged. Computer-aided analysis of the images and 3D reconstructions allowed to evaluate the quality of tubulogenesis according to the materials properties.

Results and Discussion
Proliferation studies show the biocompatibility of the tested materials with a positive effect of Si on dense material. The fibrin-gel was effective to induce the formation of tubular structures on the surface of the 4 types of materials (dense and porous HA or SiHA) (Fig. 1). Importantly, the formation of tubules seems to differ according to the ceramics microstructure. The dense biomaterials appear to be more favourable to the formation of tubules than the porous ones. These vascular structures express VEGF2 and vWF. The influence of silicon addition is currently under investigation.
From cell co-cultures, organized tubular structures are obtained whereas there is only an unorganized cell layer in cultures with C166 cell type alone. The co-culture at a C166/MC3T3 ratio of 1/2 appears to be particularly interesting.

Conclusion
In this work an efficient method was set up to study the tubulogenesis on ceramics. The first results are promising with the formation of tubular structures on the biomaterial. Quantitative analysis of the tubules number, length and diameter are currently under progress to evaluate the influence of the materials properties. A predominant effect of endothelial cell/bone cell communication was also highlighted with a more favourable 2:1 bone cell/endothelial cell ratio.

Self-assembling Soft Peptide-Hyaluronan Hydrogels as 3D Environments for Stem Cell Culture

Yichen Yuan, Jayati Banerjee, Helena Azevedo

Queen Mary University of London, School of Engineering and Materials Science & Institute of Bioengineering, London, GB

Introduction
The extracellular matrix (ECM) of tissues contains multiple proteins and polysaccharides that provide much more than mechanical support for cells. Mimicking this intricate network has been a major goal in biomaterials engineering. Peptides are obvious choices to engineer synthetic ECMs as they can be designed to self-assemble into nanostructures with defined shape (e.g. nanofibers) and display desired functionality to control cell functions (e.g. cell adhesion, proliferation, differentiation). Hyaluronic acid or hyaluronan (HA) is an essential polysaccharide of the ECM mediating activities in cellular signalling, wound repair, morphogenesis and matrix organization [1]. As such, it has attracted large interest as starting biomaterial. However, to impart stability and improve functions of HA hydrogels, covalent and noncovalent crosslinking approaches have been exploited, requiring chemical modification of HA [2]. Using small positively charged peptide amphiphiles, the cross-link of unmodified HA could be triggered by self-assembly, where stable membranes and sacs were obtained [3]. Here we present the fabrication of novel 3D supramolecular hydrogels containing HA and rationally designed peptides. The gels are formed by self-assembly without requiring any chemical modification of HA, and their biomimetic composition offer the possibility to recapitulate stem cell niches.

Experimental Methods
Peptide-HA hydrogels were formed via self-assembly by casting aqueous solutions of rationally designed peptides on top of HA (2 MDa) solution. The micro-nanostructure of the gel was examined by scanning electron microscopy (SEM), and the mechanical properties evaluated by rheology (amplitude sweeps at frequency of 1 Hz). For 3D cell culture, hydrogels were first swollen in the culture media (DMEM with 10% FBS) and then human mesenchymal stem cells (hMSCs) were seeded inside the gel. The cell viability was assessed using the LIVE/DEAD assay and analysed by confocal microscopy.

Results and Discussion
Stable peptide-HA hydrogels were obtained which could be easily handled (Figure A). SEM examination revealed randomly entangled nanofibers forming the hydrogel network (Figure B-D). Rheology measurements showed elastic modulus $G'$ of 541±163 Pa and viscous modulus $G''$ of 251±50 Pa at 1% strain (within linear range) indicating a gel state. hMSCs encapsulated in the peptide-HA hydrogel have a good viability on day 3 (Figure E). Cells tended to aggregate and form sphere-like structures, which is different from the round-shaped morphology observed when entrapped into other supramolecular peptide-polymer hydrogels [4].

Conclusion
The excellent biocompatibility of the peptide-HA hydrogels, and their possibly tunable physical and biochemical properties, suggest hydrogel application as 3D artificial stem cell niches for differentiation or self-renewal.

3D printed hydrogel scaffolds for tissue engineering applications: an in-depth mechanical analysis as the key to success

Martina Meazzo¹, Fabrizio Barberis², Catherine Van Der Straeten¹, Peter Dubruel¹

¹ Ghent University, Ghent, BE; ² Genova University, Genova, IT

Introduction
Tissue engineering (TE) is known as a methodology that mimics the physiological microenvironment by combining biology, engineering and materials science to repair or replace damaged tissue. Incorporating the three elements of the tissue engineering triad (cells, biological factors as signals and scaffolds, figure 1) needs a good scaffolding technique [1]. Additive manufacturing techniques are the most common due to their potential to fabricate organized tissue constructs to repair or replace damaged or diseased human tissues and organs. The scaffold is expected to perform various functions, including the support of cell colonization, migration, growth and differentiation. Further, for their design the physicochemical properties, the morphology and the degradation kinetics need to be considered. External size and shape of the construct are of importance, particularly if it is customized for an individual patient. Besides the physical properties of a scaffold or matrix material (e.g. stiffness, strength, surface chemistry, degradation kinetics), the micro-architecture of the constructs is of great importance for the tissue formation process [2,3].

Experimental Methods
Starting from a patented polymer family (structure cannot be disclosed), 3D scaffolds were developed using an extrusion-based 3D printing device.
The printing parameters that were varied include the printing temperature, the printing speed, the pore dimension, the strut size and the printing pattern (0°/90°, 0°/45° etc). The scaffolds were subjected to an in-depth analysis including scaffold visualization through optical microscopy and a study of the mechanical properties using different techniques.

Before being mechanically tested, the efficiency of the UV-cross-linking process of the developed scaffolds was verified through sol-gel testing. Minimal gel-values of 80-90% are targeted as go/no go criterion for further testing.

Results and Discussion
Using our newly developed polymer class, reproducible scaffolds were obtained as exemplified in the following figure.
To realize this, the printing temperature and – speed required optimization. The optimal values were 57°C and 350 mm/s respectively. The gel fraction of all developed scaffolds exceeded 90%.
In a first part of the mechanical testing, the 3D printed scaffolds were subjected to mono-axial compression using Dynamic Modulus Analysis – DMA as non-destructive technique (NDT). The studies showed that the material revealed mechanical properties relevant for various TE applications. Indeed, our preliminary tests showed a clear and definite loss modulus (i.e. the dissipative part of the Young modulus) highlighting the viscous properties of the polymer and representing energy lost as heat or dissipated during one cyclic load.
As the produced scaffolds have a cylindrical shape and water-swollen dimensions of 7 mm in height and 15 mm of diameter, two pre-set displacements of 0.2 mm and 0.3 mm were investigated in DMA. The scaffolds Young modulus between the two pre-set displacements increased with 30% due to a more compacted structure and an increase of full-to-empty ratio of the scaffolds. The increase could also be noticed by the difference in loss modulus between the two pre-set displacements. Indeed, a higher applied load resulted in more contact points within the structure and therefore, in a greater dissipation. The results achieved during the NDT were then used to optimize the 3D printing
parameters. The results showed that the complex modulus of scaffolds with the 0°/45°/90°/135° printing pattern was higher than the pattern 0°/45° and 0°/90°, most likely due to its more isotropic structure (figure 2).

In a second stage of our testing campaign, the samples applied for NDT were subjected to destructive mechanical testing and the collected data were compared to detect both the stiffness and the energy dissipation features of the developed scaffolds. The results obtained from destructive compression static testing confirmed the DMA results: the highest Young modulus was obtained for the 0°/45°/90°/135° pattern.

When developing implant materials, sample storage is an important aspect as it determines, if possible and required, the to be applied storage conditions. To remove the small fraction of soluble material from the printed scaffolds, leaching was performed in water prior to removing the water by either freeze drying or desiccation. Very interestingly, despite DMA revealing no significant effect of the drying method on the mechanical properties, scaffold visualisation through optical microscopy indicated some damaged scaffold trabeculae (figure 2). The freeze-drying thus causes some internal stresses that lead to these effects.

**Conclusion**

An in-depth mechanical analysis revealed several aspects to be extremely important in developing 3D printed hydrogel scaffolds. These include optimization of the printing pattern and the drying methodology for the anticipated sample storage.

Development of porous 3D polysaccharide-based hydrogel with microchannels for vascularization

Chau Le Bao¹², Margaux Bourhoven¹³, Frédéric Chaubet¹², Didier Letourneur¹, Teresa Simón-Yarza¹

¹ INSERM U1148, Université de Paris, X Bichat Hospital, Paris, FR; ² Université Sorbonne Paris Nord, Galilée Institute, Villetaneuse, FR; ³ École Nationale Supérieure d’Arts et Métiers, Metz, FR

Introduction
The development of hydrogel-based biomaterials that can promote vascularization presents a great challenge in tissue engineering. 3D hydrogels (HGs) which can mimic soft tissue mechanical properties are promising candidates as scaffolds for tissue regeneration. Porous HGs are ideal for vascularization strategies as they facilitate nutrient and oxygen diffusion and enable cell migration¹. However, interconnected pores alone are not sufficient to promote anastomoses with host vasculature upon transplantation. Numerous studies have shown that the addition of channels inside a porous scaffold can facilitate cell growth and rapid vascularization, resulting in enhanced tissue formation¹. In this work, porous HGs with microvessel-like tubular structures were generated via two distinct strategies: i) mechanical removal and ii) dissolution of sacrificial components. Each method allows for the formation of microchannels with simple to complex designs and varying diameters of 100-500 µm.

Experimental Methods
Porous HGs were synthesized using a patented method as previously described². For HGs with microchannels, either the removable filaments (clinical-grade polypropylene filaments) or the sacrificial components (PVA or alginate gel) were positioned in between two spacers to guide channel formation and to control gel thickness. Finally, the gels were freeze dried following an established protocol³. The 3D prints were designed using Fusion 360 Autodesk software. PVA or PLA filaments were printed using Ultimaker S3 printer with nozzle diameter of 250-400 µm. Different tubular geometries and diameters were developed. Printing parameters such as layer height and infill speed were optimized for each design to ensure smooth prints with no deformation. To form alginate gel, alginic acid sodium salt 5% w/v and calcium chloride 5% w/v solutions were prepared by mixing each substance in miliQ water. The alginate solution was applied onto a 3D-printed PLA mold. Immediately afterwards, the template was immersed into CaCl₂ solution to crosslink the alginate gel. 3D printed PVA templates were dissolved in miliQ water and alginate templates were dissolved in EDTA 1M. Scanning electron microscopy was conducted to analyze the macro- and micro-structures of HGs, using the JEOL JSM-IT100 system under low vacuum conditions. Porosity and swelling studies were conducted as previously described⁴,⁵.

Results and Discussion
Macroscopically, the freeze-dried gels had pores that are visible with the naked eyes. SEM images confirmed the porous structure HGs where macropores were observed on the surface, while interconnected, micropores were present inside the HG. For HGs with simple, straight channel, hollow microchannel was revealed in the middle of the HG with pores existing inside the channel structure. Porosity measurements showed porosity values of 30-40%. Pore size was determined to be around 200 µm. Swelling ratio was 12.5±5. All channel formation methods produced HGs with hollow, smooth, and interconnected microchannels.

Conclusion
Mechanical removal method offers a facile setup and enables formation of linear channels with diameter as small as 100 µm. Sacrificial templates produced by fuse deposition modeling technology can generate channel-like structures with complex geometries, but also adds another level of complexity in the synthesis procedures.

Tuneable fibrin scaffolds that enable on-demand secretome therapy

Christopher Lally, Abhay Pandit

NUI Galway, CÚRAM, Galway, IE

Introduction
Bone marrow stromal cells (BMSCs) exert short-range reparative effects in response to injury or disease, primarily via secreted signalling factors such as cytokines. The amount and nature of cytokine secretion are highly responsive to changes in the BMSC microenvironment. This inherent responsiveness allows for cytokine secretion to be experimentally tuned in-vitro using biomaterial scaffolds. This project aims to use fibrin, an endogenous hydrogel formed through blood coagulation, as a tuneable scaffold for BMSC implantation capable of enhancing therapeutic cytokine secretion while offsetting cell survival challenges. By varying cell density as well as fibrinogen and thrombin concentrations, this project aims to produce a fibrin-BMSC construct optimised for secretome therapy.

Experimental Methods
This study examined the effects of cell seeding density and gel formulation on the performance of a fibrin-BMSC construct intended for use in disease therapy. By combining three fibrinogen concentrations (6, 12, or 18 mg/ml) with three thrombin concentrations (2, 7.5 or 15 units/ml), nine distinct formulations were tested. 100 µl fibrin gels were prepared at a cell density of 0.1, 0.4 or 0.8 million cells/ml. All assays were performed on day three and day seven. Cell survival was measured by annexin V-FITC/propidium iodide flow cytometry. The growth and adaptation of the BMSCs throughout the fibrin gels were quantified using confocal microscopy and 3D image segmentation tools. The viscoelastic properties of the gels were compared to literature values for brain tissue via rheometry. Flow cytometry bead-based multiplex immunoassays (R&D Systems Luminex®/ Bio-Rad Bioplex®) were used to measure the secretion of cytokines and interleukins from fibrin-encapsulated BMSCs. Eighteen cytokines with potential therapeutic relevance in neurodegenerative disease and a mix of 11 pro- and anti-inflammatory interleukins were quantified.

Results and Discussion
Annexin V FITC/propidium iodide flow cytometry confirmed cell survival above 75% for all gel formulations on day three and seven. The BMSCs appeared to be adapting successfully to the 3D fibrin environment when visualised by confocal microscopy. In all gel formulations, cells grew larger and adopted a spread, fibroblastic morphology over time. The rheological analysis demonstrated that the fibrin gels had viscoelastic properties similar to published values for brain tissue. The gels also did not display significant swelling over 48 hours post-formation. Multiplex immunoassay demonstrated that cytokines and interleukins involved in angiogenesis, inflammation, CNS signalling events and regeneration were secreted by encapsulated BMSCs (Fig. 1). A mixed-model ANOVA with Tukey’s correction for multiple comparisons revealed that variations in fibrinogen and thrombin contributed significantly to differences in cytokine secretion (Table 1).

Conclusion
As cells appear to thrive in all formulations tested, it can be concluded that the system supports a broad range of tuneability without compromising cell viability. The soft, non-swelling nature of the fibrin gels minimises secondary injury risk in their intended role as an in-situ forming, space-filling hydrogel for brain applications. These results imply that a tuneable fibrin scaffold could be a useful means of delivering tunable BMSC-derived cytokine therapy to the neurodegenerative brain.

Cytokine Secretion by Day and Gel Formulation

Figure 1. Multiplex immunoassay at day three and day seven detected angiogenic and neuroprotective cytokines secreted by BMSCs encapsulated in nine different fibrin gel formulations – 6, 12, or 18 mg/ml fibrinogen with 2, 7.5 or 15 units/ml thrombin. Presented here are the results from the highest cell seeding density, 0.8 million cells/ml. Results drawn from duplicate measurements of pooled triplicate samples.

Melt-Electrowritten Scaffolds with Ultrasmall Superparamagnetic Iron Oxide Nanoparticles as Contrast Agent for Non-Invasive Magnetic Resonance Imaging

Kilian M.A. Mueller¹, Geoffrey J. Topping², Sebastian P. Schwaminger³, Younzh Zou¹, Diana M. Rojas-González¹, Elena De-Juan-Pardo⁴, Sonja Berensmeier³, Franz Schilling², Petra Mela¹

Introduction
Melt electrowriting (MEW) is an advanced fiber-forming technology for additive manufacturing of micro-structured scaffolds for tissue engineering. The translation of such constructs to the patient requires the capability to visualize them upon implantation with clinically accepted methods such as magnetic resonance imaging (MRI). To this end, this work presents the modification of polycaprolactone (PCL) scaffolds with ultrasmall superparamagnetic iron oxide (USPIO) nanoparticles as contrast agents to render them visualizable by MRI.

Experimental Methods
USPIOs were synthesized with a primary particle size of 10 nm. USPIO/PCL composites of different weight percentages (0.1, 0.2, and 0.3 % w/w) were produced. The composites were melt-electrowritten at 75 °C through a 23 G needle onto a grounded collector with pressurized air at 2 bar applied to the print head, a voltage of +5 kV at the needle and a working distance of 3.1 mm. Scaffold architecture and fiber diameter (n = 3, i =10) were assessed by SEM. The composites’ mechanical properties were investigated by tensile testing (n = 10). Their cytocompatibility was tested with a cytotoxicity assay (n = 3) and cell adhesion was verified via fluorescence microscopy. MRI of the scaffolds was performed with a 7 T scanner and a 10 mm inner diameter solenoid radiofrequency coil.

Results and Discussion
Melt electrowriting of the composites resulted in regular and highly ordered micro-structured 3D scaffolds for all USPIO concentrations, without any electrical instabilities. USPIO incorporation caused small to no decrease in ultimate tensile strength and Young's modulus. USPIO/PCL composites were cytocompatible at all concentrations. In MRI, pure PCL showed no contrast with agar-agar in R1, R2, or R2* relaxation rate maps. However, with USPIO-labeled PCL, the contrast in R2 and R2* relaxation maps strongly increased. Hence, the composite scaffolds were sensitively detected in vitro using T2- and T2*-weighted MRI.

Conclusion
This work contributes to the material library for MEW by successfully incorporating USPIOs into PCL - the gold standard polymer for MEW. Our findings open the possibility of using MRI to effectively visualize melt-electrowritten scaffolds with a clinically accepted non-invasive monitoring option.

**Ti/Ta composite hydrogel scaffolds for bone tissue engineering**

**Luis García-Fernández**¹,², Hector García-Robledo³, Basilio de la Torre³, Blanca Vázquez-Lasa¹,²

¹ Institute of Polymer Science and Technology (ICTP-CSIC), Biomaterials group, Madrid, ES; ² Centro de Investigacion Biomédica en Red, Bioingeniería, Biomateriales y Biomedicina (CIBER-BBN), Madrid, ES; ³ Hospital Ramón y Cajal, Madrid, ES

**Introduction**

The regeneration of bone tissue continues to be an important challenge in orthopaedic surgery and traumatology. Critically sized bone defects need to be filled with a bridging material, in combination with suitable cells and molecules, to promote the regeneration of bone tissue[1]. Different biomaterials have been used as graft materials or bone substitutes. In this work, natural polymers like Chitosan (Ch) and Arabic Gum (G) were chosen due to their good biological and biochemical properties to prepare a composite scaffold reinforced with either Ti or Ta microparticles due to their good osteoinductive capacity [2]. Recent studies showed that osteoinduction on Ta implant is significantly higher than in Ti implants [3]. In this work, we propose to evaluate the biocompatibility and osteoinduction capacity of Ti/Ta loaded scaffolds.

**Experimental Methods**

**Synthesis of Ti/Ta composite hydrogel scaffolds**

Ch chloride aqueous solution (1%wt) was mixed with G (Ch:G = 80:20) and the corresponding Ti or Ta microparticles (Ti, size < 44 µm; Ta, size < 45 µm). The system was crosslinked with oxidized dextran (1 wt % respect to polysaccharides) at 37 °C for 1 h under stirring. The mixture was poured in multiwell plates and left to dry. Finally, the scaffolds were washed with a NaOH solution (0.1 M) and PBS (pH = 7.4) until neutral pH.

**Release assays**

Release of metal was studied by immersion of samples in PBS at 37°C. At different periods of time aliquots of the release medium were taken and analysed. Quantitative determination of Ti and Ta aliquots was performed by inductively coupled plasma optical emission spectrometry (ICP-OES).

**Cytotoxicity analysis**

Composite scaffolds were submerged in 5 mL of culture medium and placed on a shaker at 37 °C. The medium was removed after different time periods (2, 7, 14 and 21 days) and the toxicity of the extracts was tested on Human Mesenchymal Stem Cells (hMSCs). Cell viability was analysed with the MTT reactive.

**Cell adhesion and proliferation assay**

Composite scaffolds were placed in a 48-well plate and hMSCs were seeded on them and incubated for 24 h. The medium was removed after different time periods (1, 7 and 14 days) and cell adhesion and proliferation on the samples were quantified using Alamar Blue reactive.

**Alizarin red assay**

Calcium deposition on the scaffold surfaces was evaluated by Alizarin red assay after 21 days of incubation. For this experiment, hMSCs were seeded on the scaffolds for 14 days. Ca depositions were analyzed using Alizarin Red reactive.

**Results and Discussion**

SEM micrographs of representative composite scaffolds showed smooth and uniform surface for Ch80G20 scaffolds and the presence of aggregates of Ti and Ta for the corresponding metal loaded samples (Figure 1a). Release of metals from scaffolds was very scarce (Figure 1b). In fact, it was almost negligible for either Ti or Ta that means that the majority of metallic nanoparticles remained adhered to the surface of the scaffolds.
Any synthesized scaffold did not present cytotoxicity (Figure 2a and 2b) giving values of cell viability higher than 80% in all samples, and even for those containing Ta in the highest proportion, cell viability values around 100% or superior were observed. Cell adhesion and proliferation behavior is shown in Figure 2c. Cell proliferation increased over time being higher for composite samples than for the Ch80G20 control. The presence of Ti or Ta improved the proliferation of hMSC on the surface specially for samples with (Ch/G):metal ratio 1:3 (Figure 4a). In the case of Ti samples, the decrease on cell proliferation with the concentration of Ti could be related to the increase of toxicity at 21 days (Figure 2a). Alizarin Red results (Figure 2d) showed a remarkable increase on Ca depositions with the increase of Ta concentration respect to that observed in Ti containing samples. This indicates that the presence of Ta in the composite scaffold improved the osteoconductivity of the sample.

**Conclusion**

Composites scaffold based on polysaccharides and Ti or Ta microparticles are proposed as composite systems with promising characteristics for bone defect regeneration. Specially scaffolds containing Ta can be considered a good option due to their remarkable osteoconductive properties.

Effects of the synthesis conditions on the hydrolysis of α-tricalcium phosphate to octacalcium phosphate

Ilijana Kovrlija1, Clara Barbut1, Janis Locs1,2, Dagnija Loca1,2

1 Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovation and Development Centre, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; 2 Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction

Being one of the members of calcium orthophosphates, octacalcium phosphate (OCP, Ca₈(HPO₄)₂(PO₄)₂x5H₂O) is presumed to be the precursor during the crystallization of hydroxyapatite (HAp), where the interlayered structure made of an apatite layer and a hydrated layer plays an important role. The similarity of the structure gives several benefits to OCP. Moreover, the OCP’s idiosyncrasy to be the first one to induce the bone tissue appearance made it indispensable to research it even further. The most common way to synthesize OCP is through precipitation route or through hydrolysis of α-tricalcium phosphate (α-TCP) and brushite. Even though α-TCP is often used as a precursor, the reaction can be influenced by the number of factors such as temperature, pH and time. This can lead to the formation of different CaP phases, thus the aim of the current study was to examine the influence of different parameters on the hydrolysis of α-TCP to OCP, and subsequently, to perform the scale up of the reaction.

Experimental Methods

OCP was synthesized by hydrolysis of α-TCP powder. In the first set of experiments, the synthesis in open and closed system were performed, where at least five independent trials were performed for each approach. 100 mg of α-TCP were deposited into 50 mL of 0.0016 M H₃PO₄ solution at room temperature, under constant stirring, with an initial pH of 6. In the second set of experiments, the synthesis using the same starting reagents and process parameters was scaled up tenfold. Reaction time was 24 h and 72 h, respectively. The obtained products were centrifuged for 2 min at 3000 rpm, washed with deionized water and dried overnight at 37 °C. X-ray powder diffraction (XRD) and Fourier transform infrared–attenuated total reflectance (FTIR-ATR) were employed to verify the composition of all the obtained samples, while the Specific Surface Area (SSA) was determined by Nitrogen Adsorption following the calculations applying Brunauer–Emmet–Teller method (BET).

Results and Discussion

Crystallographic structures of the synthesized materials were confirmed by the XRD patterns. Based on the OCP reference pattern (ICDD PDF 00-026-1056), all of the obtained samples exhibited the position and shape of characteristic maxima which corresponded to the structure of OCP (reflection at around 4.7, 9.8 and 32 degrees 2θ). The FTIR absorption spectra correlated with the findings from XRD, where typical attributes of OCP were observed in all the sample spectra (absorption bands characteristic of ν3 PO₄²⁻ stretching vibration in the regions 1075–1017 cm⁻¹, two sharp bands of ν4 PO₄³⁻ at 600 and 560 cm⁻¹ and ν1 PO₄³⁻ at 962 cm⁻¹, additionally bands at 1120, 916, and 860 cm⁻¹ due to HPO₄²⁻ stretching were present). The specific surface area quantified with BET method was around 70 m²/g.

Conclusion

The presented research provides evidence that OCP has been successfully produced by the direct hydrolysis of α-TCP powder, both in the closed system and with the exposure to the surrounding atmosphere. In order to perform the 10-fold upscaling and to obtain a ten times higher amount of the final product with only OCP phase present, extending the time of hydrolysis to 72h was necessary.

Thiol-ene photo-click hydrogels to stimulate osteoregeneration through recapitulation of the osteoid microenvironment

Laurens Parmentier¹, Peter Dubruel¹, Sandra Van Vlierberghe¹,²

¹ Ghent University, Polymer Chemistry and Biomaterials Group – Centre of Macromolecular Chemistry (CMaC) – Department of Organic and Macromolecular Chemistry, Ghent, BE; ² Vrije Universiteit Brussel and Flanders Make, Brussels Photonics – Department of Applied Physics and Photonics, Brussels, BE

Introduction

The most common causes for bone defects include trauma, disease, tumour removal and surgical interventions. When a bone defect exceeds the regenerative capabilities of bone tissue, a critical defect arises in which bone is unable to heal itself through bone remodelling so surgical intervention becomes required. Four million surgeries are performed annually to treat bone defects using either bone grafts or synthetic substitutes rendering it the second most transplanted tissue worldwide [1].

Given the drawbacks associated with auto- and allografts, synthetic scaffolds mimicking the composition, architecture and properties of the native extracellular matrix are gaining increasing interest. These biophysical cues are hereby converted into biochemical cues through mechanosensitive pathways that regulate cell behaviour [2]. Therefore, the aim is to develop a biomimetic hydrogel mimicking the bone osteoid. Natural polymers have the advantage that they are characterized by biodegradability and intrinsic biological signalling pathways. Considering the composition of the osteoid extracellular matrix, collagen type I is a popular candidate to be used in bone scaffold materials. However, collagen carries the risk of exhibiting an immune response. Therefore, gelatin, derived from denatured collagen, is of special interest since it resolves this issue while still maintaining the cell-interactive properties of collagen. Gelatin however suffers from its upper critical solution temperature [UCST] behavior that leads to dissolution at 37°C. To overcome this, gelatin can be modified with photo-crosslinkable groups [Figure 1].

Experimental Methods

Thiol-ene step growth photo-crosslinking was selected to enable superior control, homogeneous network formation and lower radical concentrations compared to traditional chain growth systems [3]. More specifically, norbornene-functionalised, aminated gelatin systems were combined with thiolated gelatin functioning as cell-interactive crosslinker thereby forming networks with mechanical properties capable of triggering osteogenesis. The modification degree of these derivatives was characterised through nuclear magnetic resonance spectroscopy and an orthophthalic dialdehyde assay. Furthermore, in-situ photo-rheology, swelling and gel fraction experiments, differential scanning calorimetry, collagenase degradation tests and high resolution magic angle spinning nuclear magnetic resonance spectroscopy were used to characterize the obtained networks. Furthermore, cell viability and adipose-derived stem cell osteogenesis were evaluated in vitro through Live/Dead staining, the production of alkaline phosphatase, the stimulation of collagen type I production and the presence of calcium deposits.

Results and Discussion

In order to obtain thiol-ene networks in the osteogenic range [25-40 kPa], the carboxylic acid groups present in gelatin type B were partially substituted with amine groups through addition of either diaminoethane [red] or -pentane [blue] [Figure 1A] [4]. A substantially higher degree of norbornene substitution could be obtained thanks to this amination compared to the traditional reaction exploiting gelatin type B [Figure 1B] [5]. The thiol-ene networks were benchmarked against the chain growth system characteristic for gelatin-methacrylamide [GelMA] [Figure 1C]. The presence of a higher amount of amine groups resulted in a significantly higher [Figure 2A, #] compressive modulus.
compared with conventional norbornene-functionalised gelatins [Figure 2A, green]. A further significant increase was observed when the alkyl chain of the amination reagent was longer. Being situated in the osteogenic range, 7.5 w/v% GelMA and 10 w/v% GeINBNB-GelSH [red] were further evaluated in terms of physico-chemical properties. Chemical crosslinking was the main mechanical contribution for the GeINBNB-GelSH network with a drastically reduced amount of physical crosslinks [by a factor of 300 compared to GelMA] paving the way towards processing of these hydrogels at room temperature [Figure 2B-2G]. Upon modification, the degradation properties of the newly modified gelatin were preserved [Figure 2H]. The preliminary cell viability data indicated an elongated morphology and excellent biocompatibility for the GeINBNB-GelSH networks [Figure 2I, scale bar: 500 µm].

**Conclusion**

Overall, the results showed that highly-controlled biocompatible networks could be created which could stimulate osteogenesis based on favourable mechanical properties and retained biodegradability despite the chemical crosslinking applied.

Bio-instructive Collagen-Magnesium Nanocomposite Scaffolds to Manipulate Bone Metabolism and Promote Bone Repair

Silvia S. Paiva1,2, Fergal O'Brien1,2,3, Ciara Murphy1,2

1 Royal College of Surgeons in Ireland, Dept. of Anatomy and Regenerative Medicine, Dublin, IE; 2 Advanced Materials and BioEngineering Centre, Dublin, IE; 3 Trinity Centre for Biomedical Engineering, Trinity College Dublin, Dublin, IE

Introduction

The native bone tissue holds a staggering capacity for self-regeneration owing to the metabolically dynamic process of bone remodelling. Bone remodelling is mediated through the synchronism of bone resorption (catabolism) by osteoclasts and bone formation (anabolism) by osteoblasts1. Imbalances in the bone remodelling cycle represent an underlying cause of metabolic bone diseases such as osteoporosis, and present a major risk for implant loosening due to excessive resorption activities, which hampers the correct regeneration of bone post-injury. Current biomaterials strategies to repair bone fractures often focus solely in targeting anabolism or suppressing catabolism, which may increase the risk for impaired fracture healing. In alternative, the incorporation of bioactive ions such as Magnesium (Mg2+) into biomaterials has gained remarkable attention due to their ability to stimulate suitable biological responses necessary for the repair of bone defects, in a safe and cost-effective manner2. Herein, we focus on investigating a combined versatile pro-anabolic and anti-catabolic effect of Mg2+ in modulating bone cell behaviour, to develop an engineered biomimetic bio-instructive biomaterial scaffold structurally designed to enhance bone formation while impeding uncontrolled osteoclast resorption activities to facilitate better bone regeneration and promote repair.

Experimental Methods

In vitro 2-D model: to determine the effect of Mg2+ on osteoblasts, MC3T3-E1 cells were cultured in osteogenic media exposed to increasing concentrations of MgCl2 ranging from 0–25mM, and their proliferation, gene expression, and mineralisation was assessed over 28 days. To determine the effect of Mg2+ on osteoclast progenitor cells, RAW 264.7 cells were stimulated with 20ng/mL of RANKL, and exposed to the same range of increasing concentrations of MgCl2. Multinucleated and TRAP-positive cells were labelled as osteoclast-like cells and the ability to form osteoclasts in the presence of increasing concentrations of MgCl2 was evaluated for 14 days.

In vitro 3-D model: we determined that 10mM and 25mM MgCl2 presented favourable osteogenic properties while simultaneously inhibiting osteoclast formation in 2-D, thus these concentrations were utilised in doping pro-anabolic hydroxyapatite nanoparticles (nHAp). Collagen-Mg2+ porous-scaffolds were prepared by incorporating Mg2+-doped nanohydroxyapatite (10Mg nHAp and 25Mg nHAp) into a bovine type I fibril collagen slurry, and obtained through a freeze-drying method previously optimised in our group3. Scaffolds were assessed via FTIR, SEM, water contact angle, and mechanical testing to determine the effect of Mg2+ on both physical and chemical properties. Scaffolds were cultured separately with MC3T3-E1 and RAW 264.7 cells to investigate the behaviour of bone cells in response to Mg2+, and assessed for cell viability using Live/Dead assay, proliferation, migration via histochemical characterisation, and gene expression.

Results and Discussion

In vitro 2-D study: we reported an increase in cell proliferation over time for all Mg2+-treatments in both MC3T3-E1 and RANKL-induced RAW 264.7 cells. All Mg2+-treated groups presented improved expression of alkaline phosphatase activity, with 25mM MgCl2 exhibiting superior mineral deposition when compared to positive control (osteogenic media) group (Fig. 1A). We observed a dose-responsive inhibition in the formation of TRAP-positive...
multinucleated osteoclast-like cells with increasing concentration of Mg$^{2+}$ (Fig. 1B), and elevated extracellular Mg$^{2+}$ significantly downregulating the expression of the osteoclast-specific markers TRAP and Cathepsin K.

In vitro 3-D study: we successfully developed a range of highly porous collagen composite scaffolds: Collagen as a control (Coll), Coll-hydroxyapatite (nHAp), 10Mg nHAp and 25Mg nHAp. Our developed scaffolds were able to induce the proliferation of bone cells over 14 days and cell cytompatibility was also confirmed through live/dead imaging on seeded scaffolds. Scaffolds containing 25Mg nHAp showed a significant increase in MC3T3-E1 cells proliferation, and decrease in RANKL-induced RAW 264.7 cell proliferation at day 14 relative to Coll. Histological characterisation of developed scaffolds confirmed the migration of RANKL-induced RAW 264.7 cells from day 5 in Coll and nHAp scaffolds. However, Mg-modified scaffolds presented significantly less migrated cells, suggesting an inhibitory chemotactic effect induced by the presence of Mg$^{2+}$ within the scaffolds. Mg-modified scaffolds reduced the expression of osteoclast-related genes over time, demonstrating an effect in delaying osteoclast differentiation.

Conclusion
Our research to date has demonstrated the potential of elevated extracellular Mg$^{2+}$ to concurrently enhance osteogenesis while inhibiting osteoclastogenesis in vitro in both 2D and 3D models, potentially introducing new strategies in the development of bio-instructive biomaterials to repair metabolically compromised bone fractures.

Introduction

The use of three-dimensional porous scaffolds offers various advantages over conventional treatments for bone tissue engineering, but they must fulfil some criteria as (i) an open and interconnected pore network to promote the formation of new tissue, (ii) vascularization in vivo, (iii) good biocompatibility (iv) mechanical properties similar to those of the replaced tissue (v) resistance to corrosion and (vi) ease of fabrication. Even though ceramics are the most widely studied materials, their limited degree of elasticity hampers their use in bone regeneration applications. Polymers, also considered as potential biomaterials for scaffolds, suffer from some drawbacks, such as an excessively low elastic modulus and, in some cases, poor corrosion resistance. On the other hand, biocompatible metallic scaffolds present mechanical properties more similar to those of the human bone and can be used as electrodes with different electric field intensities (or voltages) for electric stimulation (ES). Metals typically suffer from corrosion, which leads to ions release into the medium. For this reason, the use of alloying elements which release non-cytotoxic ions upon dissolution is of utmost importance. The application of an external electric field has been widely studied and successfully used in clinical practice to stimulate bone healing and it has also been shown that ES modifies osteoblast activities including adhesion, proliferation, calcium nodule formation, gene expression, protein synthesis, and bone formation markers.

Experimental Methods

In the present work we have used a palladium-coated polymeric scaffold, generated by electroless deposition, as a bipolar electrode to electrically stimulate human osteoblast-like Saos-2 cells. Osteoblasts were grown on four different conditions: untreated glass coverslip, electrically stimulated glass coverslip, untreated foam and electrically stimulated foam. Foams were individually inserted into 24-well cell culture plates and Saos-2 cells were seeded on top and cultured in DMEM with 10% FBS under standard conditions or ES. Under ES, cells were exposed daily to an arbitrary sinusoid function of 2.5 V amplitude and 200 Hz frequency for 1 h along 28 days. Osteoblasts proliferation was evaluated by Alamar Blue at days 3, 7, 14 and 28. Cell adhesion and morphology were evaluated by scanning electron microscopy and actin staining at 7, 14 and 28 days. Differentiation was assessed at 1, 7, 14 and 28 days by determining the expression profile of six osteoblast genes (alkaline phosphatase, osteocalcin, bone sialoprotein, type I collagen, osteonectin and osteopontin) and by mineralization assay at days 7, 14 and 21.

Results and Discussion

Cells grown on palladium-coated polyurethane foams under ES presented higher proliferation than cells grown on foams without ES for up to 14 days. Growth was also higher in control cells, stimulated or not. In addition, cells grown in foams in both conditions were well adhered, with a flat appearance and a typical actin cytoskeleton distribution. After 28 days in culture, cells under ES appeared rounded and not well adhered, a sign of cell death onset, while cells without ES were filling the entire structure. Cell grown on glass coverslips were also rounded and not well
adhered after 28 days under ES. When looking at osteoblast differentiation, ES seems to enhance the expression of early expressed genes.

**Conclusion**
The results suggest that palladium-coated polyurethane foams may be good candidates for osteoblast scaffolds and also demonstrate that ES enhances osteoblast proliferation at least up to 14 days, while upregulating expression genes related to extracellular matrix formation.

Properties of premixed calcium phosphate cements based on α-tricalcium phosphate

Zilgma Irbe1,2, Dagnija Loca1,2

1 Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; 2 Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction

Calcium phosphate bone cements are materials used mainly to augment bone and promote the regeneration of the bone tissue. Calcium phosphate cements set at body temperature, so they can be easily given additional functionality, such as delivery of biologically active substances to the defect site. As these materials set upon application, their application is time sensitive. One way to improve the ease handling of calcium phosphate cements is to formulate premixed compositions. Calcium phosphate cements should set rapidly after application without washout of cement particles [1, 2]. Fast conversion of starting materials [2] and mechanical strength are also considered advantageous [3].

Previously, we established that cement additives that provide low initial pH values in the cement paste can ensure very rapid setting. In this study we investigated the properties of premixed cementing calcium phosphate pastes based on α-tricalcium phosphate (α-TCP) and glycerol with additives providing low initial paste pH. The setting reactions in these pastes start upon implantation as the inert paste liquid (glycerol) is gradually displaced by water from the surrounding fluids. Soluble sodium or potassium phosphate salts were used as additives. We evaluated setting, phase composition, and anti-washout properties of these premixed pastes.

Experimental Methods

α-TCP powder was obtained by high temperature synthesis at 1400°C from calcium carbonate and dicalcium phosphate (molar ratio 1:2), followed by milling to reduce particle size. α-TCP was mixed with glycerol and additives (monosodium phosphate or monopotassium phosphate) to obtain a workable paste. Molar ratios of α-TCP:additive were 10:1, 10:2 or 10:4. Phase composition of the set cements was determined using XRD in conjunction Rietveld refinement method. Anti-washout characteristics were evaluated visually and by monitoring pH and soluble substance content of the surrounding aqueous liquid.

Results and Discussion

All investigated cement pastes set very rapidly; a hard, set layer formed immediately (< 1 min) on the surfaces in contact with water. This layer served as a barrier, and the inner mass set slowly as the water diffused through the initial set layer. The thickness of the set layer for the tested compositions was 1.8-2.5 mm after 2.5 h of contact with aqueous surrounding liquid, and it did not correlate with the amount of additive used in the paste. For pastes with α-TCP:additive ratio of 10:1, some washout occurred, and it was more pronounced in the case of monopotassium phosphate. For the pastes with α-TCP:additive ratio of 10:2 and 10:4, no washout was observed.

The use of additives did not substantially reduce the pH of the surrounding aqueous liquid. The pH values next to the setting cement were near neutral: 6.3-6.7 in the case of monosodium phosphate additive and 6.4-7.0 in the case of monopotassium phosphate additive. Larger amount of additive used resulted in slightly higher pH values. The conversion of α-TCP to hydroxyapatite (see Fig. “Conversion of starting material to hydroxyapatite”) was also affected. It was delayed if higher amount of additive was used. Two days after contact with water, the set cements contained 62-86% of hydroxyapatite and the residual unconverted α-TCP. The use of higher amount of additive resulted in slower hydroxyapatite formation.
Conclusion
We recommend using monosodium phosphate or monopotassium phosphate to ensure setting and cohesion of premixed calcium phosphate cement pastes based on α-TCP. Although complete hydrolysis of α-TCP is slower, if the used amount of additive is increased, the setting is not delayed. Investigated compositions in both cases have acceptable anti-washout properties if sufficient amount of additive is used. The pH of the aqueous liquid surrounding setting cement was not reduced below pH 6.

Composite & hybrid materials based on bioactive glass, toward optimized substitutes for bone regeneration

Amel Houaoui¹,², Jonathan Massera¹, Michel Boissière², Emmanuel Pauthe²

¹ Tampere University, Laboratory of Biomaterials and Tissue Engineering, Faculty of Medicine and Health Technology, Tampere, FI; ² CY Cergy Paris Université, Biomaterials for Health Research Group, ERRMECe, Equipe de recherche sur les Relations Matrice Extracellulaire-Cellules (EA1391), Institut des matériaux I-MAT (FD4122), CY Tech, Neuville-sur-Oise, FR

Introduction
Most of the bone fractures are simple and common traumas usually repaired by osteogenesis. However, some complex and critical size defects, due to specific traumatic or pathophysiological context, cannot be repaired without a substitute that serves as a mechanical support and/or as bone filling to assist in the bone regeneration. Such bone substitute materials must present “osteo-properties”: from osteocompatibility to osteocompetency. Bioactive glass (BAG) has the particularity of releasing calcium and phosphate ions which precipitate and form a reactive apatite layer, considered to be the first indication of bioactivity [1]. Inspired by bone, the combination of BAG with organic matrices would provide innovative materials for bone bioengineering. Here we present the development of composite and hybrid materials based on bioactive glass for bone bioengineering. Two strategies were explored, i) a composite material based on Poly (Lactic Acid) (PLA) and bioactive glass and ii) a hybrid material based on gelatin and bioactive glass. The first system finds more applications as mechanical support, whereas the second is more pertinent to address the need of filling bone defects. In this study, two BAGs were compared: 1) the 13-93 a known, FDA approved composition and 2) the 13-93B20 where the silica was partially replaced with boron, in view of accelerating the glass dissolution kinetics and increase the glass conversion to hydroxyapatite.

Experimental Methods
Each system contains 70% of organic matrix (PLA or gelatin) and 30% of BAG (13-93 or 13-93B20 particles, in weight %). The composites were processed by twin screw co-extrusion and the hybrids were synthetized by sol-gel transition. The bioactivity in vitro (related to the precipitation of an apatite layer at the materials’ surface when immersed in aqueous solution) of both types of devices was studied in Simulated Body Fluid (SBF) for up to two weeks. The ion release was quantified by Inductively Coupled Plasma - Optical Emission Spectrometry (ICP-OES) and the materials were analyzed by Scanning Electron Microscopy coupled with Energy Dispersive X-ray (SEM-EDX). Cell experimentations were done to assess the cytocompatibility of the different devices and show their ability to promote a commitment toward an osteoblastic lineage.

Results and Discussion
The characterization of the composites based on PLA and 13-93 or 13-93B20 showed that boron allows to modulate the dissolution rate of the BAG in the composites, leading to a faster dissolution. In SBF, the [P] and [Ca] concentration decreases overtime, suggesting the precipitation of a reactive layer. The reactive layer was further confirmed to be apatite. The bioactivity, in vitro, is more important with the 13-93B20 BAG. Myoblastic cells culture on the composites exhibits a decrease of myosin and increase of osteopontin. This indicates that the myoblastic cells in presence of BAG evolve toward an osteoblastic lineage (Figure 1).

The second strategy is focused on the elaboration of hybrids based on gelatin and 13-93 or 13-93B20 using a
bifunctional coupling agent, the 3-glycidoxypropyltrimethoxysilane (GPTMS). The amount of GPTMS was optimized and covalent links between the gelatin and the BAG are evident as the gels appear self-supported at biological temperature. The characterization of these materials showed that the 13-93B20 BAG allowed to accelerate the dissolution and to increase the hybrids bioactivity. The cytocompatibility of the hybrids has been demonstrated using MC3T3-E1 pre-osteoblastic cells (Figure 2).

Conclusion
The results show that the composition of the BAG is a key property towards controlling the materials properties as well as the cellular response. Boron inclusion in the formulation allows a smart tailoring of the dissolution rate of the BAG. These tailor-made materials have a real potential for mechanical support, bioresorbability, and bone regeneration via the induction of suitable cellular behaviors favored by the BAGs dissolution by-products, bringing an osteo-competent and osteo-stimulating dimension to the implant.

Evaluation of liquid phase influence on properties of $\alpha$-TCP-based biomicroconcrete-type bone substitutes

Piotr Pańtak, Ewelina Cichoń, Szymon Skibiński, Joanna Czechowska, Aneta Zima, Anna Ślósarczyk

AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Kraków, PL

Introduction
Due to the increased demand for bone tissue substitutes caused by a rapidly aging society, civilization diseases or bone injuries many biomaterial studies are conducted around the world. The main efforts are focused on the optimization of the utility parameters of those biomaterials (such as mechanical strength or surgical handiness). Among many commercially available materials for bone tissue substitution, biomicroconcretes are distinguished by specific characteristic due to their unique composition, which is inspired by classical concretes, where aggregates in the form of granules provide material with satisfactory mechanical properties. Biomicroconcretes based on calcium phosphates are self-setting, bioactive materials for bone tissue engineering with high surgical-handiness. The aims of this study were to develop and obtain novel biomaterials for bone substitution and to recognise the influence of the liquid phase composition on the physicochemical properties of obtained biomicroconcretes.

Experimental Methods
The solid phase of the investigated materials composed of: 60 wt% of highly-reactive $\alpha$-TCP powder and 40 wt% of hybrid hydroxyapatite-chitosan (HAp/CTS) granules. Mixtures of 2 wt% of disodium phosphate (Na$_2$HPO$_4$) and 5 wt% citrus pectin aqueous solutions in various ratios (0:100, 25:75, 50:50, 75:25, 100:0 wt%) were used as a liquid phase of the developed biomicroconcretes. Obtained materials were characterized by several methods: setting times measurements (Gilmore needles according to the C266-08 ASTM standard), phase composition studies (D2 Phaser diffractometer, Bruker), compressive strength tests (Instron 3345), chemical stability and bioactivity in vitro studies (H198129 Combo, Hanna). Samples microstructure observations were performed (PhenomPure, Thermo Fisher Scientific).

Results and Discussion
In this study, the effect of liquid phase composition on the properties of biomicroconcretes was investigated. Studies have shown that obtained bone substitute materials were characterised by unique physicochemical properties due to different liquid phase combinations and dual setting system originated from hydrolysis of $\alpha$-TCP to non-stoichiometric hydroxyapatite and interactions between polycationic chitosan in hybrid granules and polyanionic pectin in liquid phase. The study reviled that liquid phase in the form of pectin solution prevented the biomicroconcrete from set. However, the rest of materials were characterised by self-setting properties due to the presence of disodium phosphate. Nevertheless, the addition of pectin solution led to achieve fully-injectable materials, which was impossible for biomicroconcretes where the liquid phase was only disodium phosphate.

Conclusion
The innovative materials such as obtained and developed in this study biomicroconcretes based on highly-reactive $\alpha$-TCP powder and hybrid HAp/CTS granules combine beneficial properties of bioceramics and biopolymers and can be prospectively injectable and self-setting materials for bone cavity fillings. They also can act as an alternative to commercially used sintered ceramic implants of predefined shape and size. Surgically handy and self-setting materials are potential candidates for bone tissue engineering, supporting its regeneration.

\textsuperscript{1} University Hospital Dresden, University Center for Orthopedics and Trauma Surgery, Dresden, DE; \textsuperscript{2} TU Dresden, Medical Faculty, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE; \textsuperscript{3} Helmholtz Zentrum Dresden Rossendorf, Institute of Radiopharmaceutical Cancer Research, Department Radiopharmaceutical and Chemical Biology, Dresden, DE

Introduction
Diabetes mellitus is a huge socio-economic burden primarily for western societies. More than 9\% of the World’s population suffer from this systemic disease that not only affects glucose metabolism but can also be related to vision impairment, cardiovascular disease, kidney damage, foot ulcer, nerve damage and impaired bone metabolism. Especially the last two secondary diseases result in complicated fragmentation of the foot bones. Due to limited healing capacity that is also associated with diabetes mellitus, fracture treatment is complicated and healing takes longer than in individuals with healthy bone metabolism.

In diabetes patients, altered markers of bone turn-over were detected. For instance, the reduction of collagen, decreased mineral content and reduced osteocalcin synthesis may contribute to low bone mass and, therefore, increased fracture risk [1].

Experimental Methods
During reconstructive foot and ankle surgery, bone fragments and blood samples were obtained from patients who suffered either from diabetic neuropathy or from posttraumatic osteoarthritis. Osteoblasts were isolated by outgrowth from bone fragments. Monocytes were obtained from patient’s blood and differentiated into osteoclasts. After treatment with artificial extracellular matrix components (sGAG), alterations in osteogenic differentiation were investigated by qPCR. Osteoclastogenesis with and without sGAG was analysed by using a quantitative resorption assay [5]. The expression of osteoblast- and osteoclast-specific genes was determined by qPCR.

Results and Discussion
Osteoblasts showed increased gene expression of osteogenic genes after sGAG treatment. Especially osteoblasts from diabetes patients were affected by sGAG, which demonstrates increased gene expression of the osteocalcin and the alkaline phosphatase genes compared to the healthy control group. Although gene expression of osteoclastic genes was enhanced by sGAG, the osteoclast-specific resorption of calcium phosphate was significantly decreased in diabetes patients. The secretion of interleukin-6 (IL-6) was increased in osteoclast culture after sGAG treatment. Additionally, the cells exhibited morphological characteristics of osteoclasts such as multinuclearity and actin ring formation.

Conclusion
Artificial extracellular matrix components cause increased expression of osteogenic genes, especially in diabetic patients. On the other hand, they inhibit bone resorption by inhibiting osteoclast resorption. Since the expression of osteoclast-specific genes is not decreased, a post-translational effect of sGAG on osteoclasts is considered.

1 Royal College of Surgeons (RCSI), Department of Anatomy/Tissue Engineering Research Group (TERG), Dublin, IE; 2 Royal College of Surgeons (RCSI) & Trinity College Dublin (TCD), Advanced Materials and Bioengineering Research (AMBER) Centre, Dublin, IE; 3 Dublin College University (DCU), Fraunhofer Project Centre for Embedded Bioanalytical Systems, Dublin, IE

Introduction

A major challenge in cartilage tissue engineering (TE) is to develop scaffolds capable of providing an improved instructive biomimetic response, to drive effective mesenchymal stem cells (MSCs) differentiation and robust de novo tissue formation while retaining the essential mechanical properties of the implant [1]. The composition of biomimetic porous scaffold-based biomaterials can play a fundamental role in TE by providing essential three-dimensional (3D) cues for infiltrating cellular populations, such as MSCs, and subsequently directing the type of the engineered tissue [2]. Biomimetic implants have shown some potential to guide with good success MSCs chondrogenesis, and subsequent cartilage-like tissue formation [1]. In particular, type I collagen-hyaluronate (CI-HyA) scaffolds have demonstrated significant chondrogenic regenerative capacity preclinically and clinically [3,4]. However, we propose that the chondrogenic potential of these biomimetic implants can be further improved for enhanced and longer lasting cartilage repair. Therefore, the aim of this work was to investigate the incorporation of type II collagen (CII), a potential chondro-inductive cartilage extra cellular matrix (ECM) component, within collagen-based scaffolds and to assess its role in directing an improved cartilage-like tissue formation [5].

Experimental Methods

Novel highly porous collagen-based scaffold were manufactured by incorporating type II collagen (CII) and/or hyaluronic acid (HyA) within a type I collagen (CI) framework using a freeze-drying (lyophilisation) method previously described and regularly used in our research group [3]. Following lyophilisation, the porous scaffolds were dehydrothermally (DHT) and chemically crosslinked. The architectural, morphological and mechanical properties of cell-free scaffolds were investigated. Scaffolds were subsequently cultured with rat-derived bone-marrow MSCs in vitro under chondrogenic conditions for 28 days. The effect of matrix components, CII and HyA, on cellular viability, growth and migration within the scaffold and their capability to direct an effective MSCs chondrogenic response, that consequently results in enhanced cartilage-like tissue formation in vitro was assessed.

Results and Discussion

Type II collagen (CII) was successfully incorporated into type I collagen (CI) and/or hyaluronic acid (HyA) scaffold biomaterials with no impact on the mechanical properties. The newly developed CI/II and CI/II-HyA scaffolds exhibited highly porous interconnected structures with 99% porosity and increased pore size compared to the CI and CI-HyA scaffolds (Fig. 1). All four scaffold variants demonstrated early cartilaginous matrix deposition but the incorporation of CII in combination with HyA allowed CI/II-HyA scaffolds to accumulate increased quantities of sulphated glycosaminoglycans (sGAG) deposition per scaffold compared to the other scaffold variants at day 28 (p≤0.0001) (Fig. 2A). In addition, the incorporation of CII, in combination with HyA, allowed CI/II-HyA scaffolds to achieve more homogeneous sGAG distribution throughout the matrix compared to the other scaffold variants as shown by safranin-O staining. Gene expression analysis revealed potential for CI/II-HyA scaffolds to further improve chondrogenesis, with no signs of progression to hypertrophy or endochondral bone formation.

Conclusion
The combination of CII and HyA resulted in the development of a scaffold with potent chondrogenic benefits, with no impact on the essential architectural and mechanical properties of the scaffold. It is speculated that the biochemical nature of these components plays a significant role in directing improved cellular growth and cartilage-like deposition/distribution. In summary, the incorporation of CII into CI-HyA scaffolds has showed promise to improve cartilage-like tissue formation and has offered a simple and prospective “off the shelf” approach to enhanced and more robust cartilage repair.

Modelling adsorption of proteins and cells on biomimetic hydroxyapatite

Abdul Raouf Atif¹, Ugis Lacis², Maria Tenje¹, Shervin Bagheri², Gemma Mestres¹

¹ Uppsala University, Uppsala, SE; ² KTH Royal Institute of Technology, Stockholm, SE

Introduction
Calcium-deficient hydroxyapatite (CDHA), a biomaterial similar to the inorganic bone matrix, can be used in non-load bearing areas to promote bone regeneration. Upon implantation, CDHA is exposed to blood, leading to serum protein deposition on the surface and enabling cell attachment via membrane-bound receptors. In cell culture studies, biomaterials are often pre-incubated in serum supplemented medium to mimic this process. In this work, to study the extent the protein layer assists in cell adhesion, a Langmuir isotherm-based model for protein and cell adhesion kinetics was utilized.

Experimental Methods
CDHA was prepared through a cementitious reaction. \( \alpha \)-tricalcium phosphate powder was mixed with 2.5% \( \text{Na}_2\text{HPO}_4 \) in a liquid-to-powder ratio of 0.65 ml/g. The cement paste was cast into discs (\( \phi = 6 \text{ mm}, h = 2 \text{ mm} \)) and then set in 0.9% \( \text{NaCl} \) for 10 days, thus completing the transformation into CDHA.

To analyze protein adsorption/desorption, a two-step experiment was performed. First, CDHA discs were incubated in culture medium supplemented with 10 mg/ml bovine serum albumin (BSA) for 3 days. Subsequently, the CDHA discs were transferred to wells containing protein-free medium and further incubated for 3 days. At set intervals along both incubation periods, medium aliquots were taken and protein content was quantified using the bicinchoninic acid assay. Modelling of adsorption and desorption was performed using a diffusion equation and the Langmuir isotherm to describe time-dependent interactions between the medium and surface concentrations:

\[
\frac{D \partial c}{\partial z} = -k_a(c_s - c_m)c - k_d c_s
\]

Here, \( c \) and \( c_s \) are bulk and surface concentrations respectively, \( c_s^m \) is the maximal surface concentration, \( D \) is the diffusion coefficient, \( z \) is the depth of the medium, \( k_a \) is the adsorption coefficient and \( k_d \) is the desorption coefficient.

Cell adhesion was evaluated over time for serum pre-incubated CDHA samples. To evaluate the influence of proteins adsorbed on the surface, pristine discs (pristine-CDHA) and discs pre-incubated for 48 h (pre-incubated-CDHA) in supplemented medium (10 v/v% FBS, 1 v/v% penicillin/streptomycin) were used. MC3T3-E1 pre-osteoblasts were stained with CMFDA dye and seeded on CDHA discs at a density of 3,500 cells/cm². Samples were imaged at 0.5, 1, 2, 4 and 6 h and subsequently counted using Cellprofiler (ver 3.1.5) software. As previously, a model inspired by the Langmuir isotherm was constructed for cell adhesion, now neglecting the detachment term as MC3T3-E1 cells are adherent.

Results and Discussion
CDHA displayed strong BSA adsorption, with 50% of total protein concentration adsorbed after 72 h (Fig. 1A). As for BSA desorption, a burst release occurred over the first 2 h of incubation, which then gradually subsided over time (Fig. 1B). Only 18% of the total BSA content desorbed after 3 days, indicating a majority remained on the HA surface. The model appeared to satisfactorily fit the data, capturing the experimental trends well and approaching a plateau state which indicates BSA exchange reached equilibrium (Fig. 1A, B).

The number of adhered cells increased in the first hour of culture, before stabilizing for the rest of the culture period (Fig. 2). Pristine-CDHA and pre-incubated-CDHA displayed similar cell counts over time (Fig. 2). This behavior was captured by the model within close fit of the experimental data, thus indicating the validity of the assumptions taken. Morphology-wise, cells cultured on pre-incubated-CDHA appeared more spread compared to cells grown on pristine-
CDHA (Fig.2), which correlated with the greater protein content adsorbed on CDHA after a 48 h incubation in supplemented medium (Fig.1A).

**Conclusion**

To summarize, this work represents a conceptual study to evaluate the use of computational modelling for the analysis of protein and cell adhesion on CDHA surfaces. Modelling allowed capture of the relation between protein and cellular behavior observed *in vitro*, thus solidifying its potential as an additional form of analysis in the biomaterial evaluation pipeline. This model is envisioned as a steppingstone towards insightful numerical models of more complex cell-fluid systems.

Evaluating the bioactivities of 3D-printed hydroxyapatite-reinforced polyetheretherketone biocomposite for orthopedic and dental applications

Xingting Han¹,², Jibao Zheng³, Chuncheng Yang³, Dichen Li³, Stefanie Krajewski², Frank Rupp²

¹ Peking University, Department of Prosthodontics, Peking University School and Hospital of Stomatology, Beijing, CN; ² Tübingen University, University Hospital Tübingen, Section Medical Materials Science and Technology, Tübingen, DE; ³ Xi'an Jiaotong University, State Key Laboratory for Manufacturing System Engineering, School of Mechanical Engineering, Xi'an, CN

Introduction
In the last few decades, polyetheretherketone (PEEK) has been used as a bone reconstruction material in orthopedic and dental applications due to its good biocompatibility, chemical resistance, low density, radiolucency, and especially for the mechanical properties resembling human bone [1]. Recently the development in 3D printing technologies has made it possible to prepare customized PEEK implants[2]. However, the unmodified PEEK surface is bioinert, which impedes tissue osseointegration and hampers its clinical adoption. One possible approach to improve PEEK’s bioactivity is to prepare composites by incorporation bioactive materials into PEEK substrates, such as hydroxyapatite (HA). Some previous studies have analyzed the bioactivities of HA-PEEK composites and found that after incorporation of HA, in vitro cell adhesion, proliferation, osteogenic mineralization, as well as in vivo bone contact and new bone formation improved significantly [3]. However, most previous studies used traditional manufacturing methods to prepare PEEK composites, e.g., injection-molding. Our former research indicated that 3D printed PEEK surface demonstrated specific printing structures with enlarged surface roughness and area, which revealed increased bioactivities of PEEK material compared with the polished surfaces[4]. Until now, studies about the bioactivities of 3D printed HA-PEEK, to the best of our knowledge, are still lacking.

Experimental Methods
In this study, 10%, 20%, 30%, 40% HA-PEEK, and pure PEEK disk samples (Φ = 14 × 2 mm³) were manufactured by a fused filament fabrication (FFF) 3D printer, the printing parameters were consistent with our previous research[5]. After preparation, the sample surface microstructure, wettability, and roughness were analyzed by SEM, drop shape analyzer, and profilometry devices, respectively. SAOS-2 osteoblast cell line was used for testing the in vitro bioactivities of PEEK and HA-PEEK composites. Cell adhesion on sample surfaces was measured after culturing for 1 d by live/dead fluorescent staining. Cell metabolic activity and proliferation were evaluated after incubation for 1 d, 3 d, and 5 d using cell counting kit-8 (CCK-8) assay. The osteogenic differentiation of SAOS-2 osteoblasts was determined by alkaline phosphatase (ALP) activity and alizarin red staining (ARS) after 5 d and 21 d incubation.

Results and Discussion
Fig. 1 indicates HA-PEEK and pure PEEK surface characterization, in vitro cell adhesion, metabolic activity, and proliferation results. The SEM result demonstrated that the pure PEEK samples indicated a relatively flat surface with clear FFF printing structures, while the HA-PEEK composite surfaces displayed a rougher and more porous appearance. Surface wettability and roughness results indicated that there was no significant difference between pure PEEK and HA-PEEK groups, and a similar tendency could also be detected in cell adhesion and proliferation test. Cell metabolic activity demonstrated that 3D printed HA-PEEK and PEEK samples were not toxic, which indicated that the FFF 3D printing process of PEEK and its composites would not generate toxic effects. The similar results between HA-PEEK and PEEK samples in surface characteristics, cell adhesion, and proliferation can be
explained by the FFF 3D manufacturing methods. After printing, the HA particles were wrapped by PEEK substrate and the bioactive effect of HA particles could not reveal in the early stage of cell culture.

Fig. 2 indicates SAOS-2 osteogenic mineralization of ALP activity and ARS tests. After 5 d incubation, the ALP activity of SAOS-2 in the 40% HA-PEEK group was significantly higher than other groups ($p < 0.001$). The ARS result revealed that compared with pure PEEK samples, the calcium phosphate attached to HA-PEEK composite surfaces was significantly higher, especially for the 40% HA-PEEK composites ($p < 0.001$). The optical microscope images of HA-PEEK also indicated stronger stained bone-like nodules with lighter red color than pure PEEK samples. The result indicated that as the incubation time prolonged, the osteoinductive effect of HA particles was revealed, especially for the increase in mineralized nodules formation.

**Conclusion**

1. After the incorporation of HA particles, a more porous surface could be obtained, but a similar surface roughness and wettability were maintained.
2. FFF printing procedure would not introduce or produce toxic substances for manufacturing HA-PEEK composites.
3. The cell adhesion and proliferation between HA-PEEK and pure PEEK were similar, but the osteogenic differentiation was increased significantly for HA-PEEK composites, especially for the 40% HA-PEEK. Therefore, the FFF 3D printed 40% HA-PEEK is regarded a promising material for orthopedic and dental implants.

hMSCs response to polymer-calcium phosphate composite scaffolds containing zinc produced using additive manufacturing

Martyna Nikodym1,2, Jiaping Li1,2, David Koper1,2,3, Elizabeth Rosado Balmayor1, Lorenzo Moroni2, Pamela Habibovic1

1 Maastricht University, Department of Instructive Biomaterials Engineering, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; 2 Maastricht University, Department of Complex Tissue Regeneration, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; 3 Maastricht University Medical Center, Department of Cranio-Maxillofacial Surgery, Maastricht, NL

Introduction
Currently available options for treating critical-size cranio-maxillofacial bone defects involve the use of either autologous bone or, alternatively, a bioinert bone graft substitute. However, the use of autologous bone can result in complications including donor site morbidity, while bioinert materials lack osteointegration ability and have a high risk of implant failure (1). We propose the use of a novel bioactive composite with high ceramic content composed of poly(ethyleneoxide terephthalate)/poly(butylene terephthalate) (1000PEOT70PBT30, PolyActive, PA) and 50% beta-tricalcium phosphate (β-TCP) with the addition of zinc (Zn) in a form of a coating of the TCP ceramic. Several inorganic ions have been shown to affect biochemical functions important for different aspects of bone regeneration (2). Although Zn is found in the bone only in trace amounts, it plays an essential role in its metabolism by stimulating bone formation by osteoblasts and inhibiting osteoclasts differentiation (3). Therefore, we hypothesise that the addition of zinc to the β-TCP will result in enhanced osteogenic properties.

Experimental Methods
Additive manufactured porous 3D scaffolds composed of 1000PEOT70PBT30, 1000PEOT70PBT30 and β-TCP in 1:1 ratio, 1000PEOT70PBT30-β-TCP composites with addition of 15% or 45% of Zn in a form of TCP coating were sterilised and seeded with bone marrow-derived human mesenchymal stromal cells (hMSCs) and cultured in either basic or mineralization medium. DNA content, alkaline phosphatase (ALP) activity and extracellular matrix (ECM) formation were assessed on days 3, 7, 14 and 28.

Results and Discussion
Additive manufactured 3D composite scaffolds used in this study contained 50% of β-TCP, which is among the highest content of ceramic in a composite with a polymer achieved so far, without the need for the use of solvents. Regarding the in vitro assessment of the osteogenic properties of the porous 3D scaffolds, hMSCs cultured on all types of scaffolds proliferated and showed ALP activity. Higher cell growth and ALP production were observed on scaffolds containing β-TCP and β-TCP with the addition of zinc than on 1000PEOT70PBT30 scaffolds. Furthermore, extracellular matrix formation was observed on all scaffolds except for 1000PEOT70PBT30 scaffolds.

Conclusion
The osteogenic properties of tested scaffolds will be further investigated by evaluation of cell differentiation at mRNA level by qPCR analysis for a set of specific osteogenic markers.

**Fabrication and characterization of a novel composite Collagen-Magnesium and Silicon doped Hydroxyapatite scaffolds for bone tissue regeneration**

_Paola Nitti_¹, Sanosh K. Padmanabhan¹, Eleonora Stanca², Luisa Siculella², Antonio Licciulli¹, Christian Demitri¹

¹ University of Salento, Department of Engineering for Innovation, Lecce, IT; ² University of Salento, Department of Biological and Environmental Sciences and Technologies, Lecce, IT

**Introduction**

The bioceramic scaffold composed of pure hydroxyapatite (HA) and doped HA with osteoinductive ions like magnesium (Mg) or silicon (Si) are widely used for bone tissue regeneration. Many works have reported the codoping with both ions in the crystal structure of HA [1], whereas in this work we doped Mg²⁺ and SiO₄⁻⁴ ions separately during powder synthesis and made composite scaffolds, using polymer sponge replica method, by mixing the doped HA powders. Subsequently, to increase the bioactivity, these scaffolds were impregnated with a collagen matrix and freeze-dried, using a new approach that led to the formation of open pores on composite scaffolds surface. The bioceramic scaffolds and composite scaffolds impregnated with Collagen were evaluated for physical, mechanical, biodegradation and biocompatible properties.

**Experimental Methods**

Pure and substituted (Mg and Si) HA were synthesized by aqueous precipitation reaction. Slurries with powders previously calcinated (HA-Mg/HA-Si powder weight ratio kept 50/50), PVA 1%wt and Dolapix were prepared and used to impregnated polyurethane sponges [2]. The impregnated scaffolds were dried and sintered. The ceramic scaffolds obtained were impregnated with collagen type I slurry (0.5 % w/v). The innovative freeze-drying approach (scaffolds were placed on ice plates, immersed in cold distilled water ~ 0°C, cooled to −20°C and then lyophilized) and DHT crosslinking (121°C for 24h under vacuum) were carried out. The ceramic powders and scaffolds were analyzed by TEM and XRD. For all were evaluated the morphology (SEM) mechanical properties, biostability in Tris-HCl, pH 7.4 up 28 days and citocompatibility using Human Bone Marrow-Derived Mesenchymal Stem Cells (BMSC).

**Results and Discussion**

The XRD analysis on powders and scaffolds after calcination and sintering processes revealed the presence a secondary β-TCP in HA-Mg and HA-MgSi, absent in the other ones. All ceramic scaffolds presented Mg and Si ions homogeneously distributed (XRF analysis), porosity >90% and pore size ranging between 200- 850 μm. TEM analysis and microstructural analysis (SEM) of powders and scaffolds HA-Si showed littler grain size compared to the others ones. This decrease seems positively influence the mechanical properties of ceramic scaffolds. Indeed, HA-Si and HA-MgSi scaffolds revealed better compression trends compared to HA and HA-Mg. This trend was observed also after 28 days of soaking in TRIS, despite the overall decrease observed for all scaffolds. To increase the bioactivity, the bioceramic scaffolds are impregnated with collagen using a new freeze-drying approach studied firstly in this work. SEM analysis showed scaffolds with more open surface porosity compared to tradition freeze-drying. This new approach avoids the formation of collagen skin layer, thanks the formation of ice crystals on the scaffolds surface that lead to have open pores on the outer layer of the scaffold. The mechanical tests on bioactive scaffolds shown the same trend observed for ceramic ones but with a considerable decrease of stress at failure (σmax), probably due to the poor compressive strength of type I collagen fibrils. The HA-Si_Coll and HA-MgSi_Coll scaffolds showed better mechanical resistance before and after immersion in physiological solution. In particular, for both scaffolds after a week of soaking, the loss of the collagen component from the scaffolds made the ceramic...
component prevail, thus leading to an increase in $\sigma_{\text{max}}$ with values similar to those observed for the corresponding ceramic ones. Cells proliferation experiment showed that all scaffolds where biocompatible and composite scaffold (HA-MgSi_Coll) is more effective for cells adhesion and proliferation compared to all other scaffolds.

**Conclusion**

In this study, bioactive scaffolds with a composite structure made with a new ceramic mix (HA-MgSi) and collagen were fabricated successfully using a new freeze-drying approach. Firstly, bioceramic scaffolds produced with the new blend of HA doped were fabricated. These scaffolds showed improved mechanical properties also up 28 days of soaking in physiological conditions and good biocompatibility compared to HA, HA-Mg and HA-Si scaffolds. In addition, to improve the bioactivity, the optimized HA-MgSi scaffolds were impregnated with collagen using a new freeze-drying approach that allow having open pores on surface. The presence of collagen and open pores have in fact promotes better cells proliferation than corresponded bioceramic scaffolds.

**Doubled Crosslinked Sodium Alginate-Graphene Oxide Hydrogels for Cartilage Substitution**

Carolina M. Costa¹, Andreia S. Oliveira¹,²,³, Célio G. Figueiredo-Pina²,⁴,⁵, Ana P. Serro¹,²

¹ Centro de Química Estrutural (CQE), Instituto Superior Técnico, Universidade de Lisboa, Lisbon, PT; ² Centro de Investigação Interdisciplinar Egas Moniz (CiiEM), Instituto Universitário Egas Moniz, Caparica, PT; ³ Instituto de Engenharia Mecânica (IDMEC), Instituto Superior Técnico, Universidade de Lisboa, Lisbon, PT; ⁴ CDP2T and Department of Mechanical Engineering, Setúbal School of Technology, Instituto Politécnico de Setúbal, Setúbal, PT; ⁵ CeFEMA, Instituto Superior Técnico, Universidade de Lisboa, Lisbon, PT

**Introduction**

The articular cartilage is of utmost importance in the musculoskeletal system due to its almost frictionless surface and biomechanical properties. Hydrogels have been studied as potential cartilage substitution for their resemblance to the extracellular matrix. In particular, hydrogels based on sodium alginate (SA) are promising candidates due to the biocompatibility of this natural polysaccharide, moisture retention properties and processing flexibility, since it can be crosslinked through ionic, covalent, or physical bonds [1]. Nevertheless, the uncontrollable degradation in saline solutions of ionic crosslinked SA and the poor mechanical strength of covalent crosslinked SA hinder their application in the tissue engineering field [2]. On the other hand, graphene oxide (GO) has gained research thrust in many areas, including biomaterials for their outstanding mechanical strength, lightweight and high surface-to-volume ratio [3]. This study aimed to develop a material with suitable mechanical and tribological properties for cartilage substitution, through a double step crosslinking and incorporation of graphene oxide within the network.

**Experimental Methods**

Alginic acid sodium salt from brown algae with medium viscosity (MW = 100 000 - 200 000 g/mol) and low viscosity (MW < 100 000 g/mol) were dissolved in DD water at 50 ºC to prepare 5% wt. SA solutions. Methacrylic modification of both solutions took place at RT for 72 h. Thereafter, solutions were vacuum filtered, and the methacrylate-alginate (MA) product was dissolved in DD water to prepare three solutions with 0.05% (w/v) photoinitiator: 10% wt. with MA of medium viscosity (10M), 10% wt. with a SA:MA ratio of 50%/50% (10M 50%) and 16% wt. MA of low viscosity (16L). Those solutions were poured in petri dishes and exposed to UV light (254 nm) for 4 hours. After covalent crosslinking, the resulting hydrogels were immersed in 1 M CaCl₂ aqueous solution for one day. SA-GO hydrogels were prepared with 0.1%, 0.2% and 0.3% (w/v) of GO in 10M solutions. 10M, 10M 50% and 16L hydrogels were characterised regarding their degradation in phosphate buffered saline solution (PBS) for 72 h at 37ºC, equilibrium water content (EW₃), mechanical performance (assessed through unconfined and hydrated compression tests at a strain rate of 0.1 mm/s at RT of as-prepared hydrogel and after 72 h in PBS. The effect of the presence of GO on the mechanical properties and tribological behaviour of the material was also evaluated. Tribological tests were performed in a pin-on-disc equipment using pins of porcine knee cartilage as countersurface (reciprocating sliding at 4 mm/s with a load of 20 N, in either PBS or human synovial fluid lubricating media).

**Results and Discussion**

A chemical modification of the hydroxyl groups of SA’s backbone enabled covalent bonding by UV exposure with further ionic bonding of the carboxyl groups. 10M, 10M 50% and 16L presented an EWC of 85-89%, similar to natural articular cartilage. The degradation of hydrogels was assessed through the weight loss quantification after immersing the dried samples in PBS for 72 h. 10M, 10M 50% and 16L had a weight loss after 72 h of 4% ± 1.67, 28% ± 2.12, and 19% ± 2.31, respectively. 10M was selected to carry out mechanical and tribological testing. Compressive modulus of 10M were evaluated before (0.65 MPa ± 0.27) and after immersion in PBS (0.57 MPa ± 0.23), falling in
the range of values reported in the literature for the articular cartilage and presenting minimal degradation after 72 h. Addition of GO improved the mechanical properties, as expected. Regarding the tribological performance, the mean friction coefficient decreased as GO content increased. Smaller friction coefficients were obtained in synovial fluid compared with PBS solution. SA-GO composite hydrogels revealed a low friction coefficient, mimicking the cartilage-on-cartilage contact.

Conclusion

In summary, a dual step crosslink proved to be a suitable approach to produce SA hydrogels for load-bearing cartilage substitution. Degradability and mechanical properties can be tailored by varying covalent and ionic bonding density. The presence of GO, even in small amounts, lowered the friction coefficient of composite hydrogels.

Introduction
Critical-size bone defects are unable to heal by themselves during the patient’s lifetime. Currently, autologous bone graft is the gold standard solution to treat such defects, but it is associated with some limitation such as limited availability, high donor-site morbidity, and inconsistency of repair in very large bone defect [1]. To tackle these drawbacks, synthetic bone grafts called scaffolds are currently being developed. These scaffolds should be biocompatible, preferably biodegradable and bioresorbable, osteoconductive, osteoinductive, and have physico-chemical properties optimizing bone regeneration. A critical parameter to obtain efficient scaffolds is their internal geometry. It has been shown that an efficient scaffold should be porous [2]. However, the ideal pore size and shape have not been evidenced yet, since they depend on many parameters and could be different depending on the site of implantation. The objective of this study was to investigate the influence of scaffold geometry on bone morphogenetic protein 2 (BMP-2) incorporation on the scaffold and on in vivo bone regeneration in a sheep metatarsal critical-size bone defect.

Experimental Methods
Three different scaffold geometries were selected for the in vivo regeneration of a long-segmental critical-size bone defect in a sheep metatarsal bone based on a literature study, previous results, and a design of experiments optimizing the geometries in terms of physico-chemical properties, mechanical properties, and ability to coat them with a biomimetic film previously developed by the authors [3]. Each scaffold (cylinder 25mm high and 14mm in diameter) was implanted in a 25-mm long segmental metatarsal defect in sheep subsequently stabilized by plate osteosynthesis (Figure 1). The first scaffold geometry, called Lines, had cubic pores with a pore size of about 880µm and a central cylinder hole of 5mm in diameter (Figure 1A). The second geometry, called Gyroid, was a triply-periodic minimal surface design with a pore size of about 1mm and a central cylinder hole of 5mm in diameter (Figure 1B). Finally, the third geometry, called Double Lines, was a mix of the two first geometries: the outer of the cylinder had cubic pores with a pore size of about 1.2mm while its center (7mm in diameter) had a gyroid pore shape with a pore size of about 2mm (Figure 1C).

Scaffolds made of medical-grade poly(L-lactic) acid were 3D printed by fused deposition modeling and coated with a polyelectrolyte film as previously described [4]. BMP-2 was then loaded in the film at a targeted surface dose of 9.2 µg/cm² of film for each geometry. The scaffolds surfaces (so the film surfaces) were assessed by micro computed tomography (µCT) scans (Figure 1): 68 cm² for the geometry Lines, 44 cm² for the geometry Gyroid and 54 cm² for the geometry Double Lines. The amount of BMP-2 effectively incorporated in the film was then quantified using a UV/Vis spectrophotometer by first measuring the concentration of the loading solution prior incubation and then measuring the concentration of this same solution after incubation. Two scaffolds of each geometry were implanted in six sheep, each sheep receiving one implant. X-ray radiographs were acquired right after the implantation and...
every month until the end of the study at four months. Then, the metatarsal bone was explanted and bone formation in the bone defect area filled with scaffolds was assessed by µCT and histology.

**Results and Discussion**

BMP-2 quantification showed that, despite the fact that all scaffolds were loaded with the same surface dose, the incorporated dose was different depending on the scaffold geometry. Indeed, the geometry Lines incorporated less BMP-2 than the other geometries (4.4 ± 1.3 µg/cm²) and the geometry Gyroid incorporated more BMP-2 than the other geometries (7.7 ± 0.9 µg/cm²). The geometry Double Lines incorporated 7.5 ± 2.8 µg of BMP-2 per cm² of film. Surprisingly, scaffolds had incorporated similar total amounts of BMP-2 (about 350 µg/implant), their effective surface being different. These results suggest that the geometry of scaffolds has an influence on BMP-2 incorporation in the biomimetic film. Interestingly, X-ray radiographs showed that despite its lowest incorporated BMP-2 surface dose, the geometry Lines presented the fastest and strongest bone formation, followed by the geometry Gyroid. The geometry Double Lines did not allow bone repair (Figure 2). As the total amount of BMP-2 was similar in every scaffolds, this suggests that the scaffold geometry influenced bone regeneration kinetics and the amount of new bone formed.

**Conclusion**

Further investigation has to be led on the influence of pore size and shape on BMP-2 incorporation and *in vivo* bone regeneration but this preliminary study opens perspective to optimize the scaffold geometry in view of long bone repair. The optimization of pore size and shape along with the optimization of the BMP-2 dose could lead to efficient implants with reduced fabrication costs and reduced secondary effects.

Injectable Bone Substitute based on Demineralized Bone Matrix, using a Polymeric Viscoelastic System as a Carrier

Daniela Medrano David1, Aura M. Lopera Echavarría1, Yesid D.J. Montoya Goez1, Edison Duque Caballero5, Jaime Duque Ramírez4, Pedronel Araque Marin2,3, Martha E. Londoño López1, COLCIENCIAS

1 EIA University, Research group GIBEC, Envigado, CO; 2 EIA University, Research and Innovation Group in Chemical Formulations, Envigado, CO; 3 CECOLTEC, Research Group, Medellin, CO; 4 Foundation, Tissue Bank, Medellin, CO

Introduction

The occurrence of bone-related disorders and diseases has increased drastically over recent years worldwide. Autologous bone grafting remains the gold standard for bone tissue repair due to their histocompatibility, no immunogenicity, capacity to promote osteoinduction and osteoconduction. Despite the many advantages of bone grafting, there exist issues such as secondary damage, significant donor site injury and morbidity, deformity, scarring, in addition to surgical risks such as bleeding, inflammation, and high cost [1]. Therefore, science has now taken on the challenge of developing new materials to be used for bone regeneration, such as Demineralized Bone Matrix (DBM) which has been widely used as a bone implant due to its osteoinduction and bioactivity [2]. However, the use of DBM is limited, due it is a particulate material, is difficult to manage and implant accurately, in addition, these particles are susceptible to migrate to other sites through the bloodstream. The main reason is DBM is commonly incorporated into a variety of carriers. An injectable scaffold composed of an inorganic and organic phase presents advantages when compared to bone grafts or pre-formed scaffolds such as the ability of the injectable scaffold to flow and fill the bone cavity or defect [3]. This project aims to develop a DBM carrier with such viscoelastic properties to obtain an injectable bone substitute (IBS). The developed DBM carrier consisted of a PVA/glycerol network cross-linked with borax and reinforced with calcium carbonate as a pH neutralizer and source of calcium.

Experimental Methods

The preparation of the material is based on mixing in a ratio of approx. 1/7 a liquid phase (PVA/glycerol/water) and a solid phase (DBM/CaCO3). Two samples were tested, where the concentration of PVA was varied. F1 represents the formulation with 2% (w/w) of PVA in the liquid phase and F2 corresponds to 4% (w/w). The mixture from the two phases resulted in a putty-like consistency, moldable and homogeneous. The final IBS samples were added to a syringe to facilitate its application. The physicochemical characterization was determined using X-ray diffraction (XRD) and Scanning electron microscopy (SEM). The force required to extrude the IBS from a syringe was determined using an Instron 3345 with a 5000 N load cell and at a speed of 5 mm/min. Injectability was determined using Eq. (1).

$$\text{Injectability} \% = \left( \frac{\text{mass extruded from the staying}}{\text{total mass before injection}} \right) \times 100\% \quad \text{Eq. (1)}$$

Degradation was calculated by gravimetric technique for 28 days. The bioactivity of IBS after immersion in SBF (simulated body fluid) for 14 days was evaluated by (SEM-EDX). Cytotoxicity in SAOS-2 was indirectly assessed by the MTT assay and cell proliferation using the Alamar Blue kit for 72 h.

Results and Discussion

The results of the injectability test are summarized in Table 1. Neves et al. indicate that for a bone substitute to be considered injectable, the force to extrude it through a syringe must be less than 100 N [4]. Under this criterion, it is concluded that F1 is an injectable formulation and whose injectability is greater than 90%. The results obtained for F2 suggest that when the concentration of PVA is doubled, the resistance to flow increases and makes injectability...
more difficult. Because of this, the research continued to characterize only F1. Using XRD, the demineralized bone matrix was found to be a highly amorphous material. The developed IBS showed an amorphous content greater than 80%, this can facilitate the adhesion of osteoblasts and influences the reabsorption processes [5]. The degree of crystallinity (approx. 14.9%) is attributed to the semi-crystalline nature of PVA. The degradation results showed a stable material, at 28 days only about 18% of its mass was degraded. After 14 days of immersion of the IBS in SBF, the formation of calcium phosphates was detected on the surface, with a Ca/P ratio of 1.3 approx. (Figure 1.B). This shows that when DBM is conveyed in the developed carrier, its bioactivity is not affected. This demonstrates the biomineralization capacity of the material, which is an essential factor in promoting the osteogenic capacity of bone-binding for bone repair materials. The MTT results demonstrated the non-cytotoxicity of the created IBS. The proliferation test showed that at 72 hours of incubation, the cell viability of the osteoblasts treated with IBS doubled with respect to the untreated cells. This proliferative effect in osteoblasts is promising for further investigation. Table 1. Injectability results

Conclusion
A promising material was developed to be an injectable bone substitute, with the characteristics that the DBM offers. Their injectability, stability, bioactivity, non-cytotoxicity, and cell proliferation in osteoblasts were tested.

Surface characterization of dental ceramics before and after thermal cycling and immersion in artificial gastric acid

Panagiotis Pandoleon, Katia Sarafidou, Eleana Kontonasaki

Aristotle University of Thessaloniki, Department of Dentistry, Thessaloniki, GR

Introduction
Nowadays there is a plethora of all-ceramic materials available in the dental market. Their different composition may result in different biological and mechanical behavior. Furthermore, temperature and pH alterations in the oral cavity may affect the biological properties and surface stability of dental ceramics. The aim of the present study was to investigate the impact of thermal artificial aging and exposure to artificial gastric acid on the surface roughness of monolithic zirconia (MZ) and zirconium lithium silicate (ZLS) ceramics. The null hypothesis was that surface roughness will not be affected after each aging treatment.

Experimental Methods
The following materials were included in the in vitro testing: Katana High Translucent - Kuraray (MZ) and Celtra Duo - Densply Sirona (ZLS). Twenty specimens were fabricated from each material in the following dimensions 10x10x1.5mm. Half of the specimens in each group underwent thermal artificial cycling, whilst the other half of them were immersed in artificial gastric acid. Thermal cycling was performed in distilled water. A total of 10,000 thermal cycles were performed between 37°C – 55°C – 37°C – 5°C, with a dwell time at each temperature of 15 seconds representing 1-year clinical time [1]. The gastric acid solution consisted of 5% hydrochloric acid (pH = 2). Specimens were immersed and placed in an incubator at 37 °C for 91 hours, equivalent to 1 year of exposure to HCl in a patient with bulimia [2]. Surface characterization was performed before and after thermal cycling and exposure to gastric acid through X-Ray Diffraction Analysis-XRD and roughness was measured with a 3D optical profilometer. The main roughness parameters Sa, Sz, Sp, Sv, and Sku were recorded, and data were statistically analyzed by one-way ANOVA with the level of significance set at p<0.05.

Results and Discussion
Initial mean values of surface roughness was 0.34 (±0.1) μm for MZ and 0.33 (±0.06) μm for ZLS without presenting any statistically significant difference between the two materials. After thermal cycling, mean surface roughness (Sa) was moderately affected by both treatments (p>0.05) accepting the null hypothesis. After immersion in artificial gastric acid all roughness parameters of MZ were slightly decreased, however the differences were not statistically significant. Similarly, non-significant differences were found for the roughness of ZLS ceramics. Ahmed et al. [3] resulted in similar conclusions, regarding milled ZLS ceramics and MZ, that presented non-significant alterations in roughness’ mean values after immersion in gastric acid with pH=1.2 for 96 hours. However, al-Thobity et al. [4] reported significant increase in surface roughness of MZ after prolonged in vitro aging of 168h in an acidic environment with pH=2.2. XRD analysis revealed the presence of cubic and tetragonal zirconia on the surface of MZ ceramics, without remarkable alterations after both thermal cycling and acidic storage. However, different crystalline phases of lithium silicates (Li4(SiO4), Li2(SiO3), Li2SiO3) were observed before and after both treatments. Qualitative analysis after in-vitro testing revealed that thermal cycling and immersion in gastric acid affected the surface micromorphology of ZLS to a greater extent compared with MZ.

Conclusion
Under the limitations of this in vitro study, it can be concluded that both dental ceramics are not affected by thermal cycling or storage in artificial gastric acid, at least for the specific time evaluated. However, slight morphological changes can occur under the thermal and pH fluctuations in the oral cavity which may accelerate the degradation of...
the materials and thus should be taken into consideration with respect to the biological long-term behavior of dental ceramics. Further long-term in vitro and in vivo studies are essential to validate these in vitro outcomes.

Animal bone matrices purification based on modified supercritical CO2 fluid processes: immunological characterisations and bone tissular regeneration capacities

Solène Rota1,2, Ludovic Sicard3, Caroline Gorin3, Catherine Chaussain3, Michel Boissière1, Raphaël Bardonnet2, Emmanuel Pauthe1

1 CY Cergy-Paris Université, ERRMECe laboratory, International House of Research, Neuville-sur-Oise, FR; 2 Biobank, Lieusaint, FR; 3 Laboratory URP2496 Orofacial Pathologies, Imaging and Biotherapies, Paris, FR

Introduction
The craniofacial area is prone to trauma or pathologies, often resulting in large bone damages, that cannot heal spontaneously. Their reconstruction is a real challenge and the gold standard surgical technique remains human bone grafting (autologous and allogenic). The increasing demand for bone grafting and the relative availability of autologous or allogenic materials are important driving forces of bone replacement research [1]. In this context, the use of alternative xenogeneic materials to repair human bone defects is a promising approach, with their natural structure and properties close to human bone. However, the risk of rejection due to immunogenic molecules – such as the alpha-Gal epitope [2] – is a major concern in animal bone transplantation to the human.

Experimental Methods
To avoid immunogenicity without compromising biological and mechanical properties of the xenogeneic bone matrix, bones were treated with the Supercrit® process. It is based on the delipidation of bone tissue by supercritical carbon dioxide, combined with a chemical oxidation of the residual proteins [3]. Supercrit® is already approved on human bone, showing complete viral inactivation and good preservation of bone properties [4]. The interest of transposing it to animal bone tissues is patent.

Results and Discussion
Our in vitro results show the efficiency of the Supercrit® process on animal bone. However, remaining traces of alpha-Gal epitope are evident on the treated bone, suggesting the need to improve the purification process. An optimized process, called Supercrit +, has been developed. It results in an important reduction of the quantity of solvent used, and therefore diminishes the potential toxicity of the chemicals on bone integrity and quality. In vivo studies are currently in progress, the first one to analyze the tolerance of the treated biomaterials in subcutaneous mice ectopic sites; and the other one to assess their osteogenic capacity on bone regeneration in rat calvaria bone defect.

Conclusion
In vitro bone characterizations are conducted to complete our in vivo data. By comparing thermogravimetric analyses, scanning electron microscopy (SEM) images, and the biochemical composition of bones, the effectiveness of the Supercrit + process on animal bone has been demonstrated, with the added benefit of using less solvent.

Physiologically Engineered Scaffolds for Restoring Large Bone Defects

Dina Abdulaziz¹, Neelam Iqbal¹, Peter Giannoudis², Animesh Jha¹

¹ University of Leeds, School of Chemical & Process Engineering, Leeds, GB; ² University of Leeds, Academic Department of Trauma and Orthopaedic, School of Medicine, Leeds, GB

Introduction
Bone is a complex multiphasic tissue with significant metabolic and regenerative properties, essential for physiological and anatomical functions, which, are disrupted when the tissue is damaged. Restoring large bone defects is one of the most critical challenges in orthopaedics because of the time needed for healing such fractured injuries. The “ideal” scaffold’s material must have the following four properties collectively to avoid missed union or non-union in a damaged bone: a) osteogenic properties for inducing and maintaining the neo-osteogenesis. b) appropriate scaffold structure for supporting the circulation of blood and nutrients. c) promote angiogenesis and d) biomechanical compatibility comparable to that of natural bone to withstand the body's load. If anyone of these properties is missing the healing of bone is compromised [1,2]. The above four properties in a bone structure are controlled within the cortex, cancellous structures, and medullar canal. In the present work, we discuss the design and fabrication of a two-layered scaffold that embodies the properties b), c), and d) in a physiological analogue of a natural bone. The scaffold provides mechanical stability, biomechanical stimulation of bone growth and tissue regenerative characteristics via increased vascularisation for improved diffusion of nutrients and oxygen to cells.

Experimental Methods
Layer-1 material was prepared by mixing different ratios of titanium powder with 10% iron-doped brushite mineral. Porosity within the cortical structure was controlled by adjusting the ratio of mineral and alloy phase. The powder pressed pellets were sintered in Argon atmosphere at 850 °C, 1000 °C and 1150 °C for 2 h. For the fabrication of cancellous Layer-2, 6 g of chitosan flakes was dissolved in a 2 (v/v)% aqueous acetic acid solution under continuous mixing for 24 h, after which different quantities of brushite minerals (i.e. 20, 30, 40 and 50 (w/v)%%) were added. The mixtures were left to dry until the formation of a compact membrane and frozen at -80 °C for 24 h, then freeze-dried for 24 h. The structure of the scaffold is shown in figure 1 (a) and (b).

Results and Discussion
Fourier-transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD) techniques verified the synthesis of brushite mineral and the phase changes in the metal part. XRD confirmed that titanium samples sintered in an inert atmosphere were not oxidised regardless of the sintering temperature. While the heated iron-doped brushite (DPCS-Fe) has been transformed into β-pyrophosphate, known for its osteoconductive properties and controllable degradation rate. For both Layer-1 and Layer-2 materials, the porous structures were confirmed via SEM characterisation as depicted in figure 1 (d) and (e). The elastic modulus values obtained for the Layer-1 materials ranged between 10 - 40 GPa based on the level of porosity, brushite ratio and sintering temperature. These values are comparable with that of human cortical bone (2-18 GPa), which means they can minimise the stress-shielding effect. Also, they showed suitable yield strengths (~125 MPa) to resist permanent shape change under Loading. Contact and Extract Cytotoxicity Assay verified that Layer-1 and Layer-2 materials do not present any toxicological risks. Figure 1 (c) displays the confocal microscopy image of Alexa Fluor-488 and Dapi fluorescent stained cells on the Layer-1 porous titanium samples. Osteoblasts were able to grow and proliferate on both synthesised materials, as shown in figure 2.

Conclusion
This work investigated the fabrication of two-layered synthetic bone scaffolds which, can provide the appropriate mechanical support and biological response during bone restoring. The synthesised materials were characterised, mechanically and biologically tested. Results of both Layer-1 and Layer-2 biomaterials indicate comparable Young Modulus to cortical and cancellous bone, respectively. The scaffold materials do not present any toxicological risks, while the cell attachment and proliferation results for up to 7 days were promising. The confocal microscopy results confirmed osteoblast growth and proliferation throughout the Layer-1 and Layer-2 biomaterials.

Analysis of the recovered biopolymers-bioactive glass with gold nanoparticles after bone implantation

Klara Magyari¹,³, Alexandra Dreanca²,¹, Marian Taulescu², Milica Todea⁴,¹, Tamas Gyulavari³, Lucian Baia¹,⁵

¹ Babes-Bolyai University, ICI-BNS, Cluj-Napoca, RO; ² University of Agricultural Science and Veterinary Medicine, Faculty of Veterinary Medicine, Cluj-Napoca, RO; ³ University of Szeged, Department of Applied and Environmental Chemistry, Szeged, HU; ⁴ Iuliu Hațieganu University of Medicine and Pharmacy, Faculty of Medicine, Cluj-Napoca, RO; ⁵ Babes-Bolyai University, Faculty of Physics, Cluj-Napoca, RO

Introduction

The ideal scaffold can simulate the natural mechanism of regeneration from the human body; thus, the ideal bone scaffold has the following requirements: excellent bioactivity, good biocompatibility, osteoconductivity, osteoinductivity, simulate angiogenesis, relevant structural-mechanical properties and biodegradable properties [1]. A promising approach to solve several mentioned issues is the use of composites with polymer, ceramics, metals, cells and growth factors [2]. Excellent bioactivity could be given by bioactive glasses (BG) that can bind with bone in the living organism. BG with gold nanoparticles (AuNPs) content can stimulate keratinocytes cell proliferation [3]. In our recent study was demonstrated that alginate-pullulan-bioactive glass with spherical gold nanoparticles (Alg-Pll-BGAuSP) are promising materials for soft and bone engineering endeavors [4]. Continuing this study, the composites were implanted in bone defect in Wistar rats for 8 weeks, after that the remained materials were recovered. For the control β-tricalcium phosphate-hydroxyapatite (Alg-Pll-βTCP/HA) was used after introducing it in an alginate-pullulan composite.

The aim of this study was to understand the formation of apatite layer on materials surface implanted into the bone defect (Figure 1). This will be useful in the future for designing materials for applications in medicine.

Experimental Methods

The Alg-Pll-AuSP and Alg-Pll-βTCP/HA composites were obtained by cross-linking method. In vivo implantations were carried out in Wistar rats. A bone defect was created into the distal part of the femoral diaphysis. The implanted materials were recovered after 8 weeks and were analyzed via X-ray diffraction (XRD, Shimadzu XRD 6000), FT-IR spectroscopy (Jasco 6200), scanning electron microscopy (SEM, Hitachi S-4700 Type II ) and X-ray Photoemission Spectroscopy (XPS, SPECS PHOIBOS 150 MCD system ). For comparison the samples were immersed in simulated body fluid (SBF, pH 7.4) at 37°C for 8 weeks.

Results and Discussion

The XRD pattern of the recovered composite, like that immersed in SBF, shows the diffraction pattern of apatite. The FT-IR spectra of the recovered material, beside the specific vibration bands of apatite, presents the vibrations of the proteins and amino acids: amide I (1650 cm⁻¹), amide II (1550 cm⁻¹) and amide III (1300 cm⁻¹), proving the attachment of proteins on the material surface. The presence of the proteins and apatite layer on the samples surface also has been proven by XPS spectroscopy. The presence of the apatite layer on the composites’ surface is also confirmed by the SEM micrographs both for the recovered materials and for immersed materials in SBF. In the case of recovered materials, the granulation of apatite is smaller than after SBF immersion due to the presence of proteins.

Conclusion

The composites of alginate-pullulan–bioactive glass with gold nanoparticles and alginate-pullulan-hydroxyapatite/tricalcium phosphate were successfully synthesized by cross-linking method and implanted in the rat at the distal part of the femoral diaphysis. The surface of the recovered composites was covered by an apatite layer,
as a result of the immersion of the sample’s surface in SBF, this behavior indicating that the in vitro bioactivity assay is a good and inexpensive method for the evaluation of the materials bioactivity.

Supercritical sterilization for the processing of sensitive biomaterials

Clara López-Iglesias¹, Víctor Santos-Rosales¹, Beatriz Magariños², Carlos A. García-González¹

¹ Universidade de Santiago de Compostela, Department of Pharmacology, Pharmacy and Pharmaceutical Technology, I+D Farma Group (GI-1645), Faculty of Pharmacy, Santiago de Compostela, ES; ² Universidade de Santiago de Compostela, Department of Microbiology and Parasitology, Faculty of Biology and Center for Biological Research of the University of Santiago de Compostela (CiBUS), Santiago de Compostela, ES

Introduction
Sterility is defined as the absence of viable microorganisms and is a fundamental requirement for medical devices to minimize the risk of infection after implantation [1]. Some materials can be sensitive to standard sterilization techniques, such as steam, dry heat, UV light, ethylene oxide or gamma irradiation, and suffer important damage in their structure. This scenario is particularly challenging for the sterilization of biomaterials, including polymeric scaffolds.

Supercritical CO₂ (scCO₂) is a recognized antimicrobial agent effective against vegetative forms of a wide range of microorganisms [2]. By the incorporation of additives, such as or (H₂O₂, EtOH, …) the sterilization of, spores i.e. resistance forms, can be also achieved. Overall, the mild conditions of temperature and pressure required for scCO₂ sterilization opens up the processability of biomaterials with complex structures.

In this work, the efficacy of different supercritical sterilization methods was studied against not only Gram(+) and Gram(-) vegetative bacteria, but also bacterial endospores. In addition, the developed sterilization protocol was tested for the processing of polymeric aerogels of different sources (alginate, chitosan, starch and pectin) in terms of physicochemical and structural stability.

Experimental Methods
Staphylococcus aureus and Pseudomonas aeruginosa were selected as model Gram(+) and Gram(-) bacteria, respectively.

Liquid suspension of the bacteria (10⁸ CFU/mL) were loaded in a high-pressure autoclave (NovaGenesis, NovaSterilis Inc., Ithaca, NY, USA), which was heated to the desired temperature and pressurized with CO₂. After a certain contact time, the system was depressurized at a constant flow rate until atmospheric pressure.

The samples were recovered and seeded in tryptic soy agar (TSA) plates for colony forming units (CFU) quantification. The parameters of the sterilization trials are summarized in Table 1. The optimal conditions of pressure, temperature, duration of the process and depressurization rates were obtained.

For the sterilization of bacterial endospores, a commercial suspension of Bacillus pumillus was employed. The bacterial suspension was inoculated in a 1 cm² polymeric porous membrane, which was introduced into thermally sealed sterilization sachets in triplicate. The sterilization procedure was carried out in the NovaGenesis equipment, and afterwards the samples were incubated for 24 h in TSB. Conditions for the sterilization procedures are also summarized in Table 1.

To evaluate the stability of biopolymeric aerogels to the sterilization process, the aerogels were subjected to the same conditions and evaluated in terms of textural properties using nitrogen adsorption-desorption tests, and morphology using scanning electron microscopy and image analysis.

Results and Discussion
A sterilization process for vegetative S. aureus and P. aeruginosa was optimized at 100 bars of pressure, 40 °C of temperature, 30 min of duration and 5 bar/min of depressurization velocity without using any additives, achieving a logR of 8 both for Gram(+) and Gram(-) bacteria (Table 1). Attempts to reduce the sterilization time to 10 min resulted...
in reduction in the bacterial growth, but did not achieve complete bacterial inhibition. At these conditions, the process was more efficient for *P. aeruginosa* (logR = 6) than for *S. aureus* (logR = 7). Gram(+) bacteria are more resistant to scCO₂ sterilization due to lower diffusion of CO₂ through the peptidoglycan membrane [3].

Regarding the endospore sterilization, the process was optimized at 100 bar, 39 ºC, 30 min of duration and a depressurization rate of 17 bar/min, achieving complete endospore inhibition when including 300 ppm H₂O₂ as an additive (Table 1).

Regarding the stability of the aerogels under the supercritical sterilization conditions, the textural and morphological properties were maintained for both the optimized procedures.

**Conclusion**

Optimized sterilization procedures of short duration and mild conditions of P and T were obtained both for vegetative bacteria and bacterial endospores. The process did not affect the structural properties of biopolymeric porous materials and is therefore compatible with the sterilization of these structures.

Nanocarrier loaded pollen microcapsules as ocular delivery platform

Sandra Robla¹, Jose Manuel Ageitos¹, Rubén Varela-Calviño², Ignacio Alcalde³, Jesús Merayo-Lloves³, Noemi Csaba¹

¹ University of Santiago de Compostela, Department of Pharmacy, Pharmacology and Pharmaceutical Technology/Center for Research in Molecular Medicine and Chronic Diseases (CiMUS), Santiago de Compostela, ES; ² University of Santiago de Compostela, Department of Biochemistry and Molecular Biology, Santiago de Compostela, ES; ³ University of Oviedo, Fernández-Vega University Institute, Ophthalmological Research Foundation, Oviedo, ES

Introduction
Topical administration constitutes a challenge in the design of ocular drug delivery strategies. Despite its easy accessibility, the eye is protected by extraordinary anatomical and physiological barriers which strongly limit drug residence time and, therefore, the efficacy of drug delivery systems. In this work, we present a biomimetic strategy to overcome these limitations by using purified pollen as a specific tool for enhancing mucointeraction of drug nanocarriers.

Experimental Methods
We designed a multi-stage delivery platform based on echinate Helianthus annuus pollen grains. Purification of this natural platform was performed by sequential washing steps to remove the pollenkitt and internal components. Morphology and composition were analyzed by analytical and microscopical techniques. Processed hollow pollen microcapsules (HPMs) were loaded with model nanoparticles of different properties (i.e. size, surface charge) using freeze-drying and vacuum-driven methods. Loading efficiency was analyzed by fluorimetry. Considering the results obtained with commercial nanoparticles, biodegradable protamine nanocapsules were developed, physically characterized, and loaded into Helianthus annuus HPMs. Evaluation of the initial immune response to pollen allergens of loaded and non-loaded HPMs platforms was performed in vitro, using immature dendritic cells obtained from patient blood. In vivo histological staining of the different sections of the rat eye was accomplished with different ocular lymphocytes and dendritic cells markers to evaluate activation after pollen exposition. Biocompatibility and physical irritation effects were evaluated upon ocular administration to rat eye in vivo. Additional analysis of epithelial damage was carried out in vitro by means of measuring the transepithelial resistance (TEER) on an artificial 3D cornea model of human sclerocorneal limbus epithelium (HCLEC).

Results and Discussion
Purified HPMs prepared from Helianthus annuus kept the same external 3D structure as intact pollen grain but were free of internal compounds. Among all the prototypes, non-biodegradable model nanoparticles (200 nm) reached the highest loading efficiency (around 85%), so that we designed biodegradable polymeric nanocapsules (NCs) with similar size and surface charge characteristics. NCs were fluorescently labelled with DiD to subsequently study their localization in the pollen and eye structures. Studies in ocular environment showed that protamine NCs were stable, and no relevant signs of aggregation were observed during 24h in Simulated Lacrimal Fluid at 37°C in suspension, and upon reconstitution after freeze-drying. As next step, HPMs were combined with fluorescently labelled protamine nanocapsules, using several pollen/NCs ratios and loading procedures, achieving up to 66% association efficiency rates (nanocarriers associated/total of nanocarriers) and NCs loading capacity (mass of loaded nanocarriers/mass of pollen grain loaded with nanocarriers) of 40% at ratio 1:1 and vacuum conditions. The presence of pollen grains loaded with fluorescent nanocarriers in the cornea and conjunctiva was confirmed. Released nanocarriers could be detected in conjunctiva 30 minutes after ocular administration by fluorescence microscopy examination. The immune cell recognition assay showed that the instillation of HPMs did Page 1170 of 2028
not cause greater cell activation than that observed in non-treated eyes, which is an indicator of an optimal purification procedure able to avoid allergenicity when used via ocular route. Moreover, regarding ocular biocompatibility and tolerability, no signs of hyperemia, anormal mucus/tear secretion or animal discomfort were detected in vivo by in-situ macroscopic observation even 6 hours after pollen administration. Finally, the 3D corneal HCLEC tissue model showed that no epithelial rupture took place, showing preserved integrity over 3 h of exposure to pollen.

Conclusion

The developed purification procedure could produce hollow and resistant pollen derived microcapsules with a high internal and external surface which make them ideal candidates for the association with nanostructures, such as protamine nanocapsules. Their biocompatibility and tolerance, allergen-free composition, as well as their mucoadhesion properties make this 3D microneedle-like platform an efficient strategy to overcome the biological and mechanical barriers of ocular drug delivery.

Advanced modification of alginate dialdehyde-gelatine composite bioinks with bioactive inorganic fillers for 3D bioprinting approaches

Susanne Heid¹, Kevin Becker¹, Jiwon Byun¹, Hsuan-Heng Lu¹, Aldo R. Boccaccini¹

¹ Friedrich-Alexander University, Institute of Biomaterials, Erlangen, DE; ² Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, DE

Introduction
Recent years have seen tremendous advances in the field of biocompatible composite hydrogel-based biomaterials and their use in 3D biofabrication [1]. Encapsulating cells into such hydrogels has become an important approach for the reproduction of customized tissues in terms of healing or the replacement of damaged human tissues and cartilage. A favorable material that can be used for 3D bioprinting is sodium alginate due to its comparatively low cost, tunable properties and similarity to the extracellular matrix. In order to overcome its poor cell attachment it can be oxidized to alginate dialdehyde (ADA) and crosslinked afterwards with RGD-containing ligands for example with gelatin (ADA-GEL). Not only cell viability and proliferation but also the printability of hydrogels, which is defined by shape fidelity and printing resolution, is a crucial factor in the design of application-specific bioinks.

The aim of this project was to evaluate the 3D printability and cell compatibility of a composite bioink consisting of pharmaceutical grade alginate, gelatine and incorporated inorganic fillers with respect to 3D bioprinting approaches.

Experimental Methods
In this study, composite bioinks containing bioactive inorganic fillers were developed. Therefore, filler amounts between 0 and 0.5 wt% were incorporated into ADA-GEL hydrogels having different ratios. Degradation studies, mechanical testing, cell encapsulation of fibroblast cells and bioprinting took place. Moreover, the rheological properties of the composite bioinks were assessed. 3D printing studies were performed to analyze the smallest possible resolution and a printing window in dependence of the composition and the effect of the single components.

Results and Discussion
Hydrogel-based bioinks need to reconcile sufficient mechanical properties and a good shape stability of bioprinted 3D constructs with high cell viabilities and functionalities post-printing. As it is challenging to attain such issues with pristine ADA-GEL bioinks, a bioactive ADA-GEL composite hydrogel for 3D bioprinting was designed by incorporating different amounts of BIF like calcium silicates on the basis of research outcomes by Leite et al. [2]. The material composition was optimized and the printing resolution, strand homogeneity and shape fidelity were evaluated under the effect of gelation time resulting in a predictable printing window. We observed that both printing resolution and accuracy depend on material’s as well as printing parameters that have to be critically analyzed for every hydrogel bioink. It could be clearly shown that there was an optimal amount of incorporated BIFs in ADA-GEL and that the bioink reveals temperature-time dependent gelation kinetics due to gelatine incorporation. Furthermore, bioactive properties of BIF and their release of bivalent calcium ions can strengthen the polymer network of the composite hydrogel over time leading to enhanced viscoelastic properties and a better stability after printing. Chemical and mechanical properties of the composite bioink were examined, too. Furthermore, cell viability and cellular behavior during incubation as well as the effect of the inorganic fillers on these issues were studied using fibroblast cells proving the cytocompatibility of the ADA-GEL-BIF composite bioink for 3D bioprinting and its use in regenerative medicine.

Conclusion
Composite bioinks composed of ADA-GEL and bioactive inorganic fillers were developed and their suitability for 3D bioprinting was shown. Particle filler concentrations up to 0.1 wt% could enhance the printability and post-printing...
shape stability, whereas higher concentrations led to non-uniform ink deposition which lowered the printing resolution as well as printability. In further studies, the long-term evaluation of printed constructs with fibroblast and muscle cells will be assessed.

Bioresorbable Electrospun Sol-Gel-derived Membranes to Prevent Post-surgical Adhesions without Shrinkage Effects during the Inflammatory Phase

Bastian Christ¹, Tobias Weigel¹, Christina Ziemann², Maximilian Oppmann¹, Susann Dehmel², Martin Engelke², Jörn Probst¹

¹ Fraunhofer ISC, Translational Center Regenerative Therapies TCL-RT, Würzburg, DE; ² Fraunhofer ITEM, Hannover, DE

Introduction
Post-surgical adhesions are frequent complications after soft tissue surgeries at bowel or uterus. They often result in severe pain, reoperation, infertility or bowel obstruction.[1] Unfortunately, anti-inflammatory and immunosuppressive drug therapy is not sufficient to reduce development of adhesions, but absorbable barrier membranes seem to be more effective. Such membranes act by direct separation of wounded and healthy tissue layers during the inflammatory phase of tissue healing and prevent migration of cells through the barrier. Electrospun membranes of biodegradable polymers might represent promising new adhesion barrier materials.[2, 3] As organic electrospun membranes are known to show shrinkages under physiological conditions, which causes shear stress during the healing process, the authors decided to develop an electrospun sol-gel-based inorganic barrier membrane that remains dimensionally stable for at least 7 days and is then fully resorbable within a few weeks.

Experimental Methods
Hydrolysis and condensation of tetraethylorthosilicate resulted in a sol that was spun to a fibrous membrane by electrospinning. The electrospun membrane itself was characterized by scanning electron microscopy (SEM) and infrared spectroscopy (FTIR). The resorption process of the membrane was monitored gravimetrically, accompanied by SEM imaging. All resorption products were identified by gas chromatography, ICP-analysis and photometric assays to finally quantify soluble silicic acids. Cell culture experiments were performed with primary human dermal fibroblasts (hdf) and L-929 murine fibroblasts to evaluate both cytotoxicity and the genotoxic potential of the material [WST-1-assay, cell number, lactate dehydrogenase (LDH) release and comet assay]. A cell migration experiment was performed on a membrane pre-degraded for 7 days and potentially infiltration of the material by stained cells was visualized via confocal microscopy.

Results and Discussion
The obtained electrospun silica fiber membrane with a thickness of 200 µm consisted of fibers with a diameter of about 1 µm and reveals a microstructured surface. A gravimetrical resorption study showed full material resorption in an excess of phosphate buffered saline and o-silicic acid was identified as the only resorption product. SEM pictures of the resorbed fiber membranes indicated an open mesh structure even during material resorption, allowing nutrition and metabolite transport through the membrane. In parallel, cell culture experiments with direct material contact showed undisturbed hdf proliferation and form stability of the membrane for 4 weeks (see figure). Cyto- and genotoxicity testing of the fibrous materials demonstrated neither a toxic or genotoxic effect when tested in direct contact nor when tested in form of o-silicic acid saturated cell culture media. In a final experiment, the silica membrane was pre-degraded over a period of 7 days – equivalent to the relevant inflammatory phase causing tissue adhesions – and subsequently seeded with murine fibroblasts (L-929). After a cell culture period of 7 days, cells were live/dead-stained and growth of cells into the membrane was monitored by confocal microscopy. Living cells were detected on the entire membrane surface and the function of a barrier was given, since no cell migration was observed.

Conclusion
Page 1174 of 2028
The developed electrospun silica membrane, which fully resorbs into o-silicic acid, showed excellent properties for the use as a physical adhesion barrier against post-operative adhesions. Due to its form stability over at least 4 weeks, wound healing will not be affected by shear stresses based on material shrinkage effects. Additionally, cyto- and genotoxicity testing verified biocompatibility of the fibrous material and a barrier function of the membrane was proven in a cell colonization experiment for 14 days under physiologic conditions.

Tailoring dermal models using collagen type I from various animal sources

Maria Crespo-Cuadrado, Gema Dura, Ana Ferreira-Duarte, Kenny Dalgarno, Peter Hanson, Mark Birch-Machin, Philippe Mondon, Bhaven Chavan

School of Engineering, Newcastle University, Newcastle-upon-Tyne, GB; School of Chemistry, Newcastle University, Newcastle-upon-Tyne, GB; Mental Health, Dementia and Neurodegeneration, Translation and Clinical Research Institute, Newcastle University, Newcastle-upon-Tyne, GB; Dermatological Sciences, Translational and Clinical Research Institute, Newcastle University, Newcastle-upon-Tyne, GB; Sederma SAS, Le Perray en Yvelines, FR; Croda Europe Ltd, Snaith, East Yorkshire, GB

Introduction
Collagen type I is the most abundant extracellular-matrix components in the human body. This natural fibrillar protein provides structural support for cells and stimulates their proliferation. The different assembly and distribution of collagen fibres define the mechanical properties of tissues and organs such as skin, cornea, bones or tendons. For these reasons, collagen type I has become a widely used material for reproducing tissue models in research. Despite diverse animal sources and extraction methods having been used through the years to obtain collagen type I, they are often utilised indistinctively, and little is known on the impact of their origins on the properties of in vitro models. In this study, we explored how collagen's physicochemical properties are affected by their sources and how they ultimately influence cell behaviour.

Experimental Methods
The properties of two of the most commonly used animal sources of collagen, rat and bovine, were compared with human collagen type I properties. The effect of the collagen isolation method was assessed by comparing acid-soluble telocollagen and pepsin-extracted atelocollagen. Collagen solutions were characterised by Fourier-Transform Infrared Spectroscopy (FTIR) to determine the chemical differences between collagen sources and extraction methods. Rheological measurements were performed to study the fibrillogenesis and mechanical properties of collagen gels. Additionally, collagen fibre morphology and distribution were characterised by Scanning Electron Microscopy (SEM). To evaluate cell behaviour, 50000 fibroblasts were encapsulated per gel and samples were fixed after 1, 3 and 7 days. Proliferation was assessed by quantifying dsDNA content, whereas fibroblast morphology and distribution were studied by staining the samples with rhodamine-phalloidin and DAPI.

Results and Discussion
Although essential amide groups related to native collagen type I were present in all collagens, additional chemical bonds were found in the collagens depending on their source. These differences were observed to affect collagen's gelation, fibre morphology, and subsequently, their mechanical properties. In bovine telo-collagen, thick fibres originated by the entanglement and alignment of fibrils with different thickness resulted in stiffer collagen gels. The heterogeneity and complexity of these structures increased the time required to form the gels. In contrast, bovine atelocollagen and human collagen presented thinner and more aligned fibre networks with higher porosity, while rat collagen showed spherical bundles of thin fibres, which reduced their gelation time and final stiffness. Fibroblast attachment, morphology and proliferation were also affected by the selection of collagen source and extraction methods. Bovine collagen demonstrated to promote higher cell adhesion and proliferation than collagen from other sources.

Conclusion
The possibility to tailor key properties of collagens such as fibre morphology, gelation profile, and cellular behaviour by selecting specific collagen sources opens the door to the improvement of the reliability of *in vitro* tissue models and their production processes.

Introduction
Calcium phosphates (CaP)-based biomaterials are widely used in orthopaedics and dentistry, in the form of bone substitutes and coatings, to promote osseointegration and regeneration of native bone [1]. Together with promoting integration, implantable materials shall discourage infection, which is frequent, hard to eradicate and can have severe complications [2]. To this aim, thin films (thickness below 1 micron) having high adhesion to the substrate and a nanostructured surface texture are desired [3]. In addition, a tunable composition is required to resemble as closely as possible the composition of mineralized tissues and/or to intentionally substitute ions having possible therapeutic functions. However, the mineral phase of bone, enamel and dentine is a very complex material, a multi-substituted apatite containing several foreign ions in variable concentrations [4,5]. Each trace ion has an impact on the characteristics of the apatitic lattice, its solubility and crystallinity, and on its interactions with the host. In addition, some ions (such as zinc and fluorine) have specific therapeutic functions, including a concentration-dependent capability to inhibit microbial proliferation [4,5]. Reproducing the composition of mineralized tissues by synthetic routes, to date, is not possible. For this reason, the use of biogenic sources is receiving increasing attention [5]. Here, we propose new antibacterial bone- and enamel-like coatings, obtained by a natural fluorapatite deriving from a seashell, Lingula Anatina, for application in orthopaedics and dentistry. Different from the majority of seashells, which are composed of ion-substituted calcium carbonates, lingula consists of a rhythmic alternation of organic and mineralized layers, the latter being a carbonate-substituted fluorapatite.

Experimental Methods
Using lingula shell, nanostructured thin films are manufactured, obtained by Ionized Jet Deposition (IJD), directly by using the shell as a deposition target (Figure 1a). Morphology (FEG-SEM) and composition (ICP, EDS, FT-IR) of the nanostructured coatings are assessed (figure 1), to investigate the capability of IJD to preserve the main phase and the substitutions that are present in the shell. Then, their biocompatibility is tested on fibroblasts (Alamar blue) and their antibacterial efficacy is tested against Gram-positive and Gram-negative bacterial strains (Escherichia coli, Staphylococcus aureus, Pseudomonas aeruginosa, Enterococcus faecalis), in terms of reduction of bacterial viability and substrate adhesion.

Results and Discussion
Results show that lingula is composed by a carbonated fluorine- doped apatite, also containing traces of zinc, magnesium, strontium and manganese and by chitin, allowing a significant antibacterial activity. Once deposited by Ionized Jet Deposition, nanostructured films are obtained, composed by nanoscale aggregates having the same composition of the inorganic phase of lingula (Figure 1b,c). This indicates that IJD permits a good conservation of the target stoichiometry, avoiding the formation of secondary products and/or a poor conservation of ion doping, characteristic of many plasma-assisted techniques. Coatings cause a high reduction of viability on all the tested strains, and a moderate effect on E. coli. The effect is dose-dependent causing the delay/impairment of bacterial
growth when supplied at low concentration and exerting a toxic/killing effect towards bacteria when added at high concentration.

Conclusion

Results show that nanostructured antibacterial and biomimetic nanostructured films can be obtained by Ionized Jet Deposition of lingula seashell. The obtained coatings are promising for application in orthopaedics and dentistry.

Tribological performance of leucite reinforced with zirconia for dental applications

Ana C. Branco1,2,3, Tiago Santos4, Mário Polido3, Rogério Colaço5, Ana P. Serro1,3, Célio G. Figueiredo-Pina2,3,6

1 Instituto Superior Técnico, CQE, Lisbon, PT; 2 Instituto Politécnico de Setúbal, CDP2T, Setúbal, PT; 3 Instituto Universitário Egas Moniz, CiiEM, Monte da Caparica, PT; 4 HiTEC, Porto Salvo, PT; 5 Instituto Superior Técnico, IDMEC, Lisbon, PT; 6 Instituto Superior Técnico, CeFEMA, Lisbon, PT

Introduction
Due to the attractive aesthetic properties, ceramic materials are the ultimate choice to repair/replace damaged/lost dental tissues. Zirconia is one of the most used ceramic material for dental restorations, mainly due to its toughness [1]. However, zirconia frameworks need to be coated with a glass veneer to improve their optical properties [2]. One of the major problems of these type of coatings arises from their inability to support the high loads during biting and mastication processes, leading to chipping of the glass veneer [3]. Furthermore, the wear induced on the antagonist dental surface, mainly due to microfracture based wear mechanisms, is also an issue. Vitroceramics, like leucite and lithium disilicate, constitute an alternative to produce monolithic dental structures without the need of a surface coating, due to their excellent optical properties. However, due to their low toughness, they usually lead to fracture and extensive wear of the antagonist teeth and the prosthetic material itself [4], which limits their application to the anterior part of the dental arcade, where the mechanical requirements are lower. Thus, the aim of this work is to obtain leucite-based glass ceramics with improved tribological performance through the reinforcement with zirconia nanoparticles.

Experimental Methods
Samples were produced by mixing leucite and zirconia powders (25 wt % tetragonal zirconia stabilized with 3 mol % of yttria (3YTZP)), by unidirectional compression applying a pressure of 75 MPa. Samples of 100% leucite and 100% zirconia were also produced using the same procedure for comparison purposes. Samples containing leucite were sintered at 1000°C for 6h, while 100% zirconia was submitted to 1500°C for 2h. The mechanical properties of the materials (hardness and toughness) were characterized, as well as their tribological behaviour against natural human cusps in artificial saliva, using a chewing simulator (360000 cycles, which corresponds approximately to 1.5 years of in vivo chewing). The wear mechanisms were accessed by scanning electron microscopy (SEM) and chemical analysis was performed by energy dispersive spectroscopy (EDS). The wear coefficient of the ceramic samples was determined from the volume loss obtained from profilometer images, while for cusps it was calculated based on 3D scans performed before and after the wear tests.

Results and Discussion
A wear coefficient reduction of 18 times was found for the composite when compared to 100% Leucite (Figure 1A). The presence of zirconia in the composite material led to a mild abrasion wear mechanism (Figure 2B), in contrast to that observed for 100% Leucite, where severe wear was observed, mainly due to fracture followed by spalling of large quantities of material (Figure 2A). Regarding dental cusps, the results pointed out that the composite material led to a dramatic reduction of dental wear when compared to 100% Leucite, being very similar to that observed for 100% zirconia (Figure 1B). SEM analysis showed that 100% Leucite induced abrasion, delamination and fracture on the dental surfaces, with adhered dental particles and also particles rich in SiO2 and Al2O3 (leucite wear debris) (Figure 2C). For the cusps tested against the composite material, abrasion was the predominant wear mechanism with some adhered dental particles (Figure 2D).
Conclusion
Overall, the results obtained with the studied composite are promising, since the wear of the antagonist teeth is much lower than that observed with 100% Leucite, being close to the one obtained with 100% zirconia.

Bacterial Cellulose as Cell Substrate and Mesh to Reinforce Body Tissues

Anna Roig, Irene Anton-Sales, Soledad Roig-Sanchez, Anna Laromaine

Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Campus UAB, 08193 Bellaterra, ES

Introduction
Bacterial cellulose (BC) is an animal and donor-free natural polymer presenting some inherent characteristics that are highly regarded in the healthcare sector - purity, biocompatibility, mechanical resistance, thermal stability and a fibrilar microstructure similar to that of the collagen extra-cellular matter.

Experimental Methods
BC hydrogels were synthesized by Komagataeibacter xylinus grown on Hestrin-Schramm medium. K. xylinus cultures were culture for 3 d under static conditions at 30 °C to obtain BC fleeces that were sterilized by autoclaving. Extensive biomaterial characterization encompassing mechanical properties, microstructure and rugosity was undertaken.

Results and Discussion
Here, we will present technical data supporting the use of BC films as cryopreservable cell culture substrates for fibroblasts [1] and as cell support for limbal stem cells with the final objective to treat injured cornea (Figure 1A) [2,3]. Besides, we will also report on the use of BC as a mesh for hernioplasty gathered after the in vivo implantation of BC films in rabbits for 21 days (Figure 1B).

Conclusion
BC substrates present excellent biocompatibility and provide a self-standing and easy to manipulate mechanical substrate for the cells. It supports the formation of new daughter cells for fibroblast while additionally retaining the progenitor phenotype in the case of limbal stem cells. Regarding the use of BC as tissue reinforcement, the in vivo study revealed that BC exhibits favourable surgical features and excellent accommodation to the implantation site. Besides, mild adhesion scores involving low percentages of the implant's area together with excellent integration on the peri-implant zone could be demonstrated.

Fibroblast viability and orientation on BaTiO3 functionalized zirconia.

Laura K. Tiainen¹, Oscar Carvalho¹, Michael Gasik³, Filipe S. Silva¹, Beatriz Ferreira Fernandes²

¹ University of Minho, Mechanical Engineering Department, Guimaraes, PT; ² Universidade de Lisboa, Faculdade de Medicina Dentária, Lisboa, PT; ³ Aalto University, Department of Chemical and Metallurgical Engineering, Espoo, FI

Introduction
A successful dental implant relies on successful osseointegration and soft-tissue integration. In the present study, we investigated human gingival fibroblast (HGF) viability and orientation at poled and non-poled barium titanate functionalised yttria stabilised zirconia (BT/YSZ) and yttria stabilised zirconia (YSZ). Cell viability was evaluated at 1, 3 and 7 days with resazurin based method. To study adhesion, morphology and orientation SEM observation was done at 24h of cultivation. Fibroblasts attached well on all samples and their viability was mostly comparable to the control. However, a decrease in viability was observed in non-polarized BT/YSZ samples. Orientation was analysed from SEM backscattered electron images. The orientation of non-poled composite was different to poled composite and YSZ.

Experimental Methods
Composite samples with 5 wt.% BT in YSZ were prepared through press-sinter route (1380°C, 2h, 5"/min) from commercial 3 mol% Y2O3 stabilised zirconia powder (TZ–3YSB–E, Tosoh, Japan) and barium titanate (Ticon P., FerroR, USA). The sintered disks were ground to final dimensions ±0.02 mm with a resin bonded diamond grinding disk (Struers, MD-Piano 120) and polished (P4000 SiC, Ra<0.5um). Possible polishing induced monoclinic phase was retransformed to tetragonal by heat treatment of 2 h at 600 °C in air. Contact poling was carried out in silicone oil bath under DC 2 kV/mm electric field at 130 °C for 30 min followed with field cooling. Reference samples of YSZ were processed parallel to the composites.

Immortalized Human Gingival Fibroblasts (HGF; Applied Biological Materials Inc., Richmond, BC, Canada) are primary cells conditionally immortalized through hTERT gene. Cells were cultured at 37 °C in an atmosphere of 5% CO₂ and 100% humidity in culture medium composed of Dulbecco's Modified Eagle's Medium-DMEM (Biowhittaker, Lonza, Walksville, USA) supplemented with 10% Fetal bovine serum (Biowest, Nuaillé, France) in 75 cm² flasks (Corning, Corning NY, USA) until reaching 80% confluence. Cells were detached using trypsin-EDTA (Lonza, Veners, Belgium), centrifuged at 777 rpm and re-suspended at a density of 1 x 10⁴ cells/well and cultured at 37°C for all biological assays. All experiments were conducted using a fourth passage.

Cell viability was evaluated at 1, 3 and 7 days using a commercial resazurin-based method, CellTiter-Blue (Promega, Madison, WI, USA) according to the manufacturer protocol. The conversion rate was measured as fluorescence intensity in arbitrary fluorescence units (AU) after 1, 3, and 7 days of culture. Fluorescence intensity was detected at excitation/emission wavelengths of 560/590nm using a fluorescence spectrometer (VICTOR NivoTM HH3500, PerkinElmer., Pontyclun, UK).

For fluorescence staining, discs cultured with fibroblasts were removed after 1 day of incubation. Cytoskeleton staining was evaluated by Phalloidin reagent (Phalloidin FITC Reagent - ab235137,Abcam, Amestardam, Netherlands) and staining of cell nucleic acid, using Propidium Iodide (Sigma-Aldrich, Merck KGaA, Darmstadt, Germany, P4864-10ML), both according to manufacturers’ instructions. Images were obtained using fluorescent microscope (Olympus-BX50, filters: Ex / Em = 493/517 nm WEB - Phalloidin; Ex / Em = 535 / 617nm WG - Propidium Iodide).
Results were presented as mean ± standard deviation (SD). Group comparisons were tested using Anova (Tukey’s post-hoc) using appropriate statistical software and significance was set at $p<0.05$. The orientation of the fibroblasts on YSZ, 5%BT/YSZ poled and non-poled 5%BT/YSZ was studied by an image analysis from the BSE/SEM micrographs. The study utilized an algorithm described by Kazantseva et al. [1]. Prior the analysis the micrographs were converted to 8 bit greyscale images by applying threshold to cells only (Li filter). Noise Despekle filter was used for noise reduction.

**Results and Discussion**

Cell density on the surfaces of different samples appeared to be very similar and differences in viability were small. Non-poled samples had however, decreased viability and changes in their orientation.

**Conclusion**

The findings may give a new possibility to enhance fibroblast responses and control the formation of fibrous encapsulation without any pharmaceuticals. The control over fibroblast adhesion can hence improve results in root coverage and improve designing transgingival parts of dental implants.
Cell viability was evaluated at 1, 3 and 7 days using a commercial resazurin-based method - Cell-Titer Blue (Promega, Madison, WI, USA) according to the manufacturer protocol. The conversion rate was measured as fluorescence intensity in arbitrary fluorescence units (AU) after 1, 3, 7, and 14 days of culture. Fluorescence intensity was detected at excitation/emission wavelengths of 560/590nm using a fluorescence spectrometer (VICTOR NivoTM HH3500, PerkinElmer, Pontyclun, Reino Unido).

Green route fabrication approaches of lignin nanoparticles from different technical lignins: a comparison study

Patrícia Figueiredo¹, Maarit Lahtinen¹, Melissa Agustin¹, Kirsi Mikkonen¹.²

¹ University of Helsinki, Department of Food and Nutrition/Faculty of Agriculture and Forestry, Helsinki, FI; ² University of Helsinki, Helsinki Institute of Sustainability Science (HELSUS), Helsinki, FI

Introduction

Lignins derived from plant and wood sources have gained increased consideration from the research community because of their promising benefits, such as low production cost, antimicrobial properties and eco-friendly characteristics, such as biocompatibility and biodegradability.¹ Lignin is composed of three units, found in varying proportion according to the source of the lignocellulosic biomass (i.e., softwood, hardwood or grass), which can affect the physicochemical properties of the resulting technical lignins.¹ Despite the high abundance of lignin in nature, only ~ 2% of lignin is employed as a starting material for low value applications, mainly limited by its highly variable and complex molecular structure. However, the fabrication of lignin nanostructures can overcome these limitations, offering structural and morphological control of the lignin polymer, while enabling the typically water insoluble lignin to form stable colloidal suspensions in aqueous media. Therefore, the production of lignin nanoparticles (LNPs) has greatly increased their potential for high value applications in many fields.² However, the homogeneity and morphology of LNPs varies depending on the lignin grade and preparation method, and a systematic comparison is lacking. In this study, we aimed to find a green fabrication method with a distinct solvent fractionation of lignin to prepare LNPs using three different technical lignins as starting polymers: BLN birch lignin (hardwood, BB), alkali Protobind 1000 (grass, PB), and Kraft LignoBoost (softwood, LB).

Experimental Methods

Here, we systematically compared three anti-solvent precipitation approaches; 70% ethanol,³ acetone/water (3:1),⁴ and NaOH⁵ as the lignin solvent, and water/aqueous HCl as the anti-solvent (Figure 1). The resulting nanostructures were further characterized using dynamic light scattering (DLS), transmission electron microscopy (TEM), Fourier-transform infrared (FTIR) and nuclear magnetic resonance (NMR) spectroscopy. In addition, their phenolic content was quantified using UV spectroscopy and compared with conventional ³¹P NMR. Furthermore, the stability of LNPs at different ionic strength and pH was evaluated in order to select the best approach to obtain stable, spherical and homogeneous LNPs from the three technical lignins.

Results and Discussion

In this study, the molar mass of the technical lignins used in our study (LB > BB > PB) was shown to be inversely proportional to the hydrodynamic diameter of the LNPs (LB-LNPs < BB-LNPs < PB-LNPs). Additionally, all methods allowed production of homogeneous and monodispersed LNPs, in particular the acetone/water (3:1), with a negative surface charge. The LNP morphology was confirmed using TEM, in which the LNPs prepared with acid precipitation method appeared to be like clusters or aggregates of very small particles, while the 70% ethanol and acetone/water (3:1) led to the formation of quasi-spherical or spherical LNPs. The FTIR spectra of the raw lignins was compared with the respective LNPs, no substantial differences were observed. However, the ¹H NMR spectra suggested that the acid precipitation approach induced structural changes after fractionation of the raw lignins during the preparation of LNPs. Regarding the phenolic content determination, the UV-Vis approaches followed similar trends to the values measured with ³¹P NMR, but gave slightly different values compared to the ³¹P NMR measurement. Nevertheless, the UV-Vis represents a simple, reproducible, and low-cost approach to quantify the phenolic content when similar
types of samples are compared. Finally, the produced LNPs are stable at low to moderate ionic strength and over a pH ranging from 4 to 8, in particular the LNPs prepared with the acetone/water (3:1) method.

**Conclusion**

Overall, our results revealed that the acetone/water (3:1) mixture was the most effective solvent tested to obtain homogenous, small and spherical LNPs from the three technical lignins. Moreover, these LNPs showed an improved stability at different ionic strengths and a wider pH range compared to the other preparation methods, which can greatly increase their application in many fields, such as pharmaceutical and food sciences.

Investigation of the shrinkage phenomena during the solvent exchange step for the production of biopolymer-based aerogels

Anja Hajnal, Pavel Gurikov

Hamburg University of Technology, Institute of Thermal Separation Processes, Hamburg, DE

Introduction

Biopolymer aerogels are ultra-light porous materials that have gained interest for research, development and application in the last two decades. Their biocompatibility and biodegradability makes them especially attractive for applications in life sciences such as drug delivery, tissue engineering, food and cosmetics.

To produce biopolymer-based aerogels, a gel first needs to be formed in an aqueous solution. Due to the low solubility of water in supercritical CO$_2$ (drying fluid) at moderate pressures, it must be exchanged for a solvent that is miscible with water and supercritical CO$_2$ and suitable for life science applications (solvent exchange). This step is followed by the supercritical drying, in which the solvent in the pores is extracted by means of compressed CO$_2$.

During both solvent exchange and supercritical drying a gel volume reduction has been observed, which leads to significant changes in the gel pore structure and final aerogel properties. The gel shrinkage is mainly attributed to the interactions of gel matrix and solvent and its extent is specific to a biopolymer/solvent system. For solvent exchange step, the change of gel volume is dependent on the solvent exchange path and can be significantly reduced when gels are sequentially submitted into water/solvent solutions with smaller concentration gradients (stepwise solvent exchange). In order to make biopolymer-based aerogels suitable for commercial applications, it is necessary to find a balance between the processing costs and final material properties. To achieve this, basic principles that lead to changes in the gel matrix during solvent exchange and supercritical drying need to be understood. In this work, the focus was on experimental investigation of the shrinkage of biopolymer-based hydrogels during solvent exchange.

Experimental Methods

The gel volume change was quantified by photographing the gels in an optically accessible container using a digital camera and analyzing the moving boundary of the gel sample by means of an edge detection script. Since the shrinkage of the gel is countered by the stiffness of its matrix, the evolution of compressive strength on its path from hydrogel to alcogel was also measured for different biopolymer/ethanol systems. To study the effect of polymer/solvent interactions on shrinkage, agar gels were subjected to solvent exchange in ethanol, acetone and acetonitrile.

Results and Discussion

As the solvent exchange progresses and the shrinkage takes place, the compression strength of gels increases. This increase in gel stiffness was proportional to the decrease in volumetric yield, implying that the increase in gel strength counteracts the shrinkage. Young's moduli of alcogels increased with increasing biopolymer concentration, indicating that the final stiffness of the gel can potentially be correlated with its shrinkage in a master curve relating Young's modulus and alcogel biopolymer concentration. The influence of the polymer/solvent interactions on shrinkage was evaluated through the solubility parameters of the biopolymer and respective solvents.

Conclusion

The outcome of the work is a description of the shrinkage phenomena which encompasses both thermodynamic system properties and gel mechanics. It is achieved by deeper understanding of an interconnected influence of polymer-solvent interaction and gel matrix strength on the changes of gel volume.

Graphene nanoplatelets as an economical alternative in the reinforcement of PMMA bone cements

Eva Paz, Yolanda Ballesteros, Sara López de Armentia, Juan Carlos del Real

Universidad Pontificia Comillas, Institute for research in technology/Mechanical engineering department, Madrid, ES

Introduction
The reinforcing effect of G and GO has attracted great interest during recent decades, giving rise to nanocomposites with enhanced mechanical properties [1,2]. In previous studies, it was demonstrated that the incorporation of well-dispersed Graphene (G) and Graphene oxide (GO) can be a promising solution in augmenting the mechanical performance of PMMA bone cement (BC) in an attempt to enhance the long-term survival of the cemented orthopaedic implants [3]. It has been demonstrated that the presence of G and GO within a polymer matrix produces a deviation and detention of crack fronts during their propagation, increasing the required energy for failure [4]. In addition, it has been proven that these nanoparticles do not significantly influence the thermal properties and biocompatibility of BC, potentially allowing its clinical progression.

One of the most important constraints in the large-scale production of nanocomposite applications is that the industrial production of G and GO currently is limited by two main aspects: the scalability of the chemical production process and the cost. A wide variety of cheaper and easier-to-produce graphene derivatives have emerged as the case of graphene nanoplatelets (GnPs).

GnPs exhibit exciting properties such as light weight, high aspect ratio, electrical and thermal conductivity, mechanical toughness, low cost, and planar structure. As such, they are attractive options to replace different nanostructured fillers [5]. GnPs are cheaper than G and GO; and are comparable in modifying the mechanical properties of polymers. The objective of this study is to make a comparison of the effect that the addition of GnPs has on the mechanical performance of bone cements, compared to the use of other carbon-based nanoparticles such as G and GO.

Experimental Methods
The BC used in this study was a two-phase non-comercial bone cement. BC without filler (Control), with G (Avanzare Nanotechnology, Spain), GO and GnPs (Avanzare Nanotechnology, Spain) at different levels of loadings (0.1, 0.05, 0.025 and 0.01 wt.%) were prepared. In each case, the nanoparticle powder was dispersed into the liquid phase of the BC using ultrasonication.

The bending strength and fracture toughness of each kind of cement was studied. A four-point bending load arrangement was used to determine bending properties in accordance with ISO 5833 [36]. The fracture toughness was determined according to the standard [38]. Single edge notch bend specimens (SENB) were used to calculate the fracture toughness (Kc). The tests were conducted using a Universal Testing Machine IBTH/500 (Ibertest, Madrid, Spain) using a load cell of 5 kN, which operated at a crosshead speed of 5 mm/min. A total of three batches were tested for each cement composition with a minimum of five samples per batch. Finally, the fracture surface was evaluated using an Olympus DSX1000 digital microscope.

Results and Discussion
As each type of nanoparticle has a different density, the optimum level of loading in each case could be different. Consequently, the effect of the level of loading has been studied. In all cases, it was observed that when the loading decreased, there was an increase in fracture toughness. Figure 1 shows the average fracture toughness in the case
of GnPs for the different load levels. As can be seen, the best results were obtained for the low loading (0.01 wt.%), in this case, the fracture toughness was 20% higher than for 0.1 wt.%.

The effect of the different nanofillers at the optimum obtained level of loading (0.01 wt.%) were compared. In Figure 2 it is represented the fracture toughness of the samples with 0.01 wt. % of the different nanoparticles. It can be observed that in all cases the fracture toughness was improved in comparison with the control. In the case of the GO and GnPs, these significantly increased the fracture properties (p<0.001) by 30% and 40% respectively. This result demonstrated that the addition of GnPs is even better that the use of G and GO at this level of loading.

The bending tests were carried out at two different levels load, 0.1wt.% and 0.01wt.% and in both cases the resultant trend was similar to that obtained in the fracture tests- the addition of low loadings produced better results, and the improvement was significantly higher in the case of GnPs than G and GO.

The analysis of the fracture surfaces showed that fewer agglomerations of nanoparticles were found in the case of low loading, which could explain the obtained results. The better reinforcement effect observed in the GnPs could be related with a lower tendency of these to form agglomerates, as they are less exfoliated and are more stable, and with the better dispersability of them within the polymeric matrix.

Conclusion
The use of GnP as a reinforcing agent for BC produces very promising results with significant improvements in fracture and bending properties. Compared to G and GO, GnPs has been shown even better results, being a very interesting alternative with a lower cost.

Figure 1
Fracture toughness of the PMMA bone cement reinforced with GnPs at different levels of loading (0.1, 0.05, 0.025 and 0.01 wt.%). The variation in comparison with the control cement also indicated. ** meaning a p-value < 0.001.

Figure 2
Fracture toughness of the different PMMA bone cement with the different nanofillers (G, GO and GnPs) with 0.01 wt.% of load. The variation in comparison with the control cement also indicated. ** meaning a p-value < 0.001.

Silver- and/or titanium-doped calcium phosphate highly porous bioceramic with antibacterial activity

Liga Stipniece\textsuperscript{1,3}, Ingus Skadins\textsuperscript{2}, Dagnija Loca\textsuperscript{1,3}

\textsuperscript{1} Riga Technical University, Institute of General Chemical Engineering, Riga, LV; \textsuperscript{2} Riga Stradins University, Department of Biology and Microbiology, Riga, LV; \textsuperscript{3} Baltic Biomaterials Centre of Excellence, Riga, LV

Introduction
Regeneration and reconstruction of bone defects is significant challenge in modern medicine and often requires surgery where biomaterials are used. About 10% of these procedures are at risk of bacterial infections \cite{1}. Due to the possible systemic toxicity and growing emergence of antibiotic-resistance caused by systematic use of antibiotics methods are being sought to ensure local delivery of antibacterial agents at the site of implantation. The use of alternative antibacterial agents such as bacteriophages, bacteriophins and inorganic agents (Ag, Cu, Zn, Ti compounds, etc.) with far lower susceptibility to induce resistance than common antibiotics has resurge recently \cite{2}. Broadening of the spectrum of calcium phosphate (CaP) materials by modification with metal ions to impart advanced biological and physicochemical properties has been observed. Attaining antibacterial properties is one of the aims and the most common dopants studied in this regard are Ag(I), Cu(II), Zn(II), Co(II) etc. \cite{3}. Combining Ag(I) with Ti(IV) is a potential way to promote bone-implant integration, with reduced bacteria\textsuperscript{2} infection and enhanced bioactivity \cite{4, 5}.

The aim of this study was to impart antibacterial properties to highly porous CaP bioceramics, which could be used in orthopaedic surgery, by doping them with Ag(I) and Ti(IV) ions, and to evaluate the synergy and cumulative effects of dopants.

Experimental Methods
Method of producing highly porous Ag- and/or Ti-doped CaP bioceramic scaffolds compromised following steps:(i) preparation of porous bioceramic scaffolds (the substrates), through PU foam replica method, (ii) aqueous precipitation of Ag- and/or Ti-doped CaP (hydroxyapatite (HAp) and apatitic-tricalcium phosphate), (iii) surface modification of the substrates by depositing the Ag- and/or Ti-doped CaP layer by vacuum-assisted impregnation.

Prepared bioceramic scaffolds were analyzed for microstructure and composition using common analytical techniques - SEM, XRD, FT-IR, EDX etc.

Minimum inhibitory concentration (MIC) of the Ag- and/or Ti-doped CaP against gram-positive \textit{S. aureus} (ATCC 25923) was determined by microdilution method. The antibacterial properties of Ag- and/or Ti-doped CaP bioceramic scaffolds were determined by the broth dilution method, which involves inoculating a diluted bacterial suspension into TSB agar medium and incubating at 37 °C. A suspension of \textit{S. aureus} bacterial reference culture ATCC 25923 (10\textsuperscript{8} CFU/mL) was used.

\textit{In vitro} bioactivity of Ag- and/or Ti-doped CaP bioceramic scaffolds in semi-dynamic conditions in the SBF was evaluated. The dynamics of the decrease of Ca ions concentration in the SBF after exposure to the bioceramic scaffolds was performed using an automated titration station and Ca-ion-selective electrode. The formation of a biomimetic apatite layer on the scaffolds surface was assessed using SEM.

Results and Discussion
The obtained bioceramic scaffolds had an open porous structure and highly interconnected pores (Fig. 1). A porosity of 92 ± 2%, pore sizes in a range from 50 to 450 µm. According to FT-IR and XRD analyses the bioceramic scaffolds were composed of biocompatible phases. No impurities form the raw materials were detected at least at the detection
limits of the instruments. No significant differences in positions and intensities of the characteristic XRD diffraction peaks and FT-IR absorbance bands were observed among the compounds of various compositions. EDX results confirmed the presence of Ag and Ti in the synthesis products. The content of Ag in the samples was higher than planned, while Ti was close to the planned. However, it was observed that with increasing calcinations temperature, the Ag content decreases. Thus, for sintering the coating 900 °C was chosen to maintain Ag concentration as close as possible to the non-calcined CaP. The MIC values for all Ag- and/or Ti-doped CaPs were 10 mg / mL, except for Ag-doped and Ag- and Ti-co-doped, which showed MICs of 5 and 2.5 mg / mL, respectively. This also coincides with the results of antibacterial evaluation of Ag- and/or Ti-doped CaP bioceramic substrates. Namely, the respective bioceramic substrates showed the highest antibacterial activity. All scaffolds, regardless of composition, showed in vitro bioactivity.

**Conclusion**
The combination of polymeric foam replica and vacuum-assisted impregnation technologies is suitable for preparation of the Ag- and/or Ti-doped CaP bioceramic scaffolds with highly interconnected porous architecture. The physical properties, as well as a phase and chemical purity are sufficient to provide a suitable initial three-dimensional support for cells to grow into it and make a new bone and allows the scaffolds produced to be used for osteoconductive bone implants, tissue engineering implants. Antibacterial activity of the scaffolds depends on the phase composition which affects concentration of antibacterial ions released into the surrounding environment.

New pyrophosphate-stabilized amorphous calcium carbonate doped with bioactive ions: toward bone substitute materials?

Marion Merle, Jérémy Soulié, Christian Rey, Prescillia Lagarrigue, Christèle Combes

Institut National Polytechnique de Toulouse, CIRIMAT, Toulouse, FR

Introduction
Calcium carbonate is the most abundant biominer [1] and is often used as a biomaterial due to its excellent biocompatibility [2]. Among all polymorphs, amorphous calcium carbonate (ACC) is the least stable and the most soluble, leading to a high reactivity. Various ACC syntheses are detailed in the literature. They are mainly based on the same strategy that aims to avoid crystallisation either with kinetic parameters (such as low temperature) or with additives. Among these latter, the use of pyrophosphate as an additive is poorly documented. Such material should promote bone regeneration through the presence of carbonate, calcium and pyrophosphate [3] and allow the modulation of biodegradation rate in vivo by varying the pyrophosphate amount in the ACC matrix. The purposes of this study are to understand the influence of the pyrophosphate (from 0 to 10 %mol. with respect to carbonate content) and cation doping rates (up to 10 %mol. with respect to total cation content) on the nature, structure and multi-scale organization of the resulting calcium carbonate. Moreover, the feasibility to process these doped-ACCs in biomimetic bone cement and as macroporous composite scaffold by freeze-casting will be demonstrated.

Experimental Methods
ACC powders were synthesised by double decomposition in aqueous solution, with various pyrophosphate content and fully characterised (XRD, Raman and FTIR spectroscopy, SEM and FEG-SEM, TEM, TGA, chemical titrations and SAXS).

Results and Discussion
We determined the pyrophosphate content threshold required for avoiding the crystallisation of calcium carbonate. Above this threshold, no diffraction peaks was detected by XRD whereas some calcite formed for lower pyrophosphate content. The average particles sizes (∼ 50 nm) evaluated by SEM and FEG-SEM were quite homogeneous between the different ACC powders synthesised, and SAXS studies highlighted a nano-based hierarchical organization. This structuration is predominant as reactivity is correlated to the internal surface. Finally, calcium, carbonate (chemical titration) and water (TGA) contents were demonstrated to be correlated to the pyrophosphate content. Beyond these fundamental aspects, additional biological properties can be conferred to these materials by doping with bioactive ions such as Cu²⁺, Zn²⁺ or Sr²⁺ that could enhance angiogenesis, osteoblastic activity and/or show anti-inflammatory effects [4]. We revealed that these doped ACC can integrate high contents of bivalent ions (M²⁺/cations ratio up to 10 %mol.) via similar synthesis method and without subsequent crystallisation. All together these results are important to control the reactivity and consequently bioactivity of pyrophosphate-stabilized cation-doped ACCs in view to their use as potential bone substitute materials. These doped-ACCs can be processed not only as self-supported biomaterial, but also included in a bone mineral cement formulation or freeze-casted as a porous scaffold. We demonstrated the feasibility of in situ ACC/alginate suspension freeze-casting to obtain a composite scaffold with promising physicochemical and mechanical properties and in particular adequate macroporous anisotropic porosity mimicking bone structure (with a porosity diameter ∼ 100 - 500 µm) [5] while preserving the amorphous structure of the constitutive powder.

Conclusion
These whole results are opening new perspectives of bioactive materials with tunable properties and adaptative shape for several bone substitution applications.

Yttria Stabilized Zirconia/Clay Composites for Dental Applications

Yiğithan Tufan¹, Jongee Park², Abdullah Öztürk¹, Batur Ercan¹,³

¹ Middle East Technical University, Metallurgical and Materials Engineering, Ankara, TR; ² Atılım University, Metallurgical and Materials Engineering, Ankara, TR; ³ Middle East Technical University, BIOMATEN, Center of Excellence in Biomaterials and Tissue Engineering, Ankara, TR

Introduction

Among dental bioceramics, yttria stabilized zirconia (YSZ) is gaining increased use due to its superior mechanical properties and aesthetic concerns [1]. It is available in the market especially for the fabrication of crowns, inlays, dental implant abutments and fixed partial dentures [2]. Clay based minerals, being one of the most common ceramic raw materials, is also used for various medical purposes including antacids, gastrointestinal protectors and drug delivery modifiers [3]. Recent studies revealed that clay minerals are beneficial for osteoblast adhesion, proliferation and osteogenic differentiation [4]. For instance, enhanced osteoblast proliferation was reported after the incorporation of montmorillonite in chitosan-poly(glycolic acid) films [4]. In addition, enhanced osteogenic response of preosteoblast cell line MC3T3 was obtained with the addition of laponite in several polymeric matrices including poly(ethylene oxide), poly(ethylene) glycol and GelMA [4]. Therefore, in this study, clay was incorporated in YSZ to enhance its mechanical and biological properties for dental applications.

Experimental Methods

The starting powder was 3 mol% yttria stabilized tetragonal ZrO₂ (3Y-Z, AMS) with an average particle size of 150 nm. Nanoclay additive (avg. 800nm) was used as-received form. Various amounts of Nanoclay (0, 0.5, 1, 2, and 4 wt%) were added into YSZ using mechanical ball milling. Each batch was wet-milled in a zirconia jar at 350 rpm for 3 h. The prepared powders were then dried overnight and then uniaxially pressed under at pressure of 15 MPa to form the disc-shaped compacts. After that, all discs were sintered at 1450 °C for 2 h. The metabolic activities of osteoblasts (hFOB, ATCC CRL-11372) on YSZ/clay samples were investigated using MTT assay. A FEI Nova Nano SEM 430 microscope was used to image sample surfaces and osteoblasts. Actin filaments and nuclei of the cells were stained with F-actin Staining Kit – Red Fluorescence (abcam ab112127) and DAPI solutions, respectively. Once staining was completed, cellular images were captured with a Leica DM2500 microscope.

Results and Discussion

Backscattered SEM images of YSZ having 0 and 4% clay were given in Figure 1a and 1b, respectively. SEM images revealed that there was no pore left in the microstructure of both YSZ and YSZ/clay composites (the presence of clay is apparent in Figure 1b as darker regions) indicating the efficacy of sintering. Hardness values of YSZ samples decreased with the incorporation of clay. Indentation fracture toughness measurements of samples showed that YSZ/4% clay has the highest fracture toughness value compared to other YSZ samples having lower clay contents. Surface hydrophobicities of YSZ samples decreased with the addition of clay. This was correlated with the changes in surface chemistry of samples (no significant difference was found in the surface roughness values of samples).

The effect of clay on the biological properties of YSZ/clay composites were assessed using osteoblasts. Enhanced osteoblast proliferation and spreading was achieved on the YSZ/4% clay composites compared to YSZ samples having 0% clay. SEM images of osteoblasts at 3 days on YSZ and YSZ/4% clay composites were given in Figure 1c and 1d, respectively. Better spreading of osteoblasts were apparent on the YSZ/4% clay composites compared to YSZ sample. This was further confirmed with confocal laser micrographs at 3 days (Figure 1e and 1f) for YSZ and YSZ/4% clay, respectively. Briefly, these results indicated that YSZ/4% clay composites may provide prolonged...
osseointegration between the implant and surrounding bone tissue making them a possible alternative implant material for dental applications.

**Conclusion**

YSZ/clay composites were developed for dental applications. With the addition of clay, increased fracture toughness and decreased hydrophobicity was obtained compared to YSZ having 0% clay. Also, enhanced osteoblast proliferation and spreading on YSZ/4% clay composites were achieved indicating their potential as an alternative dental implant material.

Color stability of different aesthetic restorative materials: an in vitro study

Luca Solimei¹, Nicola De Angelis¹, Abdulkhaleq M. Garaghoolee¹, Mohamed T. El Halawani²

¹ University of Genova, Genova, IT; ² University of Alexandria, Cairo, EG

Introduction
A wide spectrum experimental campaign has been set up in order to study the capability of different categories of materials to maintain their colors in different common beverages of human feedings. This specific feature is a very important asset in commercial products and is a kpi (key performance indicator) to define overall expected quality. In details, the study is to evaluate the color stability of different dental veneer restorative materials (feldspathic ceramic, hybrid ceramic, zirconia reinforced lithium silicate glass ceramic, and composite resin) after exposure to commonly consumed beverages used as staining solutions (coffee, black tea, and red wine).

Experimental campaign was conducted at DISC (Dipartimento di Scienze Chirurgiche e Diagnostiche integrate ) and analyzed by the research Team of University of Genova medical Doctors.

Experimental Methods
Forty five specimens (n=15 each test material) were prepared into rectangular slices with fixed dimensions (10 x 12 x 2.5 mm) by milling commercial material disc and polishing the obtained samples with specific dental use polishing rubber bur (MEISINGER 9613P-900-220 SIL.). Machinable feldspathic ceramic (FC), Zirconia reinforced lithium silicate glass ceramic (LS) and a hybrid ceramic (HC), were milled using CAD/CAM procedures. Fifteen specimens of microparticle composite resin (MPC) were manually prepared by utilizing a silicone mold with the same diameters and thickness. All specimens were divided randomly into 3 subgroups (n=5) and , according to the most known testing protocol available in literature, were immersed in staining solutions (coffee, black tea, and red wine) for a period of 72 hours. A colorimetric evaluation according to the CIE-Lab system was performed for each specimen using a spectrophotometer before and after the immersion process.

Statistical analysis was done using Two-way ANOVA and One-way ANOVA to compare between the different study groups, and a Post Hoc test (Tukey) for pairwise comparisons.

Results and Discussion
The restorative material type was found to play a statistically significant role in color change (p<0.001) while there was no statistically significant difference among the staining beverages in color change (p= 0.113).

Conclusion
All the staining solutions used in the present study may cause color change in the restorative materials tested. All tested ceramic materials had better color stability compared to composite resin.

Self-assembling fibers inside a calcium phosphate bone cement

Maria Francesca Di Filippo1, Demetra Giuri1, Milena Fini2, Melania Maglio2, Gregorio Marchiori2, Paola Torricelli2, Stefania Pagani2, Claudia Tomasini1, Silvia Panzavolta1

Introduction
Calcium phosphate bone cements (CPCs) are biocompatible, bioactive and osteogenic systems which can be molded into bone defects and implant sites and then harden in situ, mimicking the mineral phase of native bone. However, their mechanical properties are far from those of bone, not only in terms of strength, but especially in terms of toughness, ductility and fatigue resistance [1]. The incorporation of fibers into a brittle cement matrix has been proven to increase the fracture toughness of the composite as well as the tensile and flexural strength by the crack arresting processes. In fact, fiber reinforcement has been extensively explored even in the field of hydraulic cements and concretes for civil engineering and building applications [1,2]. Natural fibers and man-made fibers have been used for this purpose [1], but, on the best of our knowledge, they have always been introduced inside the pasty material after their synthesis.

In order to obtain a better cohesion between fibers and cement paste thus improving the mechanical performances, in this work we demonstrate the feasibility of forming self-assembling fibers in just one step during cement setting. Fibers were obtained by the introduction of a low-molecular-weight gelator (MW<1000Da) able to form supramolecular structures stabilized by weak interactions. Addition of proper amount of Ca2+ ions promotes fibers assembling inside the cement paste thus producing a composite matrix where the fibers are strictly embedded [3]. Our gelator is composed of Boc-L-DOPA(Obn)2–OH, which chelates Ca2+ ions in order to arrange in fibers.

Experimental Methods
The cement powders are composed of a gelatin/α-TCP mix and CaHPO4·2H2O, synthesized as described in a previous article [4]. The liquid phase is made by an aqueous solution of the gelator at two different concentrations: 2 and 5% wt. The gelator was dissolved in ultra-pure water with 1.3 equivalents of NaOH and sonicated. CaCl2 was added as a trigger to the gelator solution, which was mixed with the cement powders to obtain a paste of workable consistency. Different amounts of Ca2+ and different powder to liquid ratio were evaluated. The obtained pastes were compacted for 1 min inside Teflon molds with a dynamometer. Then, cements were demolded and put in phosphate buffer pH 7.4 at 37°C for different periods of time in order to ensure cement hardening. Barium sulfate was added to the cement composition as radiopacifying agent. Mechanical properties under compression and flexural properties were evaluated, as well as porosity studies by means of MicroCT analyses. Rheological measurements and morphological investigations by mean of SEM were also performed. The compositions were optimized in order to obtain injectable cements. Eventually, in vitro biocompatibility with osteoblast-like cells MG63 and qPCR gene expression were performed to ensure the biocompatibility of the materials.

Results and Discussion
XRD patterns indicate that the cements loaded with 2% and 5% wt of gelator were totally converted after 7 days of soaking, suggesting that these amounts did not interfere with the hardening reaction. SEM images reveal the presence of the fibers, which cover the pores surfaces and are embedded into the cement’s matrix, thus demonstrating a good interaction with it (Fig 1). Also the toughness of the materials are positively affected by the presence of the gel into cement composition. Time sweep measurements before and after breaking the gel (by shaking the vial, as in the preparation of cements) demonstrated that the hydrogel is thyrotrophic. Mechanical tests
confirmed that the gelator addition to the cements enhances their mechanical strength, especially when tested in bending, and increases their work of fracture. MicroCT analyses showed no significant variation on the porosity of the composite materials, but the presence of pores with higher diameter (>50um) was observed. Moreover, biological assays ensured the biocompatibility of the materials and their ability to express the main gene markers that are necessary for bone formation.

**Conclusion**

In this work we demonstrated that this approach could represents a new, simple and effective method to obtain cements reinforced with self-assembled fibers in just a single step. The formation of fibers during the hardening reaction provides structural and mechanical support to the material without interfering with their porosity. The obtained fiber-reinforced CPC is biocompatible and able to promote the deposition of extracellular matrix.

Marginal integrity of cubic zirconia inlay-retained fixed partial dentures

Luca Solimei¹, Mohamed T. El Halawani², Nicola De Angelis¹, Alberto Lagazzo¹, Fabrizio Barberis¹

¹ University of Genova, Genova, IT; ² University of Alexandria, Alexandria, EG

Introduction
“Katana”, cubic Zirconia firstly introduced on the market by Kuraray Noritake Dental Inc., Tokyo, Japan has been introduced as a new restorative material for Inlay-retained fixed partial dentures (IRFPDs), replacing missing dentition. Various studies already exist on Zirconia on literature have been conducted on the flexural strength of such restorations; however, there is a lack of evidence on their marginal integrity i.e. the capability of the material to guarantee along the time the same mechanical and functional performances.

Evaluating the marginal integrity and the overall material behaviour of three different designs of IRFPD using monolithic translucent zirconia, “Katana”.

Experimental Methods
Thirty IRFPDs divided into the 3 groups, 10 each one, were fabricated by the medical/engineering Team of University of Genova using a translucent monolithic zirconia (Katana STML, Super Translucent Multi Layered). The three groups were created with specific design in order to sort out any possible project limit.

Group 1 received an inlay cavity preparation including a proximal box and a 2 mm deep occlusal extension, Group 2 received an inlay cavity preparation including a proximal box and a 1.5 mm deep occlusal extension, and Group 3 received only a proximal box cavity preparation without an occlusal extension.

The restorations were fabricated and cemented using a dual cure resin cement (Panavia V5 system) while all the samples underwent to cyclic loading with a force of 50 N. The load was applied on the central fossa of the pontic using a metal rod with a spherical tip. Each sample was subjected to 1,200,000 cycles at a frequency of 2 Hz and thermocycled at 5°C to 55°C to 5°C for 5,000 thermal cycles to simulate 5 years of function inside the oral cavity.

In a bath of laboratory-prepared 2% methylene blue solution at 37° C for 24 h,dye penetration test were performed on the specimens, and the values of marginal penetration were analyzed under a stereomicroscope.

Results and Discussion
During the whole 5-year aging process, no specimens showed signs of cracking, fracture or loss of retention in any of the restorations. There was a significant difference between the marginal leakages values obtained in the 3 groups of the study (H=10.208, p<0.05). Comparing the groups of the study showed significant difference in marginal leakage between Group 1 and Group 3 (p<0.05).

The group with the smaller design and consequent thicknesses of the residual wall had reduced performance.

Conclusion
The closure margins of inlay-retained fixed partial dentures IRFPD of Group 1 and Group 2 has maintained accuracy, shape and dimensional stability without color changing after aging accordingly to recommended bonding protocols for zirconia. Inlay cavity design including a proximal box and an occlusal extension exhibited better marginal stability than proximal box without any occlusal extension, included in Group 3, this design is not recommended, further studies have to be conducted.

**Introduction**

Zirconia oxide (ZrO$_2$) nanoparticles are widely used as filler particles in dentistry because of their biocompatibility and antibacterial properties$^1$. Up to date, the production of commercial monoclinic ZrO$_2$ nanoparticles could be achieved by high-temperature synthesis. Using a simple and versatile sol-gel method, yttria stabilized zirconia (YSZ) nanoparticles could be synthesized at low temperatures. Such nano YSZ with tetragonal form could be a promising alternative commercial ZrO$_2$ for dental material applications because of better mechanical characteristics and stability. So far, the biological responses to sol-gel derived nano YSZ and their dependence on sintering temperature have not been investigated. The aim of the current research is to produce YSZ nanoparticles by sol-gel method at three different temperatures and to assess their biocompatibility and oxidative stress with primary human gingival fibroblasts.

**Experimental Methods**

YSZ nanopowders were synthesized using Pechini sol-gel method$^2$. The dried gel was sintered at three different temperatures: 800, 1000, and 1200°C for 2 hours. Then, the morphology and composition of the obtained powders was investigated by Scanning Electron Microscopy (SEM) with Energy Dispersive X-Ray Analysis (EDX) and Transmission electron microscopy (TEM). For evaluation of biocompatibility MTT assay with primary gingival fibroblasts (HGF) with dilutions of nanoparticles at different concentrations (0, 1, 0.5 and 0.25 μg/mL) was performed. Optical density was determined spectrophotometrically at a wavelength of 545 nm and a reference filter of 630 nm after 24 and 72 h of cell incubation. For the detection of intracellular reactive oxygen species (ROS) levels, cell culture medium from the wells cultured for 24 and 72h was collected and we employed the cell-permeable ROS-sensitive probe 2,7-dichlorodihydrofluorescein diacetate (CM-H2DCFDA) which fluoresces at 520 nm (λex = 480 nm) upon oxidation.

**Results and Discussion**

SEM analysis (Fig. 1) showed fine submicron-sized (~10-15nm) particles with uniform spherical morphology in YSZ800 specimens. With increase of sintering temperature to 1000°C, grains become bigger in size (30-50nm) and have low agglomerated microstructure. Finally, specimens sintered at 1200°C seem more agglomerated with polyhedral morphology and particle size more than 100nm. EDX analysis detected Zr content in the range of 43.89-53.43 wt%, O content in range of 26.08-32.14 wt%, Y=2.67-3.87 wt%, and minor traces of Hf. TEM analysis of YSZ1000 revealed that the nanoparticles were uniform, well-defined and had cubic morphology. The electron pattern of crystals corresponded to tetragonal zirconia, with traces of cubic.

MTT assay of the tested specimens (Fig. 2) showed that YZS1000 and YZS1200 presented a biocompatible biological behaviour as compared to positive control. The lowest cell viability was found in the highest concentrations
of nanoparticles (0.5 μg/ml) in all groups. The lowest cell proliferation was recorded in YZS800 group at 72h, suggesting its mildly toxic behaviour. YSZ1000 and YSZ1200 nanoparticles show free radical scavenging activity, which was not dependent on NP concentrations. Higher antioxidant activity of YSZ800 nanoparticles might be due to the smaller particle size3.

Conclusion
The results of the present study suggest that the sol-gel method is an effective alternative to traditional high-temperature synthesis techniques for the stabilization of the tetragonal zirconia at room temperature. With the increase of sintering temperature nano YSZ increases in size and becomes agglomerated. The obtained nanoparticles possess good antioxidant potential and good biocompatibility and are applicable in dental biomaterials.

Chitosan – Rosmarinic Acid conjugates for wound healing applications

Miguel Huerta-Madroñal1, Javier Caro-León2, Eva Espinosa-Cano1,3, Maria Rosa Aguilar1,3, Blanca Vazquez-Lasa1,3

1 Institute of Polymer Science and Technology, Biomaterials group, Madrid, ES; 2 Centro de Investigación en Alimentación y Desarrollo, Grupo de investigación en biopolímeros, Sonora, MX; 3 Networking Biomedical Research Centre in Bioengineering, Biomaterials and Nanomedicine, Madrid, ES

Introduction

Rosmarinic acid (RA) an ubiquitous phenolic compound, is a very attractive candidate for wound healing purposes because of its antioxidant, anti-inflammatory, and photoprotective functions [1-3]. However, its poor bioavailability due to high instability, inefficient permeability through biological barriers and poor water solubility, hamper its therapeutic outcome. In this context, synthesis of polymer conjugates is presented as an alternative to enlarge its skin applications. This work describes the synthesis of novel water-soluble chitosan-rosmarinic acid (CSRA) conjugates with emphasis on their physicochemical characterization, antioxidant and biological properties.

Experimental Methods

Synthesis and characterization of CSRA conjugates. RA was conjugated to CS backbone by carbodiimide coupling using EDC as a crosslinker, at pH 5.0 and room temperature avoiding light exposure and varying CS:EDC:RA molar ratios. Chemical structure was studied by ATR-FTIR, 1H-NMR and UV (325 nm) spectroscopies, and thermal properties by TGA. Release kinetics of thin films of CSRA samples obtained by solvent evaporation were studied in PBS 7.4 at 37°C. Radical scavenger activity (RSA) of conjugates was determined by the DPPH method and compared to that of free RA sample.

In vitro cytotoxicity. Alamar Blue Reagent was used to determine cell viability of human fibroblasts (FBH), human keratinocytes (HEK) and macrophages RAW 264.7 in presence of film lixiviates.

Anti-inflammatory activity. Nitric oxide (NO) release on lipopolysaccharide (LPS) activated RAW 264.7 macrophages was determined using Griess Reagent to investigate the anti-inflammatory capacity of film lixiviates. Percentage of NO release was compared to non-activated and LPS-stimulated macrophages.

Photoprotective capacity. Cell viability and reactive oxygen species (ROS) assays were conducted to assess the photoprotective capacity of CSRA lixiviates in UVB-irradiated HFB, HEK and RAW 264.7 cells. ROS production was measured with the H2DCF-DA probe.

Antibacterial activity. Bactericidal properties of CSRA lixiviates collected in bacterial medium were investigated against E. coli and S. epidermidis. Percentages of bacteria growth inhibition of lixiviates were compared to those of bacteria in growth media or in presence of Gentamicin or Ampicillin, respectively. Also free RA and lixiviates from unmodified CS films were studied for comparative purposes.

Results and Discussion

CSRA ATR-FTIR and 1H-NMR spectra and thermal properties confirmed RA conjugation into chitosan backbone of derivatives. Composition of conjugates was determined by UV spectroscopy. Percentage of RA conjugation was calculated for all chitosan derivatives which were named as CS-XRA, where X denotes the effective percentage of RA conjugated to chitosan polysaccharide rings (i.e. CS-10RA, CS-5RA, CS-0.8RA and CS-0.4RA). The RA:CSRA ratio (ug:mg) was 173.5, 99, 17.5 and 8, respectively. Release kinetics of CSRA conjugate films showed a first initial moderate burst release and a further controlled release pattern approaching to a plateau of catechol release was observed for all derivatives. Antioxidant capacity of CSRA samples was initially studied versus concentration and compared to that of free RA. Rosmarinic acid showed a half-maximal effective concentration (EC50) of 9.6 µg/mL. However, for the conjugates, the higher the RA content, the higher the ability to donate protons and thus, the higher the antioxidant capacity (Figure 1). Interestingly, RA immobilization into the chitosan backbone improves threefold
its antioxidant effect, as free rosmarinic acid presents an EC$_{50}$ value around 10 µg/mL while CSRA EC$_{50}$ concentrations correspond to 2.8-3.7 µg/mL of free RA. **Biological evaluation.** Lixiviates from CS-5RA and CS-10RA films were toxic for all three cell lines whereas those from the CS-0.4RA and CS-0.8RA samples were not. Biocompatible CSRA lixiviates reduced NO production in LPS-activated RAW 264.7 below 40% compared to positive control. Results also showed similar anti-inflammatory capacities of lixiviates respect to free RA, and greater NO suppression with higher grafting of RA. CS-0.8RA and CS-0.4RA lixiviates increased cell viability and attenuated UVB-induced ROS effects after irradiation with respect to positive control (Figure 2). Based on the results, we attribute the photoprotective ability to the capacity of attenuation of intracellular ROS upon UVB irradiation. CS-0.8RA and CS-0.4RA had higher growth inhibition values in both types of bacteria when compared to native chitosan, however, non-significant differences were observed in the case of *S. epidermidis*. Nevertheless, in the case of *E. coli*, both CSRA showed a two-fold growth inhibition capacity when compared to free RA.

**Conclusion**
This work describes for the first time, the synthesis and characterization of novel water-soluble CSRA conjugates. Their promising biological antioxidant, anti-inflammatory and photoprotective properties envision their potential application in chronic wound healing.

Graphene oxide- and magnetic nanoparticles-enriched gelatin meshes, potential substitutes for peripheral nerve regeneration

Aida Selaru¹, Elena Olaret², Alexandra E. Dobranici¹, Izabela Stancu², Marieta Costache¹,³, Sorina Dinescu¹,³

¹ University of Bucharest, Department of Biochemistry and Molecular Biology, Bucharest, RO; ² University Politehnica of Bucharest, Advanced Polymer Materials Group, Bucharest, RO; ³ University of Bucharest, Research Institute of the University of Bucharest (ICUB), Bucharest, RO

Introduction
Advanced scaffold fabrication methods have made it possible to generate smooth tissue substitutes enhanced with nano-components which have been tremendously explored in the field of peripheral nerve regeneration (PNR). In this context, our studies are based on exploring the potential of gelatin electrospun meshes enhanced with graphene oxide (GO) and Fe₃O₄ nano-particles (MNPs) for supporting one of the slowest regeneration processes in the mammalian body, namely PNR.

Experimental Methods
Nano-composite fibrous substrates were fabricated by electrospinning technique in a controlled environment. The electrospinning precursors were prepared by dissolution of fish gelatin into GO, MNPs suspensions and mixtures of both (GO-MNPs) with different concentrations (0% w/v, 0.5% w/v and 1% w/v) of nano-structures. Morpho-structural characteristics of the fibrous substrates were observed through optical microscopy (OM) and atomic force microscopy (AFM). The influence of nanostructure presence on substrates' wettability was investigated through contact angle measurements (CAM). In addition, attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectrometry was performed. Next, these materials were put in contact with murine neuronal progenitor cells and murine Schwann cells in order to assess their cytocompatibility against the main cell types found in peripheral nerves. During one week of in vitro cell culture, the biosystems were tested for their biocompatibility by MTT, LDH and Live/Dead assays.

Results and Discussion
Overall, both cell types interacted with the composites in a biofriendly manner, namely cells spread out evenly, proliferated and populated the scaffolds, proportionally to the content in nanospecies. All composites displayed a low rate of toxicity. Moreover, the materials enriched with GO and MNPs presented significantly better cell response and proliferation rate compared to the gelatin control.

Conclusion
Based on the results, GO and MNPs-enriched meshes presented biocompatibility characteristics and can be further used for in-depth studies and PNR applications.

**Introduction**

Chronic wounds (CW) are a worldwide concern, affecting a vast portion of the population, and compromising the health and quality of life of patients. The tetrapeptide Ala-Ala-Pro-Val (AAPV) has the ability to inhibit the activity of the enzyme human neutrophil elastase (HNE), which levels, in case of excessive inflammatory processes, are abnormally high. Incorporation of peptides within polymeric structures (e.g. coaxial fibers) is very attractive to protect the payload from the surrounding environment and allow its controlled release for a sustained action. To this end, we proposed to engineer coaxial wet-spun fibrous structures loaded with the AAPV peptide. This system was designed to serve as a new delivery platform capable of a controlled and stepwise release of its content following pH-trigger, that not only fights infections but, most importantly, restores local enzymatic activity to normal levels. The outer layer (sheath) of the microfibers was made from blends of sodium alginate (SA) and gelatin (GN) combined with the N-carboxymethyl chitosan (NCMC), a chemically modified version of chitosan, responsive to basic pH (characteristic of CW) and endowed with antimicrobial action. Polymers were selected based on their biocompatibility, biodegradability and spinnability. To the authors knowledge, this is the first report on coaxial wet-spun systems loaded with AAPV for CW care.

**Experimental Methods**

AAPV peptide was synthesized by microwave-assisted solid-phase peptide synthesis[1], and characterized by 1D/2D nuclear magnetic resonance spectroscopy, Fourier-transformed infrared spectroscopy (FTIR) and UV-visible absorption (UV-VIS)/fluorescent spectroscopy. HNE evaluation was carried out by combining AAPV with elastase and evaluating their inhibitory effects via absorbance differences (UV-VIS). NCMC was produced using in house deacetylated chitosan (100-300 kDa, acetyl content determined by FTIR)[2]. The NCMC synthesis was performed in a chloroacetic acid/distilled water (dH$_2$O) mixture[3] and its degree of substitution was determined using the potentiometric titration method[4]. NCMC minimum inhibitory concentration (MIC) was defined by the broth microdilution method, in order to assess its antimicrobial potential against *Pseudomonas aeruginosa*.

SA (alginic acid sodium salt from brown algae, ≥ 2,000cP) and GN (~300 Bloom, Type A, Porcine skin) were prepared at 2% w/v and 1% w/v (in dH$_2$O), respectively, while NCMC was prepared at 2xMIC (in NaOH-containing solution). GN and NCMC were added to the SA solution under slow stirring in a proportion of 70:20:10 v/v, respectively[5]. The wet-spinning set-up was composed of two syringe pumps (NE-1600/NE-300, NewEra Pump Systems) connected to a coaxial spinneret. AAPV prepared at optimal elastase inhibition concentration was injected through the innermost port of the spinneret at a low flow rate (0.1-0.5 mL/min), to ensure the core was covered by the sheath layer (SA/GN/NCMC, flow rate of 0.5-1.0 mL/min). A calcium chloride (CaCl$_2$) solution (2 wt%, 21°C) was applied as coagulation bath. Microfibers were characterized by brightfield microscopy and FTIR. After production, coaxial fibers were incubated in physiological, acidic and basic pH buffers for 1, 2, 4, 6, 24 and 48 h to evaluate the AAPV release profile and NCMC pH-trigger dissolution, and monitored by UV-VIS. The antibacterial activity of the AAPV-loaded fibers against *P. aeruginosa* bacteria was assessed by time-kill kinetics studies for equal periods to the release. HNE inhibitory testing was again conducted, to establish the AAPV efficiency after loading.
Results and Discussion
AAPV peptide was successfully synthesized, and its purity confirmed. The peptide was seen to inhibit elastase, reducing its activity. NCMC was acquired from deacetylated chitosan and successfully transformed in NCMC, responsive to basic pH. NCMC was found effective against P. aeruginosa. To the contrary, AAPV did not inhibit the action of this bacterium. Co-axial fibers were produced from the three-polymer blend, with a smooth morphology and a hollow interior. Controlled release of AAPV from within the fibers was only accomplished in basic pH, revealing the stability of the fibers in acidic and physiological media. Time-kill kinetics tests proved the effective action of NCMC in inhibiting the growth of P. aeruginosa, as being released from the sheath of the fibers. AAPV was also seen to sustain its anti-elastase performance, guaranteeing optimal enzyme levels.

Conclusion
In the end, the potential of the engineered coaxial fibers to serve as controlled release platforms for AAPV was demonstrated. With this investigation a step further was taken in establishing wet-spun constructs for drug delivery in CW care.

Injectable hydrogel based on chitosan/polycyclodextrin/cinnamaldehyde for the local treatment of diabetic foot ulcers

Henry Chijcheapaza-Flores¹, Maria José Garcia-Fernandez¹, Mickael Maton¹, Jean-Noël Staelens², Nicolas Tabary², Frédéric Cazaux², Feng Chai¹, Bernard Martel², Nicolas Blanchemain¹

¹ Univ. Lille, INSERM, CHU Lille, U1008 - Controlled Drug Delivery Systems and Biomaterials, F-59000 Lille, FR; ² Univ. Lille, CNRS, INRAE, Centrale Lille, UMR 8207 – UMET – Unité Matériaux et transformations, F-59000 Lille, FR

Introduction
Diabetic foot ulcers are considered as a frequent complication in diabetic patients. It has been classified as a severe infection that could lead to bone infections also known as osteomyelitis. The wound healing process has become more and more difficult to manage due to poor blood circulation, sclerotic tissues, and antibiotic resistance. Traditional treatments are based on debridement, wound dressing, and systematic or intravenous antibiotic administration but even under treatment, it leads to amputations in 25% of patients (1). The most recent studies, introduce hydrogels as a potential candidate for wound healing management because of their properties as a drug delivery system and also their capacity to promote debridement and rehydration. A previous work presented by Flores C. et al (2017)(2) shows the interesting viscoelastic properties of a hydrogel based on chitosan (CHT) and poly β cyclodextrin (PCD). This project has been focused on the development of CHT/PCD hydrogels combined with a natural antimicrobial molecule, Cinnamaldehyde (CN). Since CN (obtained from Cinnamon essential oil) is considered as an efficient antimicrobial compound (3), it is a promising candidate for the local treatment of diabetic foot ulcers.

Experimental Methods
Firstly, CHT (deacetylation degree: 76% and molecular weight: 256 kDa) and PCD (molecular weight: 21 kDa and degree of substitution: 56%) were milled to obtain particles of <125 µm. Then, the first step consisted of hydrogel pre-formulation, CHT and PCD powders were co-milled at different concentrations, and the powder was suspended in distilled water and acidified with Lactic Acid (patent FR 3038318). The hydrogel formation was assessed by inversed-vial test: 1 mL of hydrogel was injected in a vial, and the resistance to flowing was evaluated. Later, hydrogel cohesion and structure stability were assessed by hydrogel injection in phosphate-buffered saline (PBS, pH 7.4). Thereafter, PCD-CN complexation was studied by the solubility phase diagram (4) and Nuclear Magnetic resonance spectroscopy (NMR H1 and ROESY). At a second stage, CN was added in the aqueous phase before the suspension of CHT/PCD powder. New CHT/PCD/CN formulation was as well evaluated and characterized by rheology (viscoelastic properties, recovery, and viscosity). CN release study was performed under dynamic conditions with USP4 apparatus (Sotax®, 37°C, 5 mL/min) and quantification was performed using a UPLC-DAD (Nexera, LC-2040C 3D Plus, Shimadzu, Japan) with diode array detector (DAD) at 287 nm. The bacterial kinetic reduction of hydrogels was proved by kill time test with strains of S. aureus and E. coli according to JIS Z 2801. Finally, the hydrogel cytocompatibility was assessed using a pre-osteoblast cell line (MC3T3-E1) according to the ISO 10993-5.

Results and Discussion
Inversed-vial test and hydrogel injection in PBS proved the hydrogel formation as well as their stability in PBS. On the other hand, Cyclodextrin (CD) has been widely used as an excipient to form inclusion complexes for drug delivery and to improve the solubility profile of molecules with low solubility. In this context, the solubility phase diagram proposed proved a complexation constant of 119.028 M⁻¹ between CN-PCD cavity and NMR spectroscopy confirmed...
the inclusion of CN aromatic group into the β-CD cavity. Once CN was added at a concentration of 1% w/w, the study of the storage modulus (G') and loss modulus (G'') by rheology confirmed the hydrogel formation. Therefore, viscosity and recovery assay proved the shear-thinning character and structure recovery after stress (>75%) respectively. These features will influence the facility for injection as well as the restructuration of the hydrogel after injection. The release and microbiological test confirmed a CN release of 5 mg/g of hydrogel and a 6 log reduction of S Aureus and E. Coli after 15 hours. Finally, 98% of cell viability was obtained in the in vitro cytotoxicity by AlamarBlue® test.

Conclusion
After hydrogel evaluation, a new promising hydrogel with interesting rheological properties and in vitro activity for the treatment of diabetic foot ulcers has been obtained. Nevertheless, further studies are needed to prove its efficacy in an in vivo model.

Skin hydration via electrospun polyimide patches with oil: *in vivo* experiments compared with numerical model

**Ewa A. Sroczyk**¹, Marek Jaszczur², Urszula Stachewicz³

¹ AGH University of Science and Technology, Faculty of Metals Engineering and Industrial Computer Science, Krakow, PL; ² AGH University of Science and Technology, Faculty of Fuels and Energy, Krakow, PL

**Introduction**

Electrospinning is an excellent method to produce polymer fibers and membranes, which are characterized by high surface area to volume or mass ratio. Moreover, they are characterized by high porosity. These features are beneficial for biomedical applications such as skin patches. In our study we focused on atopic and allergic skin. Atopic dermatitis is the most common inflammatory skin disease, it affects up to 20% of children worldwide, and significantly decreases the patient’s quality-of-life [1,2]. Both diseases require continuous skin care. Long-term hydration is a one of supporting therapies, which can be achieved by applying skin patches. The purpose of our study was to develop a numerical model of skin and hydrating electrospun patches.

**Experimental Methods**

In our study we selected polyimide (PI) polymer, because is biocompatible, rigid, thermally stable and resistant to most chemical reagents and oils. We produced PI membrane with electrospinning method and imaged the membrane with scanning electron microscope (SEM). Then we evaluated mean fiber diameter by measuring 100 diameters of randomly chosen fibers using ImageJ J1.53v.

Atopic skin is deficient in gamma linoleic acid (GLA), therefore we selected a natural oil which is one of the richest in GLA – blackcurrant seed oil [3]. The obtained PI membrane pores were filled with the oil. Then, such patches were applied on human skin. We used corneometer for skin hydration evaluation before and after patch application. The PI membrane numerical model was developed from focused ion beam – scanning electron microscope images with COMSOL Multiphysics software.

**Results and Discussion**

We electrospun PI as presented in **Figure 1a**. The PI membrane pores can be filled with beneficial components which release in a controlled manner and hydrate the atopic or allergic skin. Obtained fibers have average diameter of 0.50 ± 0.07 µm, pore size in range 0.40 – 3.45 µm with median value 1.56 µm. The membrane porosity is 95.6% and contact angle 134 ± 2° which indicated hydrophobic character.

The skin hydration significantly increased after patch application – the longer patch was applied, the more hydrated skin. Additionally, the numerical simulation of GLA diffusive transport from oil in patch to the skin model was performed as showed in **Figure 1b, c**.

Combining the excellent membrane features, which are stability, high porosity and stretchability, with beneficial blackcurrant seed oil composition, we designed patches for long-term skin hydration. These patches were tested *in vivo*, by assessing the skin hydration before and after patch application. The PI patches were designed for long-term oil release, and the simulation showed the increase of GLA passing from oil to the skin. The model confirms that the GLA transport is directly related to, and responsible for, the increase of skin hydration.

**Conclusion**

Compatibility of experiments and numerical results showed the constructed model may be applied for individually tailored dermatologic therapy. The obtained patches have a great potential in other skin applications. The prepared skin model is a first base for further developments toward other skin disorders.

Polymeric nanoparticles by design to target cancer

Gianluca Ciardelli, Clara Mattu, Giulia Brachi, Luca Menichetti, Alessandra Flori, Paolo Armanetti, Elia Ranzato, Simona Martinotti, Monica Boffito, Susanna Sartori

1 Politecnico di Torino, Turin, IT; 2 Imperial College, London, GB; 3 CNR-IFC, Pisa, IT; 4 Università del Piemonte Orientale, Alessandria, IT; 5 Fondazione Gabriele Monasterio-CNR, Pisa, IT

Introduction
Cancer nanomedicine has the potential to enhance efficacy and reduce off-target effects of chemotherapy. Nanosized drug delivery systems (called nanomedicines) have been shown to passively accumulate in certain tumors through the Enhanced Permeability and Retention (EPR) effect and to selectively interact with specific receptors on cancer cells, upon proper surface-functionalization. Polymeric nanoparticles (NPs) are appealing tools, since polymers can be largely modified to comply with the requirement of high loading, extended release, and targeting capacity. Polyurethanes (PURs) are particularly attractive in this endeavor by virtue of their tunable chemistry, biocompatibility, and ease of both, surface and bulk, functionalization. Here, we showed that proper selection of PUR building blocks can be exploited for surface-coupling of targeting ligands as well as to modulate the loading and release of single and multiple chemotherapeutics.

Experimental Methods
Different PURs were obtained by a two-step synthesis procedure and their hydrophilic/hydrophobic balance was modulated by selecting different ratios between the hydrophobic poly(ε-caprolactone) (PCL) diol and the hydrophilic poly(ethyleneglicole) (PEG). N-BOC-serinol, which bears pendant BOC-protected amino functionalities was inserted as chain extender. NPs were prepared and fully characterized in terms of size, polydispersity (PDI), zeta potential, and morphology. Active tumor targeting was achieved by surface-modification with the monoclonal antibody Herceptin (HER), which targets the HER2 receptor overexpressed by many cancer cells, including breast and colon cancer. A BOC de-protection protocol was first optimized to expose functional groups post NPs preparation, and HER was covalently attached via EDC/NHS-mediated coupling.

In another experiment, core shell PUR NPs were designed to possess different PUR cores (i.e., cores with a different hydrophilic/hydrophobic balance) and a phospholipid outer shell. In details, three polyurethanes obtained by varying the percentage of PCL from 100% to 70% were obtained and named PU100, PU80, and PU70. Two different chemotherapeutics, namely Doxorubicin and Docetaxel were co-loaded inside the PUR cores together with iron oxide NPs for imaging purpose. Cyanine 7 was attached to the surface of the NPs for dual fluorescent/photoacoustic detection. Loading efficiency of all agents, biodistribution, and tumor targeting ability were assessed both in vitro and in vivo.

Results and Discussion
Functional groups on the surface were successfully exploited for modification with HER. HER-NPs were able to selectively target HER-2 over-expressing cells in vitro. Core-shell PUR NPs were able to co-load multiple payloads with high loading efficiency (FIG. 1A), which was particularly relevant in mildly hydrophilic PURs. Moreover, contrast agents for MRI and photoacoustic imaging were also inserted in the particles, obtaining an efficient imaging tool in all tested modalities (MRI, Photoacoustic, and fluorescence (FIG 1B, 1C). When administered i.v. to mice, all NPs possessed a similar biodistribution profile, which was not affected by the composition of the PUR core. Moreover,
NPs resulted high in vivo tumor accumulation in a breast cancer flank tumor model (4T1 cells), where they were able to transport both drugs with a significantly higher efficacy as compared to non-encapsulated drugs.

**Conclusion**

We demonstrated that PURs are excellent biomaterials to design nanomedicines, as they offer high loading capacity of single and multiple payloads, extended release, cell targeting ability and high in vitro internalization.

![Figure 1](image-url).

Fiber diameter as determining factor for oil spreading and release from the electrospun skin patches

Zuzanna J. Krysiak, Urszula Stachewicz

AGH University of Science and Technology, Faculty of Metals Engineering and Industrial Computer Science, Cracow, PL

Introduction
Atopic dermatitis is widely spread skin disease affecting people regardless the age. Skin moisture is highly decreased due to transepidermal water loss. Patches, which can increase hydration in long term application are required. Electrospun fibers are reported to be applicable as membrane loaded with natural oils, beneficial for eczema [1].

Experimental Methods
Nano and micro poly (vinyl butyral-co-vinyl alcohol-co-vinyl acetate) (PVB) fibers were electrospun with low and high molecular weight polymer, respectively. Both membranes show high porosity, over 90% and high surface to volume ratio. Those properties are beneficial in a dermal drug delivery system [2]. Nano and micro PVB fibers were elongated uniaxially with tensile testing equipment. Evening primrose oil spreading was observed on both random and elongated fibers. Moreover, two different ways of oil application was analyzed, pipetting and spray brush. Biocompatible PVB membranes were examined for secretion of proinflammatory cytokines. For this purpose, human keratinocytes (HaCaT) were seeded on nano and micro fibers and cell culture medium was used as a substrate for enzyme-linked immunosorbent assay (ELISA). Obtained results, showed possibility of controlling oil behavior on the fibers by changing their geometry. Furthermore, we performed skin hydration test with evening primrose oil applied on the electrospun membranes.

Results and Discussion
The shape of oil droplet was ellipsoid for elongated fibers and circular for random. Oil area was greater in the case of nanofibers after 20 minutes. Oil spreading observation indicate that, oil pathway was through the fibers, regardless their orientation. Oil application by pipetting was selected as more efficient in comparison to the spray brush. Skin hydration test with nanofibers showed a great advantage over microfibers. Nanofibers were more attached to the skin, while microfibers were sticking out of the skin.

Conclusion
This study shows that evening primrose oil behavior was influenced by the diameter of fibers and alignment. Obtained results are promising for application electrospun PVB membranes as patches for skin hydration.

Fabrication of chitosan-based nanofibre scaffolds as potential wound dressings

Nguyen D. Tien¹, Tianxiang Geng¹, Catherine A. Heyward¹, Jonny J. Blaker¹,², Janne E. Reseland¹, S. Petter Lyngstadaas¹, Håvard J. Haugen¹

¹ University of Oslo, Department of Biomaterials, Institute of Clinical Dentistry, Oslo, NO; ² The University of Manchester, Department of Materials and Henry Royce Institute, Manchester, GB

Introduction
Chitosan is a sustainable biopolymer that has remarkable intrinsic properties, including non-toxic, antibacterial, and biodegradable [1]. Among the different physical forms of chitosan (e.g., powder, film, foam, and gel), chitosan-based nanofibres have drawn much attention due to their unique characteristics, such as larger surface-area-to-volume ratio and appropriate mechanical strength when blended with other polymers [2]. In this work, chitosan-based nanofibrous scaffolds for new wound dressings were fabricated via solution blow spinning (SBS) [3]. This wound dressing should mimic some structural aspects of the skin’s extracellular matrix, which could improve conditions for cell attachment, proliferation and growth, and thus promote skin tissue repair and regeneration with shortened healing time [4].

Experimental Methods
Chitosan powders with different degree of deacetylation (DDA, 57 – 97%) were prepared in 4 wt.% solutions in 0.5M acetic acid and mixed with 4 wt.% poly(ethylene oxide) (PEO) aqueous solutions at different weight ratios to obtain chitosan/PEO blend solutions. All solutions were spun into nanofibres using SBS. The obtained nanofibres were characterized by various techniques including SEM, DSC, TGA, FTIR, confocal fluorescent microscope, and mechanical testing. In vitro studies were conducted by culturing human fibroblasts onto the chitosan nanofibre scaffolds.

Results and Discussion
Processing neat chitosan into nanofibres is challenging due to its cationic nature and high crystallinity, therefore, PEO, an FDA-approved polymer for safe use in several medical applications, is introduced to improve the spinnability of chitosan solutions. Indeed, uniform fibre structures with submicrometer-sized fibres were successfully obtained in all compositions (Figure 1). When the PEO content in the blend increases, the fibre diameter becomes large, as well as wider fibre diameter distribution. Chitosan nanofibres containing 10 - 50 wt.% PEO produce an ultrafine fibre with near defect-free fibre network (i.e., no large droplet was seen as in case of 98/02 (98 wt.% chitosan, 2 wt.% PEO) and 95/05 (95 wt.% chitosan, 5 wt.% PEO) compositions). As a result, the 90/10 composition was selected for in vitro studies due to its nanofibrous-structural integrity, while the amount of chitosan was maximized.

Due to the fact that PEO is water-soluble, this polymer was removed from the chitosan/PEO blended nanofibres prior to cell culture. This step requires neutralization in order to prevent the chitosan fibres losing their fibrous structures. Neutralization and the total removal of PEO were completed by immersing the membrane in aqueous 1M potassium carbonate solution for 3 h. The removal of PEO was verified by FTIR and NMR analyses. Stable chitosan fibre membranes were obtained without significant loss of their nanofibrous structures. In vitro tests were performed by culturing human fibroblasts onto chitosan nanofibre scaffolds (using cell crowns) for 14 days. Attachment and organization of cells on the fibrous network can be seen in Figure 2. The cell bodies of fibroblasts were stretched and attached in a three-dimensional network of chitosan nanofibres.

Conclusion
Chitosan nanofibres with submicrometer-sized fibres were successfully fabricated using SBS. The chitosan nanofibrous structure promoted cell adhesion, showing normal cell morphology and spreading, indicating appropriate cell viability for the nanofibres. The fabricated nanofibres show promise as potential skin graft substitutes.

Neuronal Networks in a Fiber-Reinforced Hyaluronic Acid-Based Matrix

Dieter Janzen1, Ezgi Bakirci2, Julia Hauptstein3, Leonard Forster2, Jörg Teßmar2, Torsten Blunk3, Paul D. Dalton2,4, Carmen Villmann1

1 University Hospital Würzburg, Institute of Clinical Neurobiology, Würzburg, DE; 2 University Hospital Würzburg, Department for Functional Materials in Medicine and Dentistry, Würzburg, DE; 3 University Hospital Würzburg, Department of Trauma, Hand, Plastic and Reconstructive Surgery, Würzburg, DE; 4 University of Oregon, Phil and Penny Knight Campus for Accelerating Scientific Impact, Eugene, US

Introduction
Three-dimensional in vitro cell culture models are becoming essential to replicate the in vivo. Such 3D in vitro models use matrices to encapsulate cells, thus creating an extracellular environment that ideally should resemble mechanical and biological properties experienced within native tissue. For the central nervous system, creating such model systems with primary neurons and glia can be especially challenging, as weak hydrogels mimicking the softness of the brain are difficult to handle. Incorporation of reinforcing fibers created by using additive manufacturing (3D printing) technologies can improve mechanical properties of soft hydrogels and enable proper handling. One of these technologies, melt electrowriting (MEW), allows creation of small-scale, organized structures that don’t occupy significant volumes of the matrix. Recently, we successfully demonstrated high viability, network formation, and network function for cortical neurons in fiber-reinforced Matrigel. [1]

Experimental Methods
In this study, melt-electrowritten poly(ɛ-caprolactone) (PCL) fiber scaffolds were used to reinforce thiolated hyaluronic acid (HA-SH). Hyaluronic acid is one of the major components of the extracellular matrix in the brain. Cortical neurons and astrocytes were seeded into these 3D matrix composites and studied for their viability, network formation, network function, and migration.

Results and Discussion
Cortical neurons showed low viability and almost no network formation when cultured in HA-SH without supplements. However, co-culture with astrocytes seeded as a monolayer below the 3D fiber-reinforced HA-SH significantly increased viability. It is hypothesized that the secreted extracellular matrix proteins or cytokines from the astrocytes elicit the higher survival rate in the HA-SH matrix. Neuronal network formation followed by immunocytochemical stainings and characterization of the network firing activity is under investigation. Furthermore, astrocytes migrated into the hydrogel in close proximity to the cortical neurons.

Conclusion
In summary, we successfully cultured cortical cells in a fiber-reinforced hyaluronic acid-based matrix. This 3D in vitro model represents a powerful basis allowing customization of matrix formulation and study of cell-cell interactions under normal and disease conditions.

Introduction
Chronic wounds represent a major burden in human society: just in the US, there are about 6.5 million of patients, and this number is expected to increase due the upward trend of aging population, incidence of diabetes and obesity. In Europe, one out of five hospitalized patients suffer from a pressure ulcer. Moreover, the costs associated with its extensive care treatments are high; about 25 billion dollars are spent annually in the US.¹ These costs can be reduced by appropriate diagnose and treatment. Thus, research has focused on the development of new wound healing devices. However, a device that enables fast-effective closure, low cost, and scalability is still missing.

Ions such as calcium (Ca²⁺) and zinc (Zn²⁺) are essential for skin homeostasis. Calcium regulates a plethora of skin vital functions, such as platelet aggregation or epidermal stratification. We have shown that calcium-releasing platforms such as calcium phosphate nanoparticles (NPs) stimulate in vitro and in vivo wound healing.²,³ On the other hand, the skin contains about 5% of total body zinc content, and deficiencies on this ion are associated with impaired wound healing and roughened skin. Zinc’s antimicrobial properties have been recently suggested,⁴,⁵ making this ion promising for its application on wound dressings.

This work aims to develop an ion releasing platform based on nanocomposites for local and sustained calcium and zinc release at the wound site, to achieve wound closure and provide antimicrobial protection.

Experimental Methods
Submicrometric particles incorporating different amounts of Zn²⁺ and Ca²⁺ ions were combined by wet methods. Then, they were thermally treated in order to regulate their degradability. Ion release was analyzed by colorimetric methods. pH was measured with a pH-Meter. Particle size was determined by Dynamic Light Scattering (DLS) and Scanning Electron Microscopy (SEM). Particle composition was studied using X-Ray Diffraction and Energy Dispersive X-Ray Spectroscopy (SEM-EDX). Direct and indirect particle toxicity was assessed in vitro in human dermal fibroblasts (hDFs) using the MTT assay. Particles were incorporated in collagen scaffolds in order to perform in-situ ion release.

Results and Discussion
Calcium and zinc were successfully incorporated into the particles. Two different compositions (CZ1 and CZ2) where Zn²⁺ and Ca²⁺ were combined successfully. Thermal treatment of the particles diminishes degradation due to its increase in phase crystallinity. Particles showed a rounded morphology, with submicronic sizes. Backscattering images show that zinc and calcium are homogeneously mixed. In fact, they seem to be formed of Ca(OH)₂ with the presence of Zn impurities, as suggested by XRD data. Ion release was sustained for up to 1 month (assay endpoint). Particles increased pH at the first 24h and then returned at physiological levels. The lower the Zn content, the lower the toxicity. The concentration of particles had to be in both cases lower than 1 mg/mL to avoid cytotoxicity. Particles were encapsulated in collagen hydrogels to achieve particle immobilization (local delivery) of the ions at the wound bed.

Conclusion
Ion releasing platforms were successfully produced. Their composition, size, and ion release profiles indicate their potential use in soft tissue applications such as wound healing therapies. On-going research to test their wound healing potential includes cell migration, MMP regulation, proangiogenic factor production, and collagen synthesis.

Characterising the Physical Properties of Silicone Oil Tamponades Containing Polymer Based Additives for Ocular Drug Delivery

Alys E. Davies¹, Stephanie Edwards², Helen Cauldbeck²,¹, Steve Ranna²,³, Tom McDonald², Victoria Kearns¹

¹ University of Liverpool, Eye and Vision Science, Liverpool, GB; ² University of Liverpool, Chemistry, Liverpool, GB; ³ University of Liverpool, Materials Innovation Factory, Liverpool, GB

Introduction
Silicone oil tamponades are used as a treatment in retinal detachments and help prevent the formation of unwanted wound healing responses associated with diseases such as diabetic retinopathy and proliferative vitreoretinopathy (PVR). Drug releasing tamponades have the ability to reduce the incidence of PVR. This study aimed to characterise clinically relevant physical properties of novel silicone oil (SiO) based tamponades with the addition of polymer based additives¹,² to control drug release.

Experimental Methods
Reversible addition-fragmentation chain-transfer (RAFT) polymerisation was used to polymerise poly(dimethylsiloxane)methacrylate (PDMSMA) of varying molecular weights, as either homopolymers or copolymers with oligo(ethylene glycol)methacrylate (OEGMA) and blended 10 v/v% in technical and purified Siluron¹⁰⁰⁰ and Siluronxtra (Fluoron GmbH). Emulsification behaviour was tested by measuring volume of emulsion following exposure to shear in a 1:1 ratio of oil:foetal bovine serum. Viscosity was measured using ARES G2 controlled-strain rheometer and 50mm diameter 1˚ cone geometry. Light transmittance was measured using UV-Vis spectrometry over the visible light spectrum and cytotoxicity testing was conducted on a human retinal pigmented epithelium cell line, ARPE-19, to ISO10093 standard.

Results and Discussion
Emulsification studies highlighted differences in behaviour between technical and purified SiO grades. Shorter chain polymers increased emulsion volume in technical grade SiO¹⁰⁰⁰ (29.8% to 36.8%) but not purified; conversely, longer polymer chains showed opposite behaviour. In both technical and purified SiOxtra, emulsion volumes increased with polymer additives but not beyond the clinically-relevant threshold of purified SiO¹⁰⁰⁰. In the rheology studies, the presence of polymers had little difference on the purified oils. The inclusion of polymer additives also showed no detriment to the shear thinning properties of SiOxtra. Light transmittance remained above 80% in all oils. The effect of long term exposure to the modified oils on proliferating cells appeared to be inconclusive. For metabolic activity, no statistically significant differences were observed in the purified oils compared with the negative control however changes in cell number varied across the blends and showed no obvious trend. For stable monolayers, no statistically significant differences were observed in either metabolic activity or cell number when cells were cultured with the oils for extended periods.

Conclusion
Inclusion of PDMS based additives does not appear to impede clinically relevant physical characteristics of SiO tamponades. Siluronxtra is a promising base oil to develop a new, drug releasing tamponade which could provide a novel treatment to reduce the complications of retinal detachment treatment, however, caution must be taken when using technical grade materials during product development as behaviour can differ from that of purified grade materials.

Design and characterization of an in vitro 3D liver lobule model

Matteo Pitton¹, Giorgio Dallera¹, Nicola Contessi Negrini², Silvia Fare¹,³

¹ Politecnico di Milano, Dept. of Chemistry, Materials and Chemical Engineering, Milan, IT; ² Imperial College, Dept. of Bioengineering, Faculty of Engineering, London, GB; ³ National Interuniversity Consortium of Materials Science and Technology, Florence, IT

Introduction
The development of 3D in vitro models allows overcoming relevant drawbacks associated with 2D in vitro cultures and in vivo animal models, thanks to the closer reproduction of the in vivo conditions and maintenance of the stability in long-term cultures [1]. In order to fully replicate in vitro the complex architecture of the liver for the realization of a functional hepatic model, an accurate intrinsic vascularization is crucial for hepatocytes function, such as detoxification of drugs, and for the creation of the physiological oxygen gradient. The aim of this work is to design and develop a 3D in vitro liver model closely mimicking the architecture of the hepatic parenchyma and the complex vascularization of the hepatic lobules to investigate the main physiological mechanisms occurring both in the healthy and pathological liver.

Experimental Methods
Gelatin methacryloyl (GelMA) hydrogels (10% w/v) were prepared by pouring the GelMA solution in a specifically designed PDMS mold and subsequently by photo-crosslinking under UV rays (Irgacure 2959). PVA sacrificial structures were embedded before the photocrosslinking to assemble the final model. PVA was selected as the material for the sacrificial structure, carefully designed in order to mimic the radial arrangement of the hepatic sinusoids in the liver lobules. The PVA structure was printed, after processing optimization, via FDM. The dissolution of the PVA structure was investigated by stereomicroscope and perfusion tests were performed to verify the expected formation of patent channels inside the GelMA hydrogel. The final hexagonal model was investigated by analyzing the physical (degradation test in physiological-like solution, T = 37°C, up to 6 weeks), mechanical (compression cyclic test, T = 37°C, strain ramp = 2.5% min⁻¹ down to 30% and 5% min⁻¹ up to 1%) and in vitro biological (in vitro cytocompatibility tests up to 14 days, L929 cell line) properties.

Results and Discussion
The realized model is composed of a hexagonal GelMA hydrogel, resembling the structure of the hepatic lobule, in which the 3D printed PVA sacrificial structure, mimicking the vascular network of the hepatic sinusoids, is embedded. By microscope observation and perfusion test, the patency of the obtained channels was verified (Figure 1). Stability tests up to 6 weeks showed an initially expected degradation of the uncrosslinked gelatin chains, followed by the swelling plateau (after 72 h). The assembled GelMA model maintained its physical stability up to six-week weight variation analysis and therefore appears suitable for in vitro modeling. Compressive mechanical tests (Figure 2a) exhibited a compressive elastic modulus comparable to GelMA hydrogels, either with and without embedded PVA sacrificial structure (p > 0.05). On the other hand, a significant difference in stiffness (p<0.01) and in the maximum stress reached (p<0.05) was evidenced. This decrease in the mechanical properties could be due to the presence of the open channel network, after PVA dissolution, which allows the aqueous solution to penetrate more easily between the meshes of the hydrogel. This reduction in GelMA_PVA formulation is not a disadvantage for the in vitro model, as it is able to mimic the mechanical characteristics of the liver. In fact, the liver physiological values of elastic modulus [2-4] do not show differences compared to the values of the GelMA_PVA structure developed here (Figure 2b).

Preliminary results obtained by AlamarBlue assay showed that cell metabolism in the GelMA model increases...
considerably in time, reaching values closer to those achieved by cells grown on TCPS (Figure 2c). This result indicates that the proposed model adequately supports cell adhesion, spreading, and proliferation resulting. Live/Dead staining qualitatively showed that L929 cell viability increased at each considered time point for cells encapsulated in the upper face of GelMA samples and for those in the cross-section (Figure 2c).

**Conclusion**

Despite the open challenges still present to produce an accurate scalable in vitro model of the liver, due to its very complex architectural and vascular features, an attempt to mimic the lobule structure was here described and characterized. The obtained results confirm that the GelMA model, characterized by the presence of patent channels obtained by PVA sacrificial structures, is suitable to successfully replicate the compressive mechanical characteristics of native hepatic tissue as well as good cell viability in the structure.

**Figure 1**

Preparation of the crosslinked GelMA hydrogel embedding the PVA sacrificial structure; after the dissolution of PVA, channels are observable as well as their patency.

Ultra-thin ELR membranes for wound healing applications

Diana J. Gusano, Lubinda M. Mbundi, Miguel G. Pérez, José Carlos R. Cabello

Universidad de Valladolid, GIR BIOFORGE-CIBER-BBN, Valladolid, ES

Introduction
Dermal damage through trauma or diseases that affects the basement membrane is characterised by delayed healing, contractures and scarring. In this regard, biomaterials are very promising for building scaffolds for therapeutic purposes, simulating most of the properties of these tissues, such as mechanical ones, thus making them ideal supports for skin regeneration. Among novel strategies for wound healing is the development of natural polymer based ultra-thin membranes [1]. Here we report an in vitro evaluation of the efficacy of an elastin-like recombinamer based ultra-thin membrane for wound healing applications.

Experimental Methods
For the purpose of this work, two biodegradable and cell-adhesive ELRs were obtained by genetic engineering techniques, assessed by agarose gel electrophoresis, and expression in Escherichia coli bacteria, whereas its purification was performed through Inverse Temperature Cycling (ITC) as described elsewhere [2]. Then, ultra-thin membrane were produced by the catalyst-free click-chemistry based crosslinking of these two biodegradable ELRs [3] at an interface of two immiscible liquids (aqueous and organic solvents). After that, they were washed through water, acetone, methanol and collected in PBS followed by UV exposure. The ability to support the viability and activities of skin cells was determined in vitro using human foreskin fibroblasts (HFF1) and human keratinocytes (HaCat). Cells were immunostained for markers for differentiation, material-cell and cell-cell interaction and structural protein.

Results and Discussion
The novel ELR-based ultra-thin membranes could support cell viability and activities in vitro for at least 21 days in culture. The high porosity of the scaffold supported media diffusion, a characteristic that was vital for maintaining the integrity of the fibroblast and keratinocytes. Indeed, markers indicative of established cell-cell and cell-matrix interactions were observed. Moreover, cells demonstrated matrix remodeling through the production of ECM features such as collagens (I and IV), laminin and fibronectin, which are relevant for wound healing.

Conclusion
This work demonstrates the successful production of biocompatible ELR-membranes with tunable physicochemical properties such as shape, thickness, porosity, diffusion coefficient and biofunctional moieties. The ease of production and derivatisation, as well as stability in culture and robust mechanical properties suitable for handling make this novel ELR-based membrane an ideal candidate for use in the development of bioactive dermal substitutes (i.e. basement membrane) for wound healing and other tissue engineering applications.

In vitro studies of dual-responsive composites for simultaneous hyperthermia and chemotherapy

Filipe V. Almeida, Adriana Gonçalves, João P. Borges, Paula I. Soares

Universidade Nova Lisboa, CENIMAT/ i3N, Caparica, PT

Introduction
Nanotechnology-based approaches to perturb tumour’s biology and deliver therapies are gaining momentum due to their nanoscale-related properties. Iron oxide nanoparticles \( \text{Fe}_3\text{O}_4 \)-NP respond to high-frequency alternated magnetic field (HFAFM) by promoting heating. Recently, \( \text{Fe}_3\text{O}_4 \)-NP coated with oleic acid (OA NP) and dimercapto succinic acid (DMSA NP) were incorporated into thermo-responsive microgels (MG) made of poly (N-isopropyl acrylamide, PNIPAAm), which in turn were incorporated into polyvinylpyrrolidone (PVP) nanofibers. The material properties of NP/MG/PVP were thoroughly characterized recently [1], although their biological role is not yet characterized.

Experimental Methods
Here, we focus in studying the impact of PVA/MG/NP in controlling adhesion, proliferation and cell death. PVA was used, instead of PVP as previously, given their ability to form thinner fibers, which has the potential to outperform PVP functionally (i.e. heating capacity and drug releasing). To assess adhesion, we performed immunostaining analysis of focal adhesion (FA) protein vinculin and filamentous actin in different tumor cells lines (melanoma cells, WM983b, osteosarcoma, SaOs) and compared with non-malignant cells (adult dermal fibroblasts). To assess proliferation, resazurin, a colorimetric dye that measures cell viability was used, as well as 3D laser scanning confocal microscopy. Cell death was quantified by combining resazurin measurements and imaging of fluorescently probes, namely live/dead dyes (calcein-AM and Ethidium homodimer-1) and immunostaining with apoptosis markers (cleaved caspase-3).

Results and Discussion
Across the different designs (OA vs DMSA, 8% vs 10% of NP, with/without MG), PVA/MG/NP displayed similar rate of cellular adhesion and the FA staining did not change. FA were more elongated in cell seeded onto PVP fibers when compared to collagen type I coated glass. These demonstrate that neither NP nor MG altered the affinity of cells to the PVA fibers. Next, we analysed the proliferation within a period of 14 days, being the most dramatic changes observed amongst controls. This data suggests that the incorporation of MG and/or NP do not alter cellular responses in comparison with PVA alone. Currently, we are investigating the full potential of PVA/MG/NP to deliver chemotherapeutic agents in 3D cultures of tumor cells. Preliminary data shows that doxorubicin loaded NP/MG promote cell death, as measured by live/dead assay and cleaved-caspase-3 immunostaining. In the early future, we will incorporate doxorubicin loaded NP/MG into PVA fibers and analyse their ability to promote cell death in response to HFAFM.

Conclusion
We demonstrated that PVA provide good polymeric scaffold to incorporate both MG and NP without overall biocompatibility and bioactivity. Future experiments will focus in exploring the dual-responsiveness of magnetic nanocomposite, which will ultimately demonstrate its potential as novel cancer nanotheranostics.

Moxifloxacin imprinted silicone-based hydrogels for sustained ocular release

Diana Silva¹, Nadia Toffoletto¹, Herminio C. de Sousa², Maria Helena Gil², Carmen Alvarez-Lorenzo³, Madalena Salema Oom⁴, Benilde Saramago¹, Ana Paula Serro¹,4

¹ Instituto Superior Técnico, University of Lisbon, CQE, Lisbon, PT; ² University of Coimbra, CIEPQPF, Chemical Engineering Department, Coimbra, PT; ³ Universidade de Santiago de Compostela, Departamento de Farmacología, Farmacia y Tecnología Farmacéutica, I+D Farma (GI-1645), Facultad de Farmacia and Health Research Institute of Santiago de Compostela (IDIS), Santiago de Compostela, ES; 4 Instituto Universitário Egas Moniz, CIIEM, Caparica, PT

Introduction
The use of drug-loaded ophthalmic lenses has been regarded as an adequate solution to overcome the main disadvantages of conventional topical ocular treatments. In fact, therapeutic soft contact lenses (SCLs) allow achieving a higher bioavailability of the drug in the eye, minimize the drug wastage and side effects, and avoid the frequent and regular instillation of eyedrops, which may compromise the patients’ compliance with the treatments. To obtain efficient devices, several strategies have been attempted. Imprinting the hydrogels with drug molecules that create cavities in the polymeric matrix with the specific shape/binding sites is often used to increase the drug uptake capacity of the materials and prolong the drug release. In this work, imprinted silicone-based hydrogels were designed for the loading of the antibiotic drug moxifloxacin hydrochloride (MXF) and their relevant properties to be used as therapeutic SCLs was evaluated.

Experimental Methods
Four different silicone-based hydrogel formulations were prepared:

1. TRIS: A silicone-based hydrogel with the composition TRIS/NVP/HEMA 40:40:20 w/w (where TRIS refers to 3-tris(trimethylsilyloxy)silylpropyl 2-methylprop-2-enolate, NVP to N-vinyl pyrrolidone and HEMA to 2-hydroxyethyl methacrylate) obtained by thermal polymerization at 60°C for 24 h,
2. TRIS/AA: An alternative composition where acrylic acid (AA), a functional monomer that may establish potential interactions with MXF, was added at a concentration of 300 mM,
3. TRIS+D: A molecular imprinted silicone-based hydrogel with the same composition as 1, where MXF was used as template drug (added in the concentration 3 mM),
4. TRIS/AA+D: A molecular imprinted silicon-based hydrogel containing AA (same composition as 2), using also MXF as template drug (same concentration as 3).

After extensive washing, all hydrogels were loaded with the drug by soaking in MFX solution (5 mg/mL) at room temperature for 72 h. Release kinetics was investigated under sink conditions in simulated lacrymal fluid (SLF, pH=7.4) at 36°C with agitation (180 rpm). Quantification of the drug loaded and released was done by absorbance measurements at λ=290 nm. Transmittance, refractive index, swelling, wettability, ionic permeability and mechanical properties were evaluated. The most promising imprinted hydrogel was further studied in terms of antibacterial activity against S. aureus and S. epidermidis, submitted to the chorioallantoic membrane test (HET-CAM test) for potential ocular irritation, and to cytotoxicity tests according to ISO standard 10993-5 using NIH/3T3 fibroblasts. The MXF release from TRIS/AA+D was carried out in dynamic conditions, using a homemade microfluidic cell, that simulates the lacrymal fluid turnover. The obtained profiles were compared to the minimal inhibitory concentrations (MICs) range for S. aureus and S. epidermidis to estimate the efficiency of the devices.

Results and Discussion
All hydrogels showed adequate physical properties for contact lenses manufacture. TRIS+DD released a higher amount of drug than TRIS, but TRIS/AA showed a very significant increase in the amount of MXF loaded and released (Figure 1). Imprinting and adding AA functional monomers seemed to have a synergistic effect: TRIS/AA+D hydrogels hosted a larger amount of MXF and released the drug for a longer period. MXF (pH=7.2) is predominantly on its zwitterionic form (pK_{a1}=6.3 and pK_{a2}=9.3). With the carboxylic moiety at C-3 position ionized and the basic moiety at C-7 position, protonated MXF can form reversible electrostatic interactions with negatively charged AA. Moreover, hydrogen bonds may be established between MXF with available non-protonated amino and hydroxyl groups in TRIS and HEMA, respectively. The HET-CAM test revealed no ocular irritation potential, as no lysis, hemorrhage or coagulation was detected. The antibacterial activity of MXF was confirmed by the presence of inhibition halos for both bacteria. No toxicity was observed has cell viability level was well above 70%. Release studies carried out in dynamic conditions showed that MXF concentration remains above the MXF MICs for at least 10 days for TRIS/AA+D.

**Conclusion**

In summary, the MXF-imprinted hydrogels bearing AA demonstrated proper MXF release kinetics and promising properties to produce therapeutic SCLs.

¹ Instituto Superior Técnico, University of Lisbon, CQE, Lisbon, PT; ² University of Aveiro, QOPNA & LAQV-REQUIMTE, Department of Chemistry, Aveiro, PT; ³ Wenzhou Medical University, School of Ophthalmology & Optometry, Eye Hospital, Wenzhou, CN; ⁴ Instituto Universitário Egas Moniz, CIIEM, Caparica, PT

**Introduction**

Cataracts are the leading cause of blindness worldwide. The only effective treatment is surgery that involves the removal of the cloudy natural lens and the implantation of an intraocular lens (IOL). In the post-operative period, complications such as endophthalmitis can occur. To prevent this, eye drops of antibiotics and anti-inflammatories are administered with a frequent posology: antibiotics for 1-2 weeks and anti-inflammatories for 2-4 weeks. However, this drug delivery method has several drawbacks: it involves significant drug losses (>95%), leads to undesirable side effects, and demands frequent applications, which may result in poor patient compliance. An alternative to overcome these problems may be the use of IOLs as platforms for drug vehiculation. In this work, the possibility of using drug-loaded IOLs to ensure the simultaneous release of an antibiotic and an anti-inflammatory is explored both in **in vitro** and **in vivo** tests.

**Experimental Methods**

Acrylic IOLs were double loaded with the antibiotic moxifloxacin (MXF) and with the anti-inflammatory ketorolac (KTL) by soaking in a solution containing both drugs, for 2 weeks at 60°C. The IOLs were sterilized by high hydrostatic pressure combined with moderate/high temperature (600 MPa, 10 min, 70°C). The lenses were characterized regarding swelling and optical properties. **In vitro** drug release experiments were carried out in PBS in sink conditions (36°C, 180 RPM). The antibacterial activity of the release solution was tested against two of the most common microorganisms present in the ocular medium: *Staphylococcus aureus* and *Staphylococcus epidermidis*. The minimal inhibitory activity (MIC) of MXF against these two bacteria was determined. **In vivo** experiments were done with Japanese white rabbits. Sterile drug-loaded IOLs were implanted into the right eye of 5 rabbits (experimental group). Sterile blank IOLs were implanted into the right eye of another 4 rabbits (control group). In this group, the usual post-cataract prophylaxis therapy was applied: Vigamox (MXF) and Acular (KTL) eye drops were instilled in the right eyes after the surgery, 4 times a day. Vigamox was administered until the day 7 and Acular until the day 14. For both groups, the ocular inflammation was evaluated by slit lamp examinations on days 1, 3, 7, 14 and 21. Aliquots of aqueous humor were collected on the days 2, 7, 14 and 21 for the experimental group and on the days 2, 7 and 14 for the control group and the drug concentration there present was obtained by LC-MS. On day 21, the rabbits were humanely euthanized and the eye balls removed for histological analysis.

**Results and Discussion**

The loading of the drugs led to an increase in the swelling capacity of the lenses, but the transmittance in the region 500-700 nm was maintained (>90%). **In vitro** drug release experiments demonstrated that MXF and KTL were released in a controlled manner for 26 days. No loss of MXF activity was detected against both bacteria after the release. In the **in vivo** tests, the slit-lamp examinations revealed that after 7 days no inflammation was present on the eyes of the rabbits. The concentration of MXF and KTL in the aqueous humor was always higher for the experimental group than for the control group. Also, the concentration of MXF in the aqueous humor of the experimental group
was above the determined MIC (2 µg/mL for both bacteria) until 14 days, and the concentration of KTL was higher than the half maximal inhibitory concentration (IC-50) of cyclooxygenase 1 and 2 (enzymes responsible for inflammation) for almost 21 days. Histological analysis revealed good biocompatibility of the drug-loaded IOLs concerning the cornea and the iris.

**Conclusion**
The IOLs double loaded with MXF and KTL and sterilized by HHP revealed to be promising devices to replace the usual eye-drop therapy for prophylaxis of post-cataract surgery endophthalmitis.

Influence of Amino Acids on the Mechanism and Kinetics of Pt Microelectrode Corrosion

Arne K. Schierz1,2, Kristina Kebel1, Peter Behrens1,2

1 Leibniz University Hanover, Institute of Inorganic Chemistry, Hannover, DE; 2 Cluster of Excellence 'Hearing4All', Hannover, DE

Introduction

Platinum (Pt) is used for microelectrodes implanted into the human body e.g. as Cochlear implant (CI). Contact to human tissue and simultaneous electrical stimulation induces corrosion of the Pt microelectrode with correlating Pt dissolution, degeneration of neurons and finally loss of function.1,2 Different mechanisms of Pt corrosion have been published linked to different faradaic reactions occurring at the interface between the Pt surface and the electrolyte, namely oxidation reactions like the oxygen evolution reaction (OER) or chlorine formation (when the electrolyte contains chloride) as well as reduction reactions like the hydrogen evolution reaction (HER) or the formation of Pt-H bonds.3 Also, different electrolyte additives were investigated with regard to their influence on Pt corrosion, like amino acids, especially cysteine.4 In this work we have investigated Pt corrosion mechanisms and the possible suppression by additives using the rotating disc electrode (RDE) as a means to obtain deeper insight into the reactions. RDEs are commonly used for the determination of faradaic reactions and electrode kinetics. The RDE accomplishes this through a strong convective flow towards the electrode caused by the rotation, resulting in a homogenous flow rate of reagents towards the electrode surface during the electrochemical measurements.5

Experimental Methods

To investigate corrosive reactions at the Pt interface a RDE (Model: 636A; Princeton Applied Research) with a Pt disc electrode (Diameter: 5 mm), an Ag/AgCl reference electrode and a Pt mesh counter electrode were used. The electrolyte and the measuring chamber were purged with O2. The electrochemical operations were carried with a potentiostat (Model: PMC-1000; Princeton Applied Research). Cyclic voltammetry (CV) was conducted in a voltage range from 0.35 V to 0.5 V vs. Ag/AgCl with different scan rates (1 cycle each), a hold of 10 s at the vertex and without rotation. Potentiostatic electrochemical impedance spectroscopy (EIS) was performed at open circuit voltage (OCV) and an amplitude of 10 mV without rotation. To investigate reductive faradaic reactions, linear scan voltammetries (LSV) were measured in a voltage range of 0.4 to -1.6 V vs. Ag/AgCl (10 mV/s) with different rotation frequencies. For oxidizing faradaic reaction a voltage range of 0.4 to 2.1 V vs. Ag/AgCl (5 mV/s) at a constant rotation frequency of 1600 RPM was used. The electrolyte was PBS (ROTI®Cell, sterile, Carl Roth), used pure and with addition of L-methionine (≥ 98.5%, Fisher Scientific), L-cysteine (≥ 98%, Alfa Aesar), L-lysine (98%, Alfa Aesar), L-histidine (98+%, Alfa Aesar), L-phenylalanine (cell culture reagent, Alfa Aesar), L-alanine (cell culture reagent, Alfa Aesar), L-cystine (cell culture reagent, Alfa Aesar), L-thyrosin (cell culture reagent, Alfa Aesar), L-methionine sulfone (98+%, Alfa Aesar) or L-tryptophan (cell culture reagent, Alfa Aesar) at a concentration of 600 µmol/L.

Results and Discussion

LSVs in the reductive potential range lead to a constant current density with higher values for a higher rotation rate, which can be linked to a depletion of reactant during the measurement. Also the determination of half-wave potentials (E1/2) suggests a suppression of reductive faradaic reactions for different additives in comparison to pure PBS. LSVs for anodic currents likewise suggest a reduced Pt corrosion by additives. Here we used the potential at a current density of 10 mA/cm² (Ej=10) to determine the overpotential for different amino acids. Instead of a constant current density only a steep increase in current density was obtained suggesting an oxidation of the solvent. The presence
of cysteine and methionine leads to small oxidative currents before the steep increase which were linked to the oxidation of these additives. This presumption was confirmed by carrying out measurements with the corresponding oxidation products cystine and methionine sulfone.

**Conclusion**

Electrochemical characterization of a Pt disc electrode with an RDE setup showed a good sensitivity towards reductive and oxidative faradaic reactions. LSV showed a diffusion-limited faradaic reaction in the reductive potential range, which confirms the oxygen reduction reaction (ORR), while showing no diffusion limitation in the oxidative regime suggesting the oxidation of the aqueous solution to oxygen (OER). The suppression of corrosion was confirmed for different additives and also partially an oxidation of this additives. Further investigations as an possible implant modification for Pt microelectrodes with suppressed Pt corrosion and therefore a longer life cycle are needed.

**Introduction**

Skeletal muscle tissue has a high regenerative capacity, unlike many tissues, due to the satellite cells in its structure which become active as a result of injury and differentiate into myoblasts. However, in case of large damage, or in chronic muscle diseases such as muscular dystrophy, in which muscle cells are irreversibly damaged, the natural biological environment of the cells is also damaged. In this case, the self-renewal capacity of the muscle tissue remains insufficient. Cell-based therapies and different methods including natural or synthetic grafts have been proposed for the repair of damage. However, these treatments with a single functional component are often inadequate to repair complex tissue damage. In this study, a spiral form 3-dimensional (3D) matrices with electrical conductivity were developed for fast and effective treatment of major injuries to skeletal muscles. These structures were supposed to act as a carrier for muscle cells and at the same time stimulate the growth and differentiation of these cells and accelerate the formation of 3-dimensional muscle tissue.

**Experimental Methods**

The abdominal rectus muscle was decellularized using enzymatic and chemical methods. The amounts of DNA and GAGs in the samples were analyzed to determine the efficiency of the process and whether the protein structure is preserved or not. To produce a conductive oriented nanofiber membrane, a mixture of polyaniline (PANI) and polycaprolactone (PCL) polymer solutions was electrospun onto a rotating drum collector. The morphology of the nanofibers was determined using scanning electron microscopy (SEM). The electrical conductivity of the membranes was measured with a multimeter and to determine the chemical structure, FTIR-ATR analysis was performed. For 3D spiral matrices, a viscous solution of DCM was poured on the nanofiber membrane and rolled into a spiral form, and lyophilized. A tensile test and in vitro degradation studies were also conducted in PBS under physiological conditions. To evaluate the interactions of 3D matrices with skeletal muscle cells, myoblast cells (C2C12) were seeded on both surfaces of plane DCM/PANI/PCL matrices and matrices/cell constructs were analyzed using the Alamar Blue assay and Phalloidin/DAPI staining at 1, 7, and 14th days of the culture. To further assess the effect of electrical properties of 3D nanofiber matrices on cell viability, morphology and myotube formation, electrical stimulation was applied during cell culture studies. Immunofluorescence staining with anti-troponin (TNNT) and anti-desmin was performed to determine the muscle-specific marker expression of cells in tissue matrices after electrical stimulation.

**Results and Discussion**

The results revealed that more than 75% of DNA reduction and 90% of GAG and protein protection were obtained after decellularization. Nanofiber membranes have been successfully produced from a PCL/PANI polymer blend and the spiral form structures were also formed with good integration between the components as presented in SEM micrographs. The electrical conductivity of the PCL/PANI nanofiber membrane was calculated as between 3x10⁻⁹-2.5x10⁻⁹ S/cm. The presence of both components, PANI and PCL, on the surface of nanofiber membranes were
confirmed by FTIR-ATR spectra. The results from degradation studies revealed that the weight of 3D combined matrices was higher than PCL/PANI nanofibrous mats after 90 days.

Regarding cell culture with myoblast cells, it was observed that the cells on the nanofibrous surface continued to survive and proliferate until the 14th day, while the cell viability on the DCM surface decreased between the 7th and 14th days. Supporting the results of the Alamar Blue cell viability test, it was determined with DAPI/Phalloidin staining that the nanofibrous surfaces of the matrices showed well spread on the surfaces. Tube formation and alignment in the direction of electrical stimulation were observed in the cells (E+). Tube formations were observed in patches in samples without electrical stimulation (E0), but the orientation did not occur (Fig1). According to the immunofluorescent staining, TNNT and Desmin markers were observed in both groups (E0, E+). More intense anti-TNNT and anti-Desmin were observed in samples with electrical stimulation (E+).

**Conclusion**

The results obtained from the present work indicate that spiral shape combined structures possess favorable properties to serve as a matrix for the regeneration of damaged skeletal muscle tissue. In vitro cell culture tests, and cell behavior under electrical stimulation have also successfully demonstrated that these 3D combined tissue matrices are suitable for the application of muscle tissue defects.

BSA hydrogels for EPR spin-labeled anticancer drug delivery

Dura Nakarada¹, Ana Vesković¹, Anatolie Dobrov², Vladimir B. Arion², Ana Popović Bijelić¹

¹ University of Belgrade, Faculty of Physical Chemistry, Belgrade, RS; ² University of Vienna, Institute of Inorganic Chemistry, Vienna, AT

Introduction
Due to its intrinsic physiological function to bind and transport various endogenous and exogenous substances, including hydrophobic drugs, the protein serum albumin (SA) has been shown to be an excellent choice of polymer for the design of biocompatible hydrogels for controlled and targeted drug release. SA increases drug solubility in blood plasma, prolongs in vivo half-life, thereby increasing the therapeutic efficacy of the drug. Several types of SA hydrogels obtained by heat/pH induced conformational changes, disulfide linking, or by the addition of cross-linkers, have been prepared to date, from bovine and human SA (BSA, HSA), with the aim to synthesize robust hydrogels with retained physiological functions of the protein. The objective of this study was to investigate drug release kinetics from an anticancer drug-depot SA hydrogel, ultimately intended for molecular imaging of drug treatment response.

Experimental Methods
The spin-labeled cytotoxic ligand (HL) was synthesized as reported previously [1]. The hydrogels were prepared from BSA (Sigma). Electron paramagnetic resonance spectroscopy (EPR) was performed on a Bruker Biospin Elexsys II E540 EPR spectrometer. The molecular docking (MD) simulations were performed using Autodock software.

Results and Discussion
The binding and release of a highly cytotoxic modified paullone ligand bearing a TEMPO free-radical (HL) to BSA was investigated in solution, and in the thermally-synthesized hydrogel by EPR. Namely, drug binding to SA may be monitored by EPR when the drugs are spin-labeled with an "EPR-active" moiety, such as TEMPO. It has been previously shown that HL, which belongs to a class of indolo[3,2-d]benzazepines, besides inhibiting cyclin-dependent kinase and glycogen synthase kinase-3, exhibits high antiproliferative activity in human cancer cell lines, also targeting human R2 ribonucleotide reductase protein. The results show that HL binds to BSA in solution (Fig 1a), and that the binding is not affected by the heat-induced conformational change of the protein during hydrogel synthesis. Based on the EPR spectral parameters, it appears that HL is more or less immobilized. By comparison with the EPR spectrum of TEMPO incubated with BSA (Fig 1b), it is concluded that the binding of HL to BSA does not occur through the free radical moiety, but rather through the paullone backbone. Furthermore, HL is not released from the hydrogel during dialysis in NaCl physiological solution at room temperature for 48 h. After 72 h, only the strongly bound HL is detected in the hydrogel. This suggests that the SA hydrogel is a suitable drug-depot, since the water uptake during the 48 h swelling process leads only to the weakly bound ligand displacement. Additional ligand release is likely to be determined by the rate of the in vivo gel biodegradation, which certainly may be fine-tuned by varying the physicochemical properties of the hydrogel. The binding was confirmed by MD simulations which showed that HL binds to one BSA site with high affinity (Fig 1c).

Conclusion
This work shows that EPR is suitable for SA hydrogel drug release studies, with some advantages over the typically used methods (ultracentrifugation, UV/vis spectrophotometry, fluorescence, Raman spectroscopy), such as the requirement of extremely small volumes of protein (20 μl), sensitivity to minor changes in the spin-label environment (protein conformational changes), nanomolar detection limit, as well as time efficiency. The described methodology,
involving EPR spin-labeling and MD simulations, may give insight into the extent of drug binding and the affinity of the drug for SA, which is of essential importance for controlled drug release assessment.

Introduction

Oxygen is produced by photosynthetic organisms such as plants and cyanobacteria, and is the key molecule for aerobic metabolism. Several fundamental processes including mitochondrial respiration and reactive oxygen species production rely on the local availability of oxygen. Unlike other vital metabolites, such as calcium or glucose, the absence of oxygen reservoirs in the body generates an imperative need for external oxygen supply. Hence, humans have evolved sophisticated mechanisms to capture and further distribute oxygen from the environment into each cell of the body. As hypoxia is the leading cause for wound healing impairment, we have proposed that the use of photosynthetic biomaterials could contribute to tissue regeneration by increasing the local oxygen tension in wounds\textsuperscript{1–4}, an auspicious concept that has been recently confirmed by an independent group\textsuperscript{5}. However, the local and systemic response to photosynthetic cells has not yet been studied in humans, representing a major gap for the translation of photosynthetic therapies into clinical practice.

Experimental Methods

In this work, commercially available collagen scaffolds containing high concentrations of microalgae were implanted in 8 patients with full-thickness skin defects and covered with an illumination dressing (ClinicalTrials.gov identifier: NCT03960164). 21 days after implantation, a partial thickness skin autograft was used to cover the scaffold. Local and systemic response to the implanted scaffold was analyzed for up to 90 days, by means of hematological and biochemical profiles, concentration of plasma cytokines and immune cells in peripheral blood, histological and immunohistochemical analysis of biopsies, clinical aspect of the wound and patient self-evaluation.

Results and Discussion

After implanting photosynthetic scaffolds in 8 patients, macroscopic analysis of all wounds did not show signs of inflammation, such as edema or erythema, at any time point. Similarly, no clinical signs of adverse effects were detected by means of laboratory blood analysis. Additionally, complete integration between the photosynthetic scaffold and the wounds were observed. Hence, in this work we demonstrate that photosynthetic microalgae can be safely implanted in human patients, allowing key regenerative processes such as cell migration, ECM deposition, and vascularization. These results could be extremely relevant for the translation of photosynthetic therapies into clinics, but further studies need to be done in order to confirm this in a larger population of patients and against appropriate controls, such as standard of care.

Conclusion

This study represents the first-in-human trial to evaluate the safety of implanting photosynthetic scaffolds for dermal regeneration in full-thickness skin wounds.
These results will significantly help to translate photosynthetic biomaterials and therapies into clinical settings, and will contribute to the understanding of potential symbiotic relationships between humans and photosynthetic cells. This novel concept is intriguing and could have enormous translational applications, with an impact far beyond tissue engineering and regeneration.

We thank the study volunteers for their participation in this study, the staff of the Plastic Surgery Dept. at Hospital del Salvador for assistance in the execution of this clinical trial, and Ivo Carrasco for performing histological processing of the skin biopsies at Universidad de Valparaíso. We are grateful to P. García, C. Zumarán and T. González for the microbiological testing of the scaffolds, to D. Ncuñir for the graphical art, and M. McLuckie and M. J. Sikorski for the critical review of this manuscript. This work was supported by CORFO Portafolio I+D grant 18PID98887, FONDECYT 1200280, FONDECYT 1191438 and FONDEQUIP/EQM 140016.

Photosynthetic scaffold implantation

All patients presented full-thickness wounds prior to scaffold implantation. The wound bed was cleaned and photosynthetic scaffolds were then placed directly over the wound and trimmed as needed. Surgical sutures were used to fix the scaffolds among them and to the wound edges. Then, a transparent polydimethylsiloxane membrane was used to cover the scaffold and act as a draining system, which was further secured with a negative pressure wound therapy (NPWT) dressing. Finally, a light device specially designed for this study was placed on top providing specific and controlled illumination.

Photopatterning Stress Relaxation into Hydrogels for Corneal Regenerative Applications

Antonio Feliciano, Rhiannon Grant, Stefan Giselbrecht, Matthew Baker
Maastricht University, MERLN, Maastricht, NL

Introduction
Via mechanotransduction, corneal keratocytes have demonstrated the ability to migrate to areas of optimal stiffness by durotaxis. Altering stiffness can upregulate actin stress fiber production and focal adhesions, as well as alter keratocytes phenotypic markers. Stiffness however, is a static mechanical property and does not truly capture the dynamic environment of the host tissue. An alternative approach is to introduce a dynamic mechanical property, stress relaxation. Stress relaxation has been shown to influence cell behavior including migration, proliferation and differentiation. Using light activated chemistry, we grafted side groups via an ultraviolet-initiated reaction. Grafted alginate hydrogels have been shown to enhance relaxation and cell spreading, and promote osteogenic differentiation in mesenchymal stromal cells. We hypothesized that stress relaxation could be photopatterned into the hydrogels using a light-activated grafting approach and subsequently influence cell spreading and proliferation. We manufactured fast and slow relaxing gels, and assessed their impact on human primary corneal keratocytes adhesion and behavior.

Experimental Methods
Alginate was functionalized in order to allow photopatterning. Photopatternability was assessed via fluorescent image analysis on model reactions. The resulting grafted polymers were characterized by $^1$H-NMR and GPC. Mechanical properties (stiffness and relaxation) of hydrogels were characterized by rheological frequency sweeps and relaxation tests. Human primary corneal keratocytes were cultured on the hydrogels for 7 days and assessed for viability and phenotypic marker expression.

Results and Discussion
Results demonstrate controlled photopatterningability of the hydrogels with good feature reconstruction. A light activated reaction allowed us to introduce regions of localized stress relaxation. While stiffness measurements remained similar (~1000 Pa) after calcium crosslinking throughout the gel series, the stress relaxation ($\tau^{1/2}$) of these gels spanned a range from 21s to 3455s. The corneal keratocytes were found to exhibit differences in adhesion between the slow and fast relaxing hydrogels and regions.

Conclusion
Photopatterned hydrogels can be used to assess cellular response to stress relaxation. This study highlights the ability to determine optimal stress relaxation for corneal cells specifically but can be customized for other cell types. While stiffness is known to affect many areas of cell biology, with such a 3D configurable system, we begin to elucidate how dynamic material properties play a role in mechanotransduction and ultimately tissue regeneration. Furthermore, the spatiotemporal control of relaxation through photopatterning can be useful for modeling disease or regeneration in different viscoelastic microenvironments.
Photopatterning Increases PEG density and Faster Relaxation

Unravelling controlled release via structure of responsive nanocomposites for cell culture applications

Danielle Winning, Jacek Wychowaniec, Dermot Brougham

University College Dublin, School of Chemistry, Dublin, IE

Introduction

‘Smart’ polymers can respond to external stimuli such as temperature, pH and magnetic fields through reversible chemical/physical changes in their structure [1]. Thermoresponsive polymers, and microgels of these exhibit phase transitions on increasing temperature. In particular, thermoresponsive microgels have potential applications as components of composites for use in cell culture controlled release applications, once they respond to temperature changes in the range of 37 - 46 °C. Poly(N-isopropylacrylamide) (pNIPAM) is one of the most extensively studied thermoresponsive polymers, exhibiting lower critical behaviour with a phase transition c.32 °C [2], which limits its applicability for such applications. On the other hand, poly(N-isopropylmethacrylamide) (pNIPMAM) is structurally similar to pNIPAM, but has a reported LCST in the range 38 – 44 °C [3]. Some of the key aspects for controlling thermally activated diffusion of loaded molecules and biocompatibility is microgel size and structure. Surfactants such as Sodium Dodecyl Sulfate (SDS) can be exploited in polymer synthesis to provide good size control and monodispersity. Crosslinking can be carried out in situ or post synthesis, typically to increase the mechanical strength, reduce the degradability of the polymer network and allow for efficient swelling/deswelling in the loading/release of encapsulated molecules [4], [5]. Here we have incorporated thermoresponsive microgels formed from pNIPMAM into a non-responsive three-dimensional gelatine-based hydrogel matrix allowing thermally triggered release of dye/drug molecules for use in thermally responsive release applications in cell culture.

Experimental Methods

Polymer microgels were synthesized by free-radical polymerisation of the monomer N-isopropylmethacrylamide (NIPMAM) in the presence of a crosslinker, N,N’-Methylenebis(acrylamide) (BIS) and surfactant, Sodium Dodecyl Sulfate (SDS). Polymerisation was initiated using the radical initiator Potassium Persulfate (KPS). Microgels were characterised using Dynamic Light Scattering (DLS) and rheological analysis (Figure 1). Release studies of Methylene Blue (MB) and Cisplastin were carried out on pNIPMAM loaded gelatine-based hydrogels using Ultraviolet-visible Spectroscopy (UV-Vis) at 37 °C and at 45 °C, a temperature above the phase transition, to mimic suitable biological conditions. The release above LCST was also measured using a pulsed approach i.e., by subjecting the nanocomposite to variations between 37 °C and 45 °C, to mimic ‘pulsed’ release on demand. Finally, trigger of dyes was also demonstrated using magnetically driven hyperthermia approach in combination with magnetically responsive materials.

Results and Discussion

By controlling the synthetic conditions, we were able to synthesise pNIPMAM microgels with precise hydrodynamic diameters and low polydispersity (<0.2) in the range 75 to 2100 nm, and defined LCST across the range of 39 to 47 °C. The study design and outcomes will be described in detail in the presentation. We have additionally identified the maximum crosslinker content appropriate for use in biomedical applications so that the phase transition will theoretically not result in temperature-induced damage to cells, experimental assessment of this is underway. The outcomes include control over both the swollen size and the degree of deswelling of the thermoresponsive component at the phase transition. In the study presented we will describe the connection between these attributes and the extent of release of selected biologically relevant molecules at 45 °C whilst minimising release at 37 °C.
Conclusion
For the first time, we have elucidated the link between synthetic conditions and the obtained structures for pNIPMAM microgels using rheological measurements and small-angle x-ray scattering. Through the tailoring of the phase transition, size and deswelling properties of pNIPMAM microgels we have gained controlled release within the cell culture appropriate temperature range of 37 to 45 °C. Various possibilities of controlled release will be demonstrated, with both typical cumulative release over time, as well as pulsed release ‘on demand’ by precise external and remote spatiotemporal control over the temperature. In particular, demonstration of magneto-thermal pulsed release will be demonstrated. These findings establish the applicability of these microgels as thermo-responsive nanocomposite components in advanced cell culture applications, which will be discussed in the presentation.

Dynamic covalent crosslinked multi-compartmentalized hydrogel matrix

Clio Siebenmorgen, Guangyue Zu, Patrick van Rijn
UMCG, Biomedical Engineering, Groningen, NL

Introduction
Extensive research has been done to create a three-dimensional network that mimics the native cellular environment in order to encapsulate cells in vitro.\[1\]
Especially, hydrogels which are swollen polymer networks are a promising candidate. These networks are biocompatible, have a high water content, and show tunable chemical and physical properties. Hereby, well-defined microenvironments can be generated, which match the mechanical properties of the desired tissue. In order to successfully mimic the corresponding environment, a dynamic system is required, which is able to adapt the cell environment by e.g. incorporating biologically relevant molecules and allowing a triggered response to external stimuli.\[2]\[3\]
The aim of this project is the development of a hydrogel-based matrix using dynamic covalent chemistry. Making use of amine containing and ketone containing NIPAM nanogels, spontaneous matrix formation is facilitated in a reversible manner with tunable hydrogel-capsule hybrid structures in terms of physicochemical properties. Ultimately, this nanogel-based matrix can be used to mimic native cellular environments in order to encapsulate and expand cells, requiring a micro/macro-porosity, which was considered in the systems development.

Experimental Methods
The matrix formation is based on an imine formation of ketone functionalized and amine functionalized NIPAM hydrogels. Hollow structures are being formed on the interface of two immiscible solvents based on a Pickering emulsion. A schematic overview is depicted in Figure 1. Hereby, chloroform containing ketone hydrogel is tip sonicated with an amine hydrogel aqueous phase. The resulting matrix is separated for imaging and its pH responsiveness, and stability is being investigated.

Results and Discussion
Upon tip sonication of amine and ketone functionalized microgels, the matrix formation was investigated using fluorescence microscopy. Hereby, Nile Red in CHCl\(_3\) containing ketone functionalized hydrogels and H\(_2\)O containing Nile Blue labelled amine functionalized hydrogels were imaged. The network consists of capsules with CHCl\(_3\) as their inner core. The corresponding matrix shows capsules in sizes of several microns up to 100 μm. Formation of a dynamic covalent crosslinked nanogel matrix based on imine bonds, allows the incorporation of a pH responsive system, as imine bonds only remain stable under neutral conditions.\[4\] We analyzed the stability of the matrix under pH 4, 7 and 10. Figure 2b displays the instability of the matrix in basic and acidic conditions after 20 h. Whereas, the matrix remained stable under neutral conditions, proofing the formation of imine bonds between amine and ketone functionalized hydrogels.

Conclusion
In this work we present the successful formation of an external stimuli responsive dynamic covalent crosslinked nanogel-based matrix based on imine bonds. To successfully encapsulate and culture cells, further investigations on the physical properties, such as stability upon oil removal and stiffness of the matrix need to be investigated in order to mimic the desired cell niches.

Citric acid crosslinked methylcellulose hydrogels for cell sheet engineering

Lorenzo Bonetti¹, Luigi De Nardo¹,², Silvia Farè¹,²

¹ Politecnico di Milano, Department of Chemistry, Material and Chemical Engineering, Milan, IT; ² National Interuniversity Consortium of Materials Science and Technology (INSTM), Florence, IT

Introduction
Methylcellulose (MC) hydrogels have been described as noteworthy materials in the field of cell sheet engineering (CSE) since they allow to control cell attachment/detachment on their surface by means of a temperature trigger [1]. However, their reduced water-stability and mechanical properties may limit the breadth of their possible applications [2]. Citric acid (CA)-crosslinked MC hydrogels have been recently reported to possess superior physical and mechanical performances, also preserving their thermo-responsive behavior [3]. This work aims at exploiting the possibility to use CA crosslinked MC-based hydrogels to obtain cell sheets (CSs). The crosslinked MC substrates were characterized from a mechanical point of view, in vitro tested, and the obtained CSs were studied to assess their regenerative potential.

Experimental Methods
MC hydrogels (8 % w/v MC in 50 mM Na₂SO₄[3,4]) were crosslinked by adding CA (1, 3, 5 % wCA/wMC) to the hydrogel solutions, followed by oven-drying and thermal treatment (T = 165, 177.5, 190 °C) [4]. Following a Design of Experiment approach, three crosslinked MC hydrogels, MC-L, MC-M, MC-H (low, medium, and high crosslinked, respectively), were obtained. Non-crosslinked MC hydrogels were used as control. All the specimens were tested, investigating their tensile mechanical and in vitro biological characteristics. Indirect cytotoxicity was assessed culturing L929 murine fibroblasts in contact with 24, 48, and 120 h extracts for 24 h. CSs were harvested 48 or 120 h after L929 cells seeding on the MC substrates, simply by lowering the temperature to 4 °C. The detached CSs were characterized by immunofluorescence and image analysis (ImageJ, NIH). Lastly, the CSs regenerative potential was assessed by evaluating their adhesion and proliferation capability after their transfer to a new tissue-culture substrate.

Results and Discussion
CA crosslinking effectively modulated the mechanical properties (i.e., Young’s Modulus, E) of MC hydrogels. The E values were found in the range 5 kPa - 3.5 MPa, increasing the crosslinking degree (Figure 1A). Cell viability around 100 % (Figure 1B) was observed for each specimen (MC, MC-L, MC-M, MC-H), suggesting that the CA amounts used to achieve crosslinking did not cause any in vitro cytotoxic effect on L929 cells. CSs were then harvested simply by lowering the temperature at 4 °C. Intact CSs were detached from MC, MC-L, and MC-M hydrogels. Conversely, CSs harvesting was not feasible from MC-H hydrogels, confirming previous results which disclosed that a high crosslinking degree leads to the loss of MC hydrogels thermo-responsiveness [4]. Fluorescence images of the detached CSs (Figure 2A) revealed the presence of widespread actin filaments in the cytoskeleton, contributing to cell-cell junctions in the obtained CSs. For all the detached CSs, cell count was found to increase (p < 0.05) between 48 and 120 h of cell culture (Figure 2B). No significant differences (p > 0.05) in terms of cell count were observed among the CSs obtained for the differently crosslinked samples (MC, MC-L, and MC-M). Adhesion and proliferation assay on a new tissue-culture multiwell plate revealed that the CSs started to adhere to the new substrate shortly (~ 20 min) after their transfer. Optical microscopy observation 72 h after CSs transfer revealed that L929 cells migrated from the CS to the bottom of the new well (Figure 2C), indicating the potentiality of the obtained CSs for tissue regeneration.
Conclusion
This work reports for the first time the use of crosslinked MC substrates in CSE. CSs were successfully detached from the surface of mild crosslinked MC hydrogels (MC-L and MC-M). Conversely, high crosslinked MC hydrogels (MC-H) did not exhibit the expected thermo-responsive character, preventing CSs harvesting. The obtained CSs displayed no differences in terms of cell viability, compared to CSs obtained from control (pristine MC hydrogel).

Light-sensitive supramolecular hyaluronan hydrogels for the intraocular delivery of therapeutic biomolecules

Yaqi Lyu, Helena S. Azevedo

Queen Mary University of London, School of Engineering and Materials Science, London, GB

Introduction
By delivering drugs into the vitreous cavity directly, intravitreal injection remains as the most acceptable and efficient way to deliver therapeutics to posterior eye since it goes beyond the physiological ocular barriers. However, frequent injections are required to maintain sufficient drug concentrations which are uncomfortable and can lead to complications, such as retinal detachment [1]. Hyaluronic acid (HA) is the main component of the vitreous, being an attractive option for the formulation of an injectable ocular delivery platform. In addition, HA is biodegradable, biocompatible and easily amenable to chemical modifications [2]. Herein, a light-sensitive supramolecular hydrogel, based on host-guest moieties conjugated HA, was prepared for the sustained and on-demand delivery of therapeutic biomolecules (proteins, peptides) for the treatment of posterior eye segment diseases.

Experimental Methods
Cyclodextrin (CD) and azobenzene (AB) were first conjugated to HA separately. HA-CD and HA-AB were mixed (1:1 molar ratio) to form a hydrogel by self-assembly. The mechanical properties and light-sensitivity of the self-assembled HA-CD/HA-AB hydrogels were characterized using a rheometer equipped with UV-visible light sources. BSA was used as a model protein to examine the release profile in vitro with or without irradiation.

Results and Discussion
A hydrogel is formed immediately upon mixing HA-CD and HA-AB via host-guest interaction between CD and AB groups (Figure 1-A). Rheology tests show a significantly higher storage modulus G’ compared to the loss modulus G”. HA-CD/HA-AB hydrogels respond to irradiation in seconds and are reversible upon UV-visible light cycles (Figure 1-B). The HA-CD/HA-AB gels are relatively soft (G’ =1-2 kPa) allowing their easy injection (Figure 1-C) while being stable in PBS for 30 days. The gels have high protein loading capacity and show sustained and on-demand release of BSA with irradiation.

Conclusion
The HA supramolecular hydrogels with high drug-loading capacity and light sensitivity represent a less invasive delivery platform for light-triggered release of drugs into the back of the eye.

Hydrogel films based on bovine serum albumin and partially oxidized gellan with β-cyclodextrin/curcumin inclusion complex immobilized with applications in dermatological diseases

Camelia E. Iurciuc (Tincu)², Christine Jerome³, Marcel Popa¹,⁴, Lacramioara Ochiuz²

¹ "Gh. Asachi" Technical University of Iasi, Iasi, RO; ² "Grigore T. Popa" University of Medicine and Pharmacy, Iasi, RO; ³ University of Liege, Liege, BE; ⁴ Romanian Academy of Scientist, Bucharest, RO

Introduction
Previous studies have reported that curcumin has antibacterial and anti-inflammatory activity and, in topical applications, was successfully used to treat rashes and skin infections. The main disadvantage is its water insolubility and low bioavailability. The inclusion complex of β-cyclodextrin with curcumin has been prepared to improve water solubility. BSA was used to improve the hydrogel film’s biocompatibility and immune response capacity.

Experimental Methods
The films were obtained by cross-linking as a result of the reaction between the bovine serum albumin amine groups with the aldehyde groups from partially oxidized gellan, working at different molar ratios -NH₂ / -CH =O. The aldehyde groups’ content in the oxidized gellan was determined indirectly by dosing the residual periodate in a reaction mixture by iodometric titration with Na₂S₂O₃. The gellan oxidation was performed with NaIO₄ to form aldehyde groups by cleaving the C2-C3 bond from the glycosidic structure. FT-IR and ¹H-NMR spectroscopy was used to demonstrate the aldehyde groups’ formation in partially oxidized gellan. Molecular weight (Mw) of oxidized gellan determined by the viscosimetric method was calculated using the Kuhn–Mark–Houwink equation (K = 7.49 x 10⁻³ and α = 0.91).

Results and Discussion
The gellan oxidation degree was 57.16% after an oxidation time of 117 h, being influenced by the amount of NaIO₄ used, time, and temperature.

FTIR spectroscopy results showed that almost all spectra of oxidized gellan a new characteristic absorption peak occur between 1730-1740 cm⁻¹ assigned to the C = O group from aldehydes that demonstrates that the oxidation reaction between gellan and NaIO₄ took place. The ¹H-NMR spectra of standard gellan and oxidized gellan (for 72 hours) were tested and compared. A peak of 10.2 ppm in the spectrum of oxidized gellan occurs in the region greater than 8.05 ppm belonging to aldehyde groups. Molecular weight (Mw) of oxidized gellan determined by the viscosimetric method in 0.1 M acetate buffer solution at 23°C decreased when the oxidation degree increased.

Different molar ratios between albumin amine groups and aldehyde groups from oxidized gellan were used to obtain the films. The covalent cross-linking reaction between the albumin amine groups with the aldehyde groups within the oxidized gellan results in forming an imine bond, also called Schiff base. Figure 1 shows schematically the structure of the obtained albumin films cross-linked with oxidized gellan.

The number of amino groups in albumin that did not participate in the cross-linking reaction decreased, and the conversion index increases when the oxidized gellan amount was higher within the films. The inclusion complex of Page 1261 of 2028
β-cyclodextrin with curcumin was included in the albumin/oxidized gellan films from the preparation stage. The inclusion complex encapsulation efficiency within the films increased when the molar ratio was higher.

**Conclusion**

The results showed that the swelling degree values depend on hydrogel film hydrophilicity and pH; its values increase at pH=7.4 and when the number of carboxylic groups increases. The antioxidant activity for curcumin-loaded hydrogel film was improved compared with free curcumin, and the polymeric matrix has a protective role for curcumin against UV radiations. The curcumin release kinetics from films was studied in two mediums of different pH (5.5 and 7.4), and the release efficiency and permeability were higher at pH=7.4, the results being consistent with the swelling degree.

Therapeutical innovation for the treatment of radio-induced gastro-intestinal syndrome

Rodolphe Migneret¹, Frédéric Chaubet², Didier Letourneur¹, Teresa Simon-Yarza¹

¹ Inserm, LVTS U1148, Hôpital Bichat, Paris, FR; ² Université Sorbonne Paris Nord, LVTS U1148, Villetaneuse, FR

Introduction
Nuclear risk is a worldwide concern due to radiological and nuclear accident. Irradiation may cause severe gastrointestinal lesions named radio-induced gastro-intestinal syndromes (ri-GIS). Treatments rely on palliative and symptomatic therapies, such as anti-emetics, antibiotics, anti-ulcerants, anti-diarrheal, anti-pyretics, a supply in water, nutriments, electrolytes and finally hyperbaric oxygen therapy. This work is part of the INTRUST project whose hypothesis is that a multimodal and global approach will be much more efficient to treat ri-GIS. In particular, we want to develop an innovative treatment to
1) physically protect the mucosal barrier quickly after the irradiation,
2) locally deliver pro-regenerative therapeutics,
3) control the intestinal inflammation, and
4) fight bacteria.

Of note, chronic intestinal inflammatory diseases, such as Crohn disease and other GIS, could also benefit from this new treatment¹.

Thus, we propose to develop a novel biomaterial able to fit these specifications. In particular, polysaccharide (PS) hydrogels (HG) are particularly interesting, since they have a similar composition and properties that the intestinal mucosa and can be loaded with the chosen drugs, either by adsorption, ionic interaction or through covalent bonds. In this work we explore different strategies to covalently link anti-TNFα protein².

Experimental Methods
HG are made with two PS, pullulan (200kDa) and dextran (500kDa), and crosslinked in alkaline condition with sodium trimethaphosphate as previously described³. Two methods were followed to obtain gels coupled with proteins:
Method 1: Covalently linking the protein to the PS prior to HG formation. Divinylsulfone (DVS)⁴ was grafted onto the PS (mpS=500mg, CDVS=4.10⁻²M V=25mL and COH=100mM) and then bovine serum albumin (BSA, 66kDa, Sigma), that was used as a model drug, reacted with the vinyl group⁵ (mpS=50mg, CBSA=850µM in 2.5mL PBS). The grafted PS was washed with dialysis against DI-water after both reactions for at least 5 times during 1,5h (cut-off membrane 100kDa).
Method 2: Covalently grafting the protein after HG formation. 5mg of dried hydrogel was swollen with 2.5mL of a solution of DVS (4.10⁻³M) in NaOH (0.1M) to react for 5 minutes under agitation at room temperature. The grafted-HG was washed with water to remove the excess of DVS, then freeze-dried again. The HG grafted with the DVS, was swollen with a solution of BSA (10mg/mL) in PBS for 42h at room temperature under agitation, then washed with water to eliminate the non-grafted proteins.

Several parameters have been studied to optimize both reactions, such as concentration of DVS, concentration of BSA, time of reaction, pH and temperature. All experiments have been done in triplicates.

Results and Discussion
Method 1: Concerning the grafting of DVS on PS, the degree of substitution evaluated with NMR 1H, was 8% for dextran and 14% for pullulan in similar conditions. Concerning protein grafting, elementary analysis showed a gap in N content of 3% between grafted and non-grafted PS. This is equivalent to 619µg±5 BSA/mg of PS.
Method 2: Regarding protein binding on the HG, elementary analysis showed an increase in N and S contents in the grafted HG (0.56%±0.08 for N, 1.26%±0.11 for S, equivalent to 35µg±5 BSA/mg of PS). When compared to HG where the protein was just loaded through adsorption (21µg±11 BSA/mg of PS), we observed an increase of 60% protein loading and reduced variability within the samples.

The differences observed in the amount of protein linked to the PS compared to the HG can be due to the reduction of available hydroxyl groups, due both to crosslinking through STMP and through DVS. The addition of DVS on the HG probably causes crosslinking between hydroxyl groups as suggested by the fact that a reduction of the concentration of DVS led to higher swelling of the gels and an increase of protein content.

For future studies with anti-TNFα, method 2 will be used since anti-TNFα are potent drugs and the doses needed for a local treatment can already be reached with this method. Besides, the risk to lose protein activity during HG synthesis is avoided.

**Conclusion**

We have successfully grafted a model protein on polysaccharide HGs by using DVS by two different methods. Experiments are ongoing to graft the functional anti-TNFαMP6-XT22. After performing in vitro release studies under physiological-like conditions, in vitro and in vivo experiments will be done to prove the efficacy of the treatment.

Synthesis of bioactive hydrogels for the control of stem cell differentiation: Impact on bone tissue engineering

Cristina Lopez Serrano, Murielle Rémy, Chanseau Christel, Laroche Gaétan, Durrieu Marie-Christine

Introduction

Successful tissue engineering strategies depend on an accurate replication of key characteristics of the cell environment. Traditionally, the focus has been put on chemical signals, which basically consists in interactions between cell receptors and ligand molecules. Over the past decades, mechanobiology has emerged as a key field in bioengineering. It is now known that cells detect and respond to the mechanical properties of their surroundings. Accordingly, the in vitro differentiation of stem cells is affected by the stiffness of the substrate on which they are cultured [1]. However, it is necessary to further define the effect of matrix stiffness in 3D cell cultures as well as the interplay between these mechanical characteristics and the presence of bioactive molecules such as adhesion or differentiation peptides. In this context, our research challenge is to develop the optimal 3D microenvironment to enhance osteoblastic differentiation of human mesenchymal stem cells (hMSCs).

Experimental Methods

To address this objective, polymer-based hydrogels are synthesized in a biologically relevant range of stiffnesses. To do that, solutions of PEG-diacylate at different concentrations are photocrosslinked under UV light to form a reticulated polymer network.

Results and Discussion

Atomic Force Microscopy (AFM) is used to measure the surface mechanical properties (Young’s modulus) of the hydrogels. XTT assays have shown negative cytotoxicity of the gels, making them good candidates as substrates for cell culture (Fig. 1). Previous research has shown that the bifunctionalization of materials with adhesion and differentiation peptides boosts the osteogenic potential of hMSCs [2]. For this reason, hydrogels are covalently grafted with RGD and BMP-2 mimetic peptides. By tagging the peptides with a fluorescent dye, we were able to assess the homogeneity and density of grafted domains using fluorescent microscopy.

Conclusion

Further work will focus on the fabrication of PEG-based 3D scaffolds with similar characteristics in terms biofunctionality and mechanical properties in order to compare the cellular response between 2D and 3D cultures.
Fig 1: Cytotoxicity test results
Cell viability tests on pure material extract and dilutions at 50 and 10% (p<0.05). The non-cytotoxic control (medium that has not been in contact with the material) is used as reference and a phenol dilution is used as a positive control of cytotoxicity.

Introduction

Diabetes is a chronic and possibly fatal disease, which affects more than 400 million people worldwide—and the number is continuously increasing. Patients suffering from type 1 diabetes need exogenous injections of insulin to survive. [1] [2] Although, there are many great insulin therapies available on the market there are still some challenges connected to these such as controlling the glycemic balance. Beta-cell therapy is a potential way to overcome this challenge and numerous studies have already shown promising results. However, a major obstacle in cell therapy is the hypoxic environment created at the transplantation site immediately after transplantation. [3] [4] Calcium peroxide (CPO) has previously been investigated as an oxygen releasing agent in different cell therapy approaches and found to improve cell survival in hypoxic environments. [3] [5]

Experimental Methods

In this study, hydrogels composed of thiolated hyaluronic acid (HA), 8-arm-Poly(ethylene glycol)-Acrylate (PEGA), and CPO (Figure 1), were manufactured in order to obtain an oxygen releasing system for cell encapsulation. The hydrophilic HA is a natural polymer that, like the synthetic polymer PEGA, is known for its high biocompatibility and non-immunogenic properties. The incorporation of CPO into the hydrogel system was evaluated by FTIR and Alizarin Red staining. Hydrogels with varying concentrations of CPO were characterized in terms of their chemical, rheological, and mechanical properties. The oxygen release kinetics were assessed in an oxygen release study. Lastly, cell survival and functionality of insulin-secreting cells were investigated after encapsulation.

Results and Discussion

Hydrogels containing 0, 7.5, and 30% CPO were fabricated, and the incorporation of CPO was confirmed by both Alizarin Red and FTIR. The hydrogel system containing 7.5% CPO was found to release oxygen for at least 10 hours, whereas hydrogels containing 30% CPO released oxygen for a minimum of 30 hours. In terms of rheological and mechanical properties, all three hydrogel conditions were found to be shear thinning and suitable for beta-cell encapsulation in terms of their Young's modulus. Additionally, CPO was found to intensify the hydrogel cross-linking and thus increase the toughness and compressive modulus of the system. Insulin secreting INS-1E reporter cells were successfully encapsulated in the hydrogel system to investigate their viability and functionality. The in vitro encapsulation study indicated that CPO improved cell survival; however, the insulin secretion was found to be impaired upon incorporation of CPO in the system.

Conclusion

In summary, this work suggests that the CPO-laden tHA hydrogels have promising physiochemical properties, which may be useful in beta-cell therapy.

Introduction

Injectable composite hydrogels are becoming increasingly popular in the field of biomedicine, replacing the traditional clinical practice. In this way, a minimally invasive procedure can be performed, deeply hidden anatomical sites can be accurately implanted, and irregularly shaped bone defects can be repaired. These benefits result in reduced patient’s recovery time and risk of infection, while at the same time the procedure leaves smaller scars. Injectable hydrogels must uphold a number of requirements in order to be used for biomedical purposes and some of the pivotal ones are biocompatibility, biodegradability, stability, mechanical properties, porosity, viscosity etc. Hyaluronic acid (HA) is a natural, linear, and at physiological pH, negatively charged polysaccharide which is the major component of the extracellular matrix (ECM). HA is widely used because of its physico-chemical and biological properties such as biodegradability, biocompatibility, hygroscopicity, viscoelasticity, and mucoadhesivity. ε-Poly-L-lysine (ε-PL) is a water soluble, non-toxic, biodegradable polypeptide which provides an antibacterial effect. By adding an inorganic phase such as hydroxyapatite (HAp), which is osteoconductive, biodegradable, biocompatible and similar to the inorganic phase of human bone, it is possible to improve the mechanical properties and bioactivity of hydrogels for bone tissue regeneration. The main objective of the current research was to prepare injectable hyaluronic acid-based HAp/ε-Poly-L-lysine hydrogels and characterize them towards the gel fraction, injectability and rheological properties.

Experimental Methods

HA/ε-PL and HA/ε-PL/HAp (inorganic phase content 60wt%) hydrogels were physically crosslinked and characterized. To determine the insoluble part of the hydrogel, the lyophilized samples were immersed in 200 mL of deionized water for 48 h at room temperature. The rheological measurements were observed using Anton Paar SmartPave 102 rheometer equipped with a parallel plate geometry of 25 mm and the measuring gap of 1 mm. Time-dependent storage and loss modulus (G’ and G’’) were measured subjecting the hydrogels to 1% strain with constant frequency of 1 Hz. The force applied to the syringe plunger to inject the hydrogels was measured using Tinius Olsen 25ST material testing machine with a load cell of 2.5 kN with cross head speed 1 mm/sec.

Results and Discussion

Results indicated that with an addition of inorganic phase, statistically significant increase in gel fraction results was observed (65.36% ± 1.3% in case of HA/ε-PL and 84.11% ± 0.6% in the case of HA/ε-PL/HAp). Rheology measurements showed that the storage modulus (G’) was always greater than the loss modulus (G’’) over the entire time interval for both samples. This implies that the gel was formed immediately after the liquid phase was added to the solid phase. The addition of the inorganic phase increased the G’ value of the material, resulting in stiffer composite. Also, it was found that the maximum injection force value of HA/ε-PL hydrogel was 90.37±13.9, while for HA/ε-PL/HAp hydrogel it reached 64.62±15.5, indicating no statistically significant effect of inorganic phase addition on the force values.

Conclusion

During the research it was established that through the addition of inorganic phase to HA/ε-PL hydrogels, the gel fraction and storage modulus could be increased. Moreover, the injection force values were not statistically affected by the addition of inorganic phase to HA/ε-PL hydrogels.

Formation of a versatile hydrogel based on chemoselectively modified Elastin-like polypeptides (ELPs) for tissue engineering applications

Nadia Mahmoudi1,2, Bruno Paiva dos Santos1, Hugo De Oliveira1, Elisabeth Garanger2, Sébastien Lecommandoux2, Joëlle Amédée1, Bertrand Garbay2

1 Tissue Bioengineering Laboratory (BioTis), Inserm U1026, University of Bordeaux, Bordeaux, FR; 2 Univ. Bordeaux, CNRS, Bordeaux INP, LCPO, UMR 5629, Pessac, FR

Introduction
Extracellular matrix-like hydrogels are increasingly used as scaffolds for tissue engineering. Elastin-like polypeptides (ELPs) are a class of recombinant polymers of interest for hydrogel manufacture, because they are monodisperse, cross-linkable, biocompatible, biodegradable and non-immunogenic. ELPs are repeated sequences of (VPGXG) pentapeptides that are derived from the hydrophobic domain of tropoelastin. The guest residue X can be any amino acid residue but proline. ELPs are thermosensitive polymers in aqueous buffers, being soluble at a temperature below a transition temperature (Tt), and aggregating above this Tt. Our objective is to develop a bioactive ELP-based hydrogel for tissue engineering applications.

Experimental Methods
The recombinant ELP used in this study, noted ELP[M\(^{1V_{3-80}}\)], has the following sequence: MW[(VPGVG)(VPGMG)(VPGVG)]\(^{20}\). It contains a total of 21 methionine residues that were chemoselectively modified by a thioalkylation reaction to introduce an alkene function [1] for subsequent cross-linking (ELP[M(alkene)\(^{1V_{3-80}}\)]. A consequence of this reaction is the apparition of positively charged sulfonium groups. To eliminate these charges, a demethylation reaction [2] was applied leading to the derivative noted (ELP[M(dem-alkene)\(^{1V_{3-80}}\]). These three ELP derivatives were characterized by mass spectrometry, nuclear magnetic resonance, and size exclusion chromatography. Their Tts were measured by spectrophotometry at different concentrations. While the starting ELP[M\(^{1V_{3-80}}\] presented a Tt of 27.3°C at 100mM, ELP[M(alkene)\(^{1V_{3-80}}\)] did not present any thermal responsiveness due to the polar sulfonium groups. Demethylation of this derivative led to the restoration of the thermosensitivity of ELP[M(dem-alkene)\(^{1V_{3-80}}\] (Tt = 26.1°C at 100 mM). Cross-linking of ELP chains was achieved using a peptide with no specific biological activity but presenting two cysteine residues flanked at the C- and N-terminal ends allowing a thiol-ene reaction under UV irradiation in the presence of Irgacure D-2959 [3] [4]. To find the optimal conditions for hydrogel fabrication, we varied the ELP and peptide concentrations, the thiol/alkene ratio, and the UV irradiation duration. The resulting hydrogels were characterized by rheology using a temperature ramp between 10°C and 50°C.

Results and Discussion
Gels based on ELP[M(alkene)\(^{1V_{3-80}}\)] presented a constant storage modulus (G') of 0.8 kPa over all the temperature range. In contrast, the G' value measured for the gels obtained from ELP[M(dem-alkene)\(^{1V_{3-80}}\)] increased from 1.2 kPa to 1.8 kPa, illustrating gel thermoresponsiveness. Then, these hydrogels were freeze dried, and analyzed by scanning electron microscopy to visualize pore formation. Finally, preliminary experiments were performed with human cell lines to evaluate the toxicity of these ELP-based hydrogels.

Conclusion
In conclusion, we produced and characterized three different ELP derivatives with different properties. The alkene-containing versions served as hydrogel backbone for biocompatible hydrogels in vitro. This is a general strategy that allows the utilization of different biomimetic peptides that can increase the biologic functionality of the hydrogels.

Natural biopolymer-based antibacterial hydrogels for tissue engineering

**Artemijs Sceglovs**1,3, Aigars Reinis2, Kristine Salma-Ancane1,3

1 Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; 2 Riga Stradins University, Faculty of Medicine, Department of Biology and Microbiology, Riga, LV; 3 Headquarters at Riga Technical University, Baltic Biomaterials Centre of Excellence, Riga, LV

**Introduction**

In recent years, development of novel biomaterials that meet certain requirements and provide multifunctional properties has become actual researcher interest in different fields of biomedicine. Furthermore, health care sector has been facing with the bacterial infections during post-surgery period and antibiotic resistance, and therefore design and development of such biomaterial class as hydrogels for tissue engineering with an antibacterial function are a main focus in biomedical research. The aim of this study is to develop and investigate novel antibacterial hydrogels based on natural biopolymers: antibacterial ε-polylysine (ε-PL) and intrinsic biocompatible hyaluronic acid (HA).

**Experimental Methods**

During experimental part parallel samples of hydrogel series based on ε-PL and HA (mass ratios of ε-PL and HA are 40:60, 50:50; 60:40; 70:30 and 80:20 wt%) were *in situ* synthesized via chemical cross-linking using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and N-hydroxysuccinimide (NHS) crosslinking agents (with molar ratio of EDC:NHS = 1:1) [1]. Molecular structure and morphology of all synthesized hydrogels were evaluated using Fourier transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM). In addition, gel fraction and swelling properties tests were obtained to get broad overview of physico-chemical properties. *In vitro* evaluation of antibacterial properties of samples was obtained by using modified ASTM E2149-10 standard test techniques against Gram+ (*S.aureus*) and Gram- (*E.coli*) bacterial cultures. All data were statistically processed using IBM SPSS software.

**Results and Discussion**

FTIR spectra indicated interaction between ε-PL and HA and successful formation of cross-linked copolymer via amide bond linkage. SEM micrographs of the lyophilized hydrogels revealed homogeneous and microporous structure. Cross-linking degree and swelling behavior tests showed the existence of newly formed matrix and insoluble part in synthesized samples. *In vitro* evaluation against *E.coli* and *S.aureus* revealed positive antibacterial tendency of the prepared hydrogels with the increase of mass ratio of ε-PL in presented series.

**Conclusion**

In the described study, the novel hydrogels based on chemically cross-linked ε-polylysine and hyaluronic acid copolymer system were synthesized and investigated. The evaluation of antibacterial behavior indicated inhibition ability against Gram+ and Gram-bacterial cultures. It is concluded that the developed hydrogels can be considered as promising antibacterial biomaterials for tissue engineering.

Engineering of Stable Thermoresponsive Multilayers Based on Cross-linked PNIPAM-\textit{grafted}-Chitosan and Heparin for Cell Sheet Generation

Yi-Tung Lu\textsuperscript{1}, Kui Zeng\textsuperscript{2}, Kai Zhang\textsuperscript{2}, Bodo Fuhrmann\textsuperscript{3}, Thomas Groth\textsuperscript{1}

\textsuperscript{1} Martin Luther University Halle-Wittenberg, Department of Biomedical Materials, Halle(Saale), DE; \textsuperscript{2} Georg-August-University of Goettingen, Department of Wood Technology and Wood-based Composites, Göttingen, DE; \textsuperscript{3} Martin Luther University Halle-Wittenberg, Interdisciplinary Center of Material Research and Interdisciplinary Center of Applied Research, Halle(Saale), DE

Introduction
Poly(N-isopropylacrylamide) (PNIPAM) exhibiting a lower critical solution temperature (LCST) around 32 °C can enable detachment of complete cell sheets from cell culture substrata for engineering of tissues like skin, cornea, etc. by reducing the temperature below LCST. This study focusses on the development of a thermoresponsive polyelectrolyte multilayer (PNIPAM-PEM) using layer-by-layer (LbL) technique. It can help us to understand the physical and biological properties of the sophisticated PEM systems containing PNIPAM.

Experimental Methods
PNIPAM with different sizes are covalently grafted onto chitosan (Chi) to obtain different degrees of substitution (DS) of PNIPAM-grafted-chitosan (PChi). Nuclear magnetic resonance spectroscopy and dynamic light scattering are used to analyze DS and conformational change of PChi with temperature, respectively. The PNIPAM-PEMs are built at pH4 with PChi as polycation and bioactive heparin (Hep) as polyanion. Subsequently, the systems are chemically cross-linked to stabilize the PEM. The growth behavior, thickness, and wetting properties and temperature effects of the PNIPAM-PEMs with either PChi- or Hep-terminal layer are investigated by different analytical methods. In addition, the stability of the PEMs is tested by rinsing with PBS, pH 7.4 and DMEM. Furthermore, the association of adhesive protein vitronectin with PNIPAM-PEMs at 20 and 37 °C is studied for their biological function. The application of PNIPAM-PEMs as cell culture substrate is finally examined using multipotent mouse stem cells.

Results and Discussion
PChi with higher DS and sizes show significant increase in the diameter above LCST. They have the ability to form PNIPAM-PEM with heparin. After rinsing with buffer and culture medium, the thickness significantly decreases in non-cross-linked compared to negligible changes in cross-linked PEM. As the temperature changes, the PNIPAM-PEM is slightly more hydrophobic at 37 °C than at 20 °C. This might also take account of higher adsorption of vitronectin on PNIPAM-PEM at 37 °C. Finally, higher adhesion and more spreading of cells on cross-linked PEM particularly with Hep-terminal layer are observed owing to the superior bioactivity of heparin.

Conclusion
In conclusion, the amide bonds make an irreversible bond formation between PChi and Hep to enhance stability of PEM. In addition, the PNIPAM immobilized on the surface affects the wetting properties of the surfaces. Therefore, the PNIPAM-PEMs with cross-linking provides greater stability and biological function as a cell culture system for further investigation of cell sheet generation in tissue engineering.

Anionic hydrogel contact lenses with affinity for atropine

Inés García Del Valle, Maria Vivero-Lopez, Angel Concheiro, Carmen Alvarez-Lorenzo

Universidade de Santiago de Compostela, Departamento de Farmacología, Farmacia y Tecnología Farmacéutica I+D Farma (GI-1645), Santiago de Compostela, ES

Introduction
Topical ocular delivery of atropine is attracting growing attention. Despite atropine is used since ancient times for mydriatic and cycloplegic purposes, a better knowledge of the very wide mechanisms in which atropine may participate in the ocular tissues is notably expanding its therapeutic profile [1]. Treatment of accommodative spams and chronic ulcers, counteraction of chemical weapons, and prevention of myopia can strongly benefit of ocular controlled release of atropine. Since atropine is prevalently cationically charged (pKa 9.43) at physiological pH, the aim of this work was to elucidate the feasibility of developing anionic hydrogels suitable as contact lenses (CLs) with enhanced affinity for atropine.

Experimental Methods
2-Hydroxyethyl methacrylate (HEMA) was used as main structural monomer, and methacrylic acid (MAA) and 2-acrylamido-2-methylpropane sulfonic acid (AMPSA) were added in various proportions. After polymerization, the hydrogels were evaluated regarding swelling degree, light transmittance, mechanical properties, and ocular irritancy. The loading of all formulations was carried out by soaking in atropine (1 mg/mL in water or NaCl 0.9%) solution at 25 °C and 180 rpm. Release experiments were carried out in NaCl 0.9% for all formulations at 36 °C and 180 rpm. The amount of atropine loaded and released was monitored by HPLC considering a validated calibration curve of atropine in water.

Results and Discussion
All HEMA-based hydrogels showed physical properties adequate for CLs. The light transmittance values were above the 90% required for CLs materials and the swelling degree was in good agreement with other CLs hydrogels. When soaked in atropine aqueous solution, HEMA hydrogels loaded 1.16 (s.d. 0.05) mg/g and released the drug in one hour. Copolymerization with MAA enhanced the amount of atropine loaded up to 19.5 (s.d. 1.0) mg/g and the release was completed in one hour. Copolymerization with AMPSA notably promoted the affinity of the network for atropine, and the hydrogels loaded 43.4 (s.d. 1.2) mg/g and the release was extended for two hours. The loading was clearly driven by ionic interactions since the soaking in atropine solutions prepared in NaCl 0.9% led to remarkably lower uptake. The hen's egg-chorioallantoic membrane test (HET-CAM) indicated that atropine-loaded hydrogels can be considered as non-irritant since no lysis, hemorrhage or coagulation was observed.

Conclusion
Anionic comonomers are revealed as adequate to endow HEMA hydrogels with affinity for atropine. The proportion of anionic charges can be tuned to regulate the total amount loaded, while the nature of the anionic moieties may allow controlling drug release.

PVA-based hydrogels loaded with diclofenac for cartilage replacement

Andreia Oliveira, Inês Monteiro, Pedro Nolasco, Ana C. Branco, Rogério Colaço, Célio G. Figueiredo-Pina, Ana P. Serro

Introduction
The articular cartilage may suffer deterioration mainly due to trauma, osteoarthritis and rheumatoid arthritis, leading to pain and motion difficulties. When the lesion is on an end-stage, the most common treatment relies on an invasive surgical approach (total joint arthroplasty), which is defined by the total removal of the cartilage tissue and replacement by a simple mechanical device produced with materials such as titanium, cobalt chromium alloys, alumina and ultra-high molecular weight polyethylene. However, in previous stages, a less invasive approach can be attempted, involving the replacement of the cartilage damaged areas by natural (autograft) or synthetic materials with properties comparable to articular cartilage. Hydrogels present a huge potential to be used for this application, since they have a biphasic structure and can be tailored to present mechanical properties similar to articular cartilage. In particular, polyvinyl alcohol (PVA) hydrogels, have raised special interest due to their biocompatibility, low friction coefficients and good swelling ability [1]. The later allows the incorporation of drugs and other molecules with therapeutic action, that can be locally released after implantation surgery. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used to reduce pain and other inflammatory signs. This work aims to develop PVA-based hydrogels with improved mechanical and tribological properties and ability to ensure a controlled release of diclofenac, an anti-inflammatory generally used in orthopedics.

Experimental Methods
Different PVA based hydrogels were produced by the freeze-thawing method: PVA (from a solution 13.5% w/w of PVA), PVA/PAA (where PVA is mixed to PAA (polyacrylic acid) in a proportion 10:3 (w/w)), PVA/PAA+PEG (where the previous hydrogel is immersed in 100% PEG (polyethylene glycol) for 1 h and then dried at 60 °C for about 5 days) and PVA/PAA+PEG+A (where the previous hydrogel is submitted to an annealing treatment at 120ºC for 1h). The hydrogels were characterized in terms of swelling behavior, mechanical properties (compression and tensile tests), wettability (captive bubble method) morphology (scanning electron microscopy) and friction coefficient (pin-on-plate tests). The best performing hydrogel was loaded by soaking with diclofenac (0.2% w/v in PBS, 3 days, at 37ºC) and its release ability was studied, as well as its irritability for tissues (HET-CAM test).

Results and Discussion
The results showed that the addition of PAA increased the swelling capacity of the material in about 43%. Contrarily, PEG-doped and annealed hydrogels presented lower and comparable values of swelling, with a reduction of about 52% in relation to the PVA values. Regarding wettability, all hydrogels are hydrophilic (~45º). Materials with PAA showed a reduction of ~50% in the tensile elastic modulus and ultimate tensile strength relatively to PVA, while the immersion in PEG and the annealing treatment led to higher elastic modulus (0.7–1.2 MPa), elongation-to-break (298–335%), tensile strength (3.0–3.6 MPa), and toughness (5.4–6.3 MJ/m²). For the compressive tests, it was found that PVA/PAA presented the smallest elastic modulus (~0.2 MPa), being the material that suffers the highest deformation under loading. PVA/PAA+PEG and PVA/PAA+PEG+A did not show significant differences relatively to PVA. All the materials demonstrated a viscoelastic behavior at compression, recovering their original dimensions when unloaded. Through SEM analysis, it was observed that both PVA and PVA/PAA have similar porosity, but the
latter material presents slightly larger pores. The addition of PEG into the PVA/PAA hydrogel and the annealing treatment led to considerably less porosity. PVA/PAA materials presented the highest friction coefficient value (0.13), while PVA/PAA+PEG+A led to the lowest value (0.06). Given the superior mechanical and tribological behavior of the last hydrogel, it was selected for the drug release studies. The results showed a significant improvement in the diclofenac release profile relatively to PVA (Figure 1). In fact, while PVA released a small amount of the anti-inflammatory in a few hours, PVA/PAA+PEG+A was able to release a much higher quantity of drug in a sustained way during at least 3 days. The irritability tests demonstrated that this hydrogel does not induce lysis, hemorrhage or coagulation.

**Conclusion**

In conclusion, the addition of PAA to PVA, followed by immersion in PEG and an annealing treatment led to a significant improvement of the mechanical properties of PVA and induced lower friction coefficients. Furthermore, such hydrogel revealed a high potential to be used as a drug delivery platform at local level of the anti-inflammatory diclofenac, leading to a controlled release for more than 3 days, without presenting any irritant behavior for the biological tissues.

Introduction

Poly(ethylene glycol) (PEG) hydrogels are one of the most anti-adhesive explored to date, and have been widely used as a “blank slate” with tunable physicochemical and biological properties. However, they are mechanically weak, which prevents their use in load-bearing biomedical applications (e.g. intervertebral disc, vascular grafts). Graphene is a promising candidate to solve this challenge. It is a single-layer of sp2-bonded carbon atoms, with outstanding stability, mechanical and electrical properties. There are several graphene-based materials (GBM), varying in lateral size (diagonal size of planar sheet), thickness (number of layers) and oxidation degree (number of oxygen-containing groups). Oxidized forms, in particular, are proven to be cytocompatible [1]. Only a handful of papers report the incorporation of GBM in PEG-based hydrogels [2,3]. However, most of these works focus on the characterization of compressive or rheological properties [4], and little is shown about the tensile properties of PEG hydrogels – which is essential for their application in tissues/devices subjected to tensile stress (e.g. vascular grafts) [5]. Hence, we propose the use of GBM as nanofillers to mechanically reinforce PEG hydrogels and obtain composites that are stiffer, stronger, but as anti-adhesive as neat PEG hydrogels.

Experimental Methods

PEG dimethacrylate (molecular weight 8000 g/mol) hydrogels (15 wt%) with different GBM types – graphene oxide (GO), few-layer graphene (FLG), FLG oxide (FLGO) – and with a range of concentrations – 0.1-4 wt% GO, 1 wt% FLG, 0.1-1 wt% FLGO – were produced by chemical crosslinking (using redox initiators). The mechanical properties were evaluated by tensile tests until rupture using a texture analyzer, obtaining the Young’s modulus (YM; indicating stiffness), ultimate tensile strength (UTS; indicating strength) and elongation at break (EB; indicating ductility). GO and FLGO composites were characterized regarding GBM dispersion in the matrix (brightfield microscopy), surface roughness (SEM imaging), wettability (water contact angle) and swelling degree (water uptake). The cytotoxicity of 24h extracts and anti-adhesiveness of composite hydrogels was evaluated using human umbilical vein endothelial cells (HUVEC) according to ISO 10993-5 and 10993-12, assessing cell metabolic activity (resazurin assay) and morphology (phalloidin/DAPI staining and fluorescence microscopy).

Results and Discussion

We started by evaluating the effect of various GBM parameters, particularly oxidation degree, thickness and concentration, in the tensile reinforcement of PEG hydrogels. Considering oxidation degree, the incorporation of oxidized forms (1% FLGO) reinforced PEG hydrogels, unlike reduced forms (1% FLG). Regarding thickness and the effect of concentration, both single-layer (GO) and few-layer (FLGO) forms were able to reinforce hydrogels. The incorporation of 4% GO resulted in stiffer and stronger composites, with 162 kPa YM and 174 kPa UTS (9x and 18x increase, respectively, from neat PEG hydrogels). 1% FLGO composites presented a 174 kPa YM and 177 kPa UTS (9.7x and 13x increase, respectively, from neat PEG hydrogels), but had a lower EB than GO composites. Both GO
and FLGO were homogeneously dispersed in the hydrogel matrix, despite some aggregates. Although SEM images showed increasing surface roughness for higher GBM concentrations (particularly GO), they caused no alterations to the hydrophilicity of PEG hydrogels (water contact angles <20°). Neat PEG hydrogels have a great swelling degree (149% vs. samples after gelation and 1898% vs. dried samples). The swelling degree of composites tended to decrease for higher GBM concentrations, but remained >50% vs. samples after gelation and >787% vs. dried samples.

The extracts obtained from GO and FLGO composites caused no cytotoxicity on HUVEC, presenting cell viability ~100%, and phalloidin staining revealed a normal morphology (vs. control medium). Also, upon direct contact with composites, HUVEC did not adhere, as confirmed by resazurin assay and fluorescence microscopy. These results show that PEG/GBM composites maintained the high anti-adhesiveness and cytocompatibility of neat PEG hydrogels.

Conclusion

Overall, these results show that oxidized forms of graphene can be used as nanofillers to reinforce PEG hydrogels. GO and FLGO composite hydrogels have great tensile properties, are hydrophilic, cytocompatible and anti-adhesive towards HUVEC. To the best of our knowledge, this is the first work to report an increase up to 1887% of the tensile properties of PEG hydrogels using GBM, while still maintaining appreciable ductility. This work paves the way for the exploitation of PEG hydrogels for load-bearing applications, such as vascular grafts or catheters.

Development of a new magnetically responsive device for localized cancer theranostics

Paula I.P. Soares, Adriana Gonçalves, Beatriz Correia, João Magalhães, Jorge C. Silva, João P. Borges

NOVA School of Science and Technology, FCT-NOVA, CENIMAT/i3N, Materials Science Department, Caparica, PT

Introduction
Cancer is a major worldwide problem, with an estimated 19.3 million new cases and 10 million cancer deaths in 2020. Cancer diagnostic and treatment have significantly improved in recent years, which increased life expectancy. Nevertheless, current treatment limitations and the elevated incidence, mortality, and cancer disease heterogeneity lead to growing concern and expectation over the development of new and improved cancer diagnostic and/or treatment.[1] Consequently, an unmet medical need in cancer treatment is: How to effectively deliver drugs to the tumor site and improve their efficacy while reducing side effects?

In this context, cancer theranostics emerged as a promising tool to decrease treatment delays, improve patient care, and act as a personalized cancer approach. In recent years, magnetic nanoparticles (mNPs) demonstrate a considerable potential to substantially improve theranostics platforms for cancer. Their unique properties, particularly the ability to respond to an external magnetic field, enable their use as imaging probes in the diagnostic feature and as magnetic hyperthermia agents in the treatment feature. Additionally, magnetic responsiveness can be used as a trigger for controlled drug release.[1, 2] Magneto-responsive devices can provide a real-time response upon application of an external magnetic field. An external magnetic field as the trigger is optimal since it has good tissue penetration without almost any physical interaction with the body.[3, 4]

The main goal of this work is to develop a novel magnetically responsive device for cancer theranostics application. This device is composed of mNPs incorporated into polymeric nanofibers produced by additive manufacturing techniques (electrospinning and paste extrusion). Following device implantation in a solid tumor, an external alternating magnetic field remotely activates the magnetic component (mNPs), which generates heat due to their superparamagnetic properties. mNPs concentration will be tailored to obtain localized heat in the tumoral tissue. The application of an external alternating magnetic field induces heat generation by mNPs to sensitize tumor cells and allow treatment monitoring through MRI.

Experimental Methods

Magnetic nanoparticles were prepared by chemical precipitation technique and stabilized as previously described.[5] mNPs were incorporated into a polymeric matrix using electrospinning technique. Electrospinning of selected polymers (PLA, PCL, PVA) was tested in different conditions to achieve monodisperse micro/nanofibers without defects. Optimization comprised study of solution properties, processing conditions, and environmental conditions. Magnetic properties of plain mNPs and magnetic fibers were evaluated by VSM. Characterization included scanning electron microscopy (SEM), mechanical properties (tensile tests), swelling behavior, and surface properties evaluated through static and dynamic contact angle measurements.

Results and Discussion

Superparamagnetic iron oxide mNPs with 10 nm in diameter were successfully prepared. According to the amount of oleic acid added during stabilization step, these mNPs can be easily dispersed in either hydrophobic or hydrophylc solvents, enabling their incorporating directly in polymeric solutions prior to electrospinning. Polymeric solutions containing mNPs were electrospun with the optimized conditions to produce monodisperse nanofibers without defects. PLA fibers were produced with two different morphologies: porous and non-porous fibers. Porous fibers...
displayed larger diameters (around 500 nm) than non-porous fibers (around 200 nm). PVA and PCL fibers also displayed smaller diameters (around 200 nm) (Figure 1). SEM and TEM analysis demonstrated the presence of mNPs dispersed throughout the fibers. Mechanical properties and swelling behavior of the magnetic membranes were highly dependent on fiber composition (i.e., polymer); however crosslinking degree and the presence of mNPs improved membranes' rigidity while decreasing the membrane overall swelling ability. Magnetic hyperthermia measurements were performed during 10 min of an AC magnetic field application with magnetic flux density of 300G and 418.5 kHz of frequency. The results demonstrated that the heating ability of magnetic membranes is largely dependent on mNPs concentration, although it is also influenced by membrane composition (type of polymer). Cytotoxicity assessment demonstrated that despite the concentration of mNPs incorporated, the magnetic membranes are not cytotoxic and suitable for biomedical applications.

**Conclusion**

More interesting results are being achieved under the recently financed project DREaMM (Ref. PTDC/CTM-REF/30623/2017) to engineer dual-stimuli responsive magnetic nanofibrous membranes as controlled drug release systems and magnetic hyperthermia agents for cancer treatment using additive manufacturing techniques.

Visible Light-driven Polyurethane Actuators for Bionic Hands

Lei Wu, Meng Wang

University College London, Division of Surgery and Interventional Science, London, GB

Introduction
Light-driven soft robotics made from photo-responsive materials are able to mimic the biological functions, such as swimming, walking, crawling, which have attracted intense scientific attentions recently. However, many efforts should still be taken in the field of developing photo-responsive materials with good mechanical and biological performance and simple synthetic process for constructing potential light-driven soft robotics in biomedical applications.

Experimental Methods
Synthesis of the photo-responsive polymer.
Design and fabrication of the light-driven soft actuators.
Characterization of chemical, thermal and mechanical properties of the photo-responsive polymer.
Characterization of the performances of the light-driven soft actuators.

Results and Discussion
Herein, we developed a new visible light-responsive elastomer (i.e. PAzo) by introducing photo-responsive molecule (i.e. azobenzene derivatives) into the main chain of the biocompatible polyurethane (i.e. PCL-PUU). Casting PAzo onto the commercial Kapton sheet, a visible light-driven bilayer actuator was fabricated and systematically characterised. Specially, two bending modes of the actuator were observed under the illumination with different light intensities. The correlated actuation mechanisms with photothermal and photochemical coupling effects were thoroughly studied by experiments, theoretical calculations and FEA simulations. Furthermore, based on this actuator, an application of visible light controlled soft robotic fingers for playing piano was demonstrated.

Conclusion
The present work may guide the design and manufacture of light-driven wearable robots or assistive devices for medical rehabilitation and assistance.

Introduction

Polymer hydrogels can be instrumental to generate defined sets of exogenous signals that direct the fate and functionality of embedded cells. Biohybrid polymer networks containing sulfated glycosaminoglycans have been shown to offer particularly valuable options and are therefore increasingly used in the preparation of materials to enable regenerative therapies in vivo and in advanced human tissue and disease models in vitro.[1] Scalable, standardized production of such cell-instructive biohybrid hydrogels at low compositional variation, high batch-to-batch reproducibility, and material compliance can benefit from the adaptation of commercial synthesis and liquid handling robots. Using an exemplary, well-established peptide-functionalized multi-armed poly(ethylene glycol) (starPEG)-heparin hydrogel system[2], we herein report on an approach to set up a dedicated workflow for the fabrication of reactive hydrogel precursors and cell-laden hydrogels.

Experimental Methods

Hydrogel precursor synthesis was carried out using a customized BioSyntheSizer3.1 platform (GeSiM, Germany) for pipetting, pH adjustment, temperature control and vacuum/inert gas applying, to implement a synthesis procedure from our previously reported manual method.[1] (N-hydroxysulfosuccinimide) (sulfo-NHS) and 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) were added to a heparin solution cooled to 4 °C one after the other (Fig. 1). Carboxylic acid groups were activated for 20 min, followed by addition of N-(2-aminoethyl) maleimide trifluoroacetate and 1 h reaction time at 20 °C. The prepared solutions were pipetted automatically and temperature-controlled by the synthesis robot through a coolable vial rack. The sequence protocol accurately maintains activation and reaction time. Two equal precursor solutions prepared in parallel were then combined by injection into the dynamic dialysis device. The dialysis medium was sodium chloride solution and Milli-Q water. The purified precursor solution was aliquoted automatized and freeze-dried afterwards. The final product was analyzed by nuclear magnetic resonance of protons (1H-NMR).

The obtained reactive heparin-maleimide precursor and matrix metalloproteinase (MMP)-cleavable peptide-end-functionalized starPEG were crosslinked in aqueous solution using a commercial liquid handling robot (TECAN Fluent, Switzerland) to form a hydrogel network, optionally containing cells to be cultured within these matrices. The hydrogels were imaged using the microscope Opera Phenix (Perkin Elmer, USA) and the analysis software Imaris (Andor Technology, United Kingdom).

Results and Discussion

An automated multistage workflow was developed to synthesize hydrogel precursors, form hydrogels formation, and perform cell culture experiments with cells embedded in the gel matrices. The protocol combines two robotic fluid handling systems and a microscope for automated sample imaging and cell analysis. The customized heparin maleimidation, including purification, was implemented by the BioSyntheSizer3.1. Controlled cooling was achieved by a thermostat (instead of an ice-bath as used in manual synthesis). The sequence protocol enables compliance of activation and reaction time with constant mixing conditions. Optimized purification of the precursor by dynamic dialysis provided a purity and yield comparable to previously established manual protocols. Subsequent liquid aliquotation and automated sterile freeze-drying facilitated further processing. As a proof of principle, the synthesized precursor was applied to a recently developed high throughput combinatorial pipetting scheme in a 384-well plate,
including formation of the cell-hydrogel-dispersion, medium addition and exchange. Cell viability and tube formation of human umbilical vein cells (HUVECs) were analyzed and quantified automatically. The results confirm comparable network performance in this cell culture experiment.

**Conclusion**

Our newly developed automated hydrogel precursor synthesis method can ensure the quality and scalable production of GMP-compliant biohybrid hydrogel materials. Automated hydrogel preparation, cell culture and analysis can further empower combinatorial approaches to biomedical applications of cell-instructive materials.

Introduction
Articular cartilage injuries have a limited potential to heal and, over time, may lead to osteoarthritis, an inflammatory and degenerative joint disease associated with activity-related pain, swelling, and impaired mobility [1]. Regeneration and restoration of the joint tissue functionality remain unmet challenges. Stem cell-based tissue engineering is a promising paradigm to treat cartilage degeneration [1]. In this context, hydrogels have emerged as promising biomaterials, due to their biocompatibility, ability to mimic the tissue extracellular matrix and excellent permeability [2]. Different stimulation strategies have been investigated to guarantee proper conditions for mesenchymal stem cell differentiation into chondrocytes, including growth factors, cell-cell interactions, and biomaterials [3]. An interesting tool to facilitate chondrogenesis is external ultrasound stimulation. In particular, low-intensity pulsed ultrasound (LIPUS) has been demonstrated to have a role in regulating the differentiation of adipose mesenchymal stromal cells (ASCs) [4]. However, chondrogenic differentiation of ASCs has been never associated to a precisely measured ultrasound dose. In this study, we aimed to investigate whether dose-controlled LIPUS is able to influence chondrogenic differentiation of ASCs embedded in a 3D hydrogel.

Experimental Methods
Human adipose mesenchymal stromal cells at 2*10⁶ cells/mL were embedded in a hydrogel ratio 1:2 (VitroGel RGD®) and exposed to LIPUS stimulation (frequency: 1 MHz, intensity: 250 mW/cm², duty cycle: 20%, pulse repetition frequency: 1 kHz, stimulation time: 5 min) in order to assess its influence on cell differentiation. Hydrogel-loaded ASCs were cultured and differentiated for 2, 7, 10 and 28 days. At each time point cell viability (Live & Dead), metabolic activity (Alamar Blue), cytotoxicity (LDH), gene expression (COL2, aggrecan, SOX9, and COL1), histology and immunohistochemistry (COL2, aggrecan, SOX9, and COL1) were evaluated respect to a non-stimulated control.

Results and Discussion
Histological analysis evidenced a uniform distribution of ASCs both at the periphery and at the center of the hydrogel. Live & Dead test evidenced that the encapsulated ASCs were viable, with no signs of cytotoxicity. We found that LIPUS induced chondrogenesis of ASCs embedded in the hydrogel, as demonstrated by increased expression of COL2, aggrecan and SOX9 genes and proteins, and decreased expression of COL1 respect to the non-stimulated control.

Conclusion
These results suggest that the LIPUS treatment could be a valuable tool in cartilage tissue engineering, to push the differentiation of ASCs encapsulated in a 3D hydrogel.

Introduction
Intervertebral disc (IVD) herniation involves annulus fibrosus (AF) failure, and is a process still under investigation. Most of the ongoing research relies on rodent in vivo models or on bovine in vitro organ cultures that do not mimic the human IVD herniation. A bioengineered in vitro model that could recapitulate human AF at distinct stages of herniation progression would be of paramount importance to better understand AF failure. Replicating tissue-oriented organization in vitro has been widely studied in the recent years, with both natural and synthetic materials in combination with magnetic fields to establish anisotropic conditions \cite{1-3}. More specifically, magneto-responsive polyethylene glycol (PEG) microgels have demonstrated to form a unidirectional hydrogel, called Anisogel, which aligned cell growth \cite{2}. In this study, we aim to develop an AF 3D model based on collagen type I hydrogel with oriented PEG microgels, with the final goal to align collagen fibers and direct cell growth to improve our knowledge on IVD herniation.

Experimental Methods
Collagen hydrogels precursor solutions (3.2 mg/ml) are prepared and gelation is induced after pH adjustment with NaOH at 37°C for 45 min. PEG microgels are produced in rod-shape, following a previously established protocol using a mold-based soft lithography \cite{2}. Two microgel size conditions are evaluated (2,5x2,5x25 and 2,5x2,5x50 μm\textsuperscript{3}) at a volume concentration of 0.45% and 0.6%, respectively, inside the entire collagen gel. An external magnetic field of 70 mT is applied to allow for microgels orientation within the collagen hydrogel precursor solution. Microgel orientation and collagen fiber formation are evaluated by two-photon microscopy and histologic analysis using Sirius Red staining under polarized light. The hybrid hydrogel mechanical properties are evaluated by rheological studies.

Results and Discussion
To establish the best conditions for microgel alignment inside a collagen precursor solution, the protocol has been optimized: an initial incubation at 4°C for 10 min, prior to the incubation at 37°C for collagen polymerization, all in the presence of a magnetic field. The two-photon microscopy confirmed microgel orientation in these conditions for both microgel sizes. Polarized light evaluation of Sirius Red stained samples showed that the two tested microgels conditions did not impair fiber formation in collagen hydrogels. On going analysis of these samples is being performed to evaluate collagen fiber orientation. Rheological analysis showed similar storage modulus for collagen control hydrogels and oriented collagen hydrogels with 2,5 x 2,5 x 50 μm\textsuperscript{3}. Further studies are currently being conducted for 2,5 x 2,5 x 25 μm\textsuperscript{3} microgels.

Conclusion
The experimental results so far indicate promising conditions to establish a 3D unidirectional collagen hydrogel that could be further used to modelling AF structure. Further studies are being conducted to understand if the anisotropy
given by the PEG microgels is accompanied by collagen fiber alignment and how AF cells response to this physical guidance.

Design of Polypeptide-Polysaccharide based Hydrogels for Bone Tissue Regeneration

Inta Kreicberga¹,², Jevgenija Luginina³, Kristine Salma-Ancone¹,²

¹ Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; ² Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV; ³ Riga Technical University, Institute of Technology of Organic Chemistry, Faculty of Materials Science and Applied Chemistry, Riga, LV

Introduction
In recent years development of bioinspired natural biopolymer-based hydrogels is a research hotspot in the field of bone tissue regeneration because their structure can mimic the native features of the extracellular matrix (ECM) of bone tissue. Hyaluronic acid 1 (HA), as one of the main components of ECM, is an optimal material to design biomimetic cell-interactive hydrogels, as well ε-poly-L-lysine (ε-PL) is an excellent candidate for preparing antibacterial hydrogels.

The aim of this study was to evaluate the impact of various aqueous solvents on the zero-length chemical cross-linking reaction and formation of HA/ε-PL hydrogels.

Experimental Methods
The bioinspired hydrogels were synthesized using zero-length carboxyl-to-amine crosslinkers 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and N-hydroxysuccinimide (NHS) at room temperature in various aqueous solvents - deionized water, sodium dihydrogen phosphate buffer, sodium chloride, sodium hydroxide and hydrochloric acid solution. The intermediate products, final products and by-products were characterized by FTIR, NMR, UV/VIS spectroscopy. The swelling ratio of the synthesized hydrogels was evaluated.

Results and Discussion
The crosslinking reaction was analyzed step by step and the structure of the formed intermediates 3, by-products and final product 4 was investigated. FTIR and NMR spectra revealed that the chemical crosslinking reaction occurred in all aqueous solvents by the formation of stable hyaluronic acid N-hydroxysuccinimide ester intermediate 3 which further reacted with the primary amino groups of ε-PL 2 and leaded the formation of the crosslinked hydrogels 4. The crosslinking reaction was influenced by the amount and pH of aqueous solvent, as well as the reaction time. During the chemical cross-linking reaction, a parallel reaction of EDC hydrolysis occurred in all solvents, forming a reaction by-product - EDC urea derivative. The synthesized hydrogels showed high swelling ability up to 700% and reached an equilibrium swelling state within 2 h.

Conclusion
The impact of the various aqueous solvents on the zero-length chemical crosslinking reaction and the formation of hydrogels were evaluated. In the development of biomaterials, it is important that this reaction can be performed in a biocompatible media, such as a 0.9% NaCl saline fluid at room temperature. Our research shown that the efficiency of this chemical cross-linking reaction can be modeled by nature of solvent, solvent amount and reaction time, adjusting the degree of cross-linking.

Hyaluronic acid and ε-poly-L-lysine cross-linking reaction
Preparation of poly(3-hydroxyoctanoate) porous patches containing diclofenac modified oligomers as potential materials for biomedicine

Katarzyna Haraźna¹, Anna Walczyk¹, Ewelina Cichoń², Małgorzata Witko¹, Bartosz Leszczyński³, Andrzej Wróbel³, Maciej Guzik¹

¹ Polish Academy of Sciences, Jerzy Haber Institute of Catalysis and Surface Chemistry, Cracow, PL; ² AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Cracow, PL; ³ Jagiellonian University, Faculty of Physics, Astronomy and Applied Computer Science, Cracow, PL

Introduction
Poly(3-hydroxyoctanoate) (P(3HO)) is an elastomeric material, which belongs to medium chain length polyhydroxyalkanoates (PHAs) polymer family. P(3HO) is accumulated in bacterial fermentation processes, under nutrient deficiency conditions. Thanks to several interesting properties such as biocompatibility, biodegradability as well as mechanical properties, our research focused on P(3HO) use in design and construction of patches, which can be used in skin regeneration processes, especially in wounds caused in sport injuries. Successfully decorating of molecules derived from decomposition of P(3HO) with biomolecules such as non-steroidal anti-inflammatory drugs, i.e. diclofenac, can be effective method, which may help deliver drugs directly to place of injury [1-5].

Experimental Methods
Strain of Pseudomonas Putida KT2440 was used in order to generate P3HO polymer in a 5L fermentor. As a carbon source in fermentation process the mixture of octanoic and butyric acid was used. After successfully finished bioprocess, the polymer was isolated from dried cells and purified by chemical methods [1-2].

The oligomers containing diclofenac (oli-P(3HO)-Dic) were prepared using modified protocol described by Haraźna et al. In this order, the reaction was carried out in melt and was catalysed using 4-toluenesulfonic acid monohydrate [3]. The structures of obtaining oligomers were confirmed by electrospray ionization tandem mass spectrometry (ESI-MS), infrared spectroscopy (IR) and nuclear magnetic resonance (1H NMR) techniques. Moreover, the amount of covalently attached diclofenac in prepared conjugates was established by 1H NMR.

In the next experiment, the prepared diclofenac modified oligomers (oli-P(3HO)-Dic) were incubated in phosphate buffered saline (PBS) (pH = 7.4, 100 mL) at 37 °C for 54 days [4]. The collected at appropriate time intervals supernatants were subjected to ultra high pressure liquid chromatography tandem with mass spectrometry (UHPLC-MS) analyses.

Finally, the porous polymeric patches were prepared by solvent casting combined with porogen leaching techniques [5]. In this purpose, different ratio of polymer to porogen were taken. As porogen, sodium chloride with 100 - 300 µm grain size was used. At the same time, analogous patches containing 100 µg of oli-P(3HO)-Dic / 1 g of P(3HO) were prepared. Description of the prepared samples is shown in Picture 1.

The porosity of obtaining patches were determined using X-Ray microtomography (µCT). The structures of materials were observed using scanning electron microscopy (SEM). Moreover, the mechanical properties of prepared materials i.e. tensile strength, Young modulus and elongation at break were determined.

Results and Discussion
1H NMR analysis showed a small amount of physically bound diclofenac (0.37 mg / 100 mg oligomers). Moreover, based on mentioned analysis, the content of the covalently attached drug were determined (22.6 mg / 100 mg oligomers). In order to define the amount of releasing diclofenac, oligomers were incubated in PBS (pH = 7.4, 100 mL) at 37 °C for 54 days. After mentioned time, 27.49 ± 2.69 % of diclofenac were released.
For the prepared soft foams, mechanical tests were carried out. These analyses showed that a small addition of diclofenac-modified oligomers causes a twofold increase in Yong’s modulus, tensile strength and elongation at break. The high value of elongation at break of patches no. A-Dic containing diclofenac modified oligomers (102.96 ± 22.30 %) in compared to patches no. A (56.83 ± 6.52 %) proves the excellent application properties of prepared functionalised polymeric foams. It is desirable that the potential patches should characterise with adequate strength, preventing it from tearing at the slightest tension. Moreover, the µCT analysis showed the porosity of foams no. A and no. B at 97 % and 96%, respectively. Additionally, it was shown that in the case of foams no. A, a homogenous pore size was observed, compared to foams no. B.

**Conclusion**

Therefore, the best structural and mechanical parameters for foams of 5% mas. P(3HO) were obtained, we decided to choose those patches as a future dressing material that will undergo in-depth characterisation in vivo. For this purpose, two series of foams – first composed of P(3HO) (no. A) and second one – composed of P(3HO) and oli-P(3HO)-Dic (no. A-Dic) were prepared. Due to the possibility of long-term release of active substances directly into the place of injury, the materials submitted for in vivo tests are an excellent alternative to commercially available wound dressings.

BioV²alve - Development of a biohybrid textile-reinforced minimal-invasive venous valve implant

Caroline Emonts¹, Alexander Kopp², Heinz-Werner Henke³, Philipp Bruners⁴, Stefan Jockenhoevel⁵, Thomas Gries¹

¹ RWTH Aachen University, Department of Medical Textiles, Institut für Textiltechnik, Aachen, DE; ² Meotec GmbH, Aachen, DE; ³ Innovative Tomography Products GmbH, Bochum, DE; ⁴ Universitätsklinikum Aachen, Klinik für Diagnostische und Interventionelle Radiologie, Aachen, DE; ⁵ RWTH Aachen University, Department of Biohybrid & Medical Textiles, Institute of Applied Medical Engineering, Aachen, DE

Introduction
With a prevalence of 3-5% the chronic venous insufficiency is one of the most common adult diseases in the western population and shows a considerable socio-economic significance. By insufficient venous valve closure, the returning blood flow to the heart is disrupted thus leading to a local overpressure in the venous system of the legs. The most common symptoms are dilated veins, varicose veins, heavy and painful legs with swelling, skin and tissue changes and in the final stage chronic lower leg ulcers. Nowadays, the current therapies are mainly symptomatic. Surgical and interventional approaches to reconstruct the venous valve function have not been successful due to the special coagulation situation in the venous flow. In this setting, the aim of BioV²alve project is to develop a biohybrid implant to restore the venous valve function.

Experimental Methods
Two textile structures form the main components of the innovative venous valve implant, namely a braided magnesium structure and a warp-knitted mesh. The braided magnesium stent frame offers an initial fixation of the synthetic biohybrid valve in the vessel. After ingrowth of the valve structure in the vessel wall, the magnesium stent degrades. The warp-knitted mesh which forms the two leaflets of the valve. The warp-knitted mesh serves as reinforcement and it will be covered by a hydrogel.

Three different designs of single-wire manually braided stents are investigated regarding their mechanical properties measured by a radial force tester. Furthermore, the crimp ability and dilatation of the stents is tested as well as the possibility to incorporate the textile valve structure.

For the warp-knitted meshes PET yarns of different fineness are used. The drapability and the morphological characteristics as the wall thickness, the pore size and the porosity are evaluated. The mechanical characteristics are tested by means of tensile testing in lengthwise and circumferential direction. Furthermore, the suture retention is tested to ensure a safe processing of the textiles.

Results and Discussion
All stent designs show a radial force in the range of commercially available venous stents so that the suitability for the application in lower limb veins is ensured. Regarding the function as valve delivery structure, two stent structures demonstrate a better performance due to less elongation during the crimping process and therefore less risk of damaging the synthetic valve.

The mesh structures with finer PET yarns show a better drapability and handling during the further processing. The porosity and pore size are decreased so that the textile offers better support for the hydrogel coating of the valve.

Conclusion
The data illustrates that the biodegradable magnesium wire is suitable to manufacture new stent designs for venous valve implants. Furthermore, it is shown that the incorporation of textile reinforced valve leaflets comparable to native
venous valves is possible. Both textile processes, braiding and warp-knitting offer a high flexibility in adjusting the textile characteristics to the requirements of the implant.

Ultrasound responsive polymer microbubbles for an efficient targeted treatment of thrombotic diseases

Louise J. Fournier, Rachida Aid-Launais, Abderrahmane W. Aissani, Veronique Ollivier, Murielle Maire, Olivier Couture, Didier Letourneur, Cédric Chauvierre

1 INSERM U1148, LVTS, Université de Paris, X Bichat Hospital, PARIS, FR; 2 Université de Paris, UMS34 FRIM, PARIS, FR; 3 Laboratoire d'Imagerie Biomédicale Sorbonne Université, UMR 7371 - U1146, PARIS, FR; 4 INSERM U1148, LVTS, Université Sorbonne Paris Nord, VILLETANEUSE, FR

Introduction
Cardiovascular diseases are the first worldwide mortality rate, it is fair to admit research in this field is a priority. Our team focus on thrombosis innovative targeted treatments and molecular diagnostic tools. Indeed, current treatments to prevent blood clots from obstructing vessels are intravenous injection of rt-PA (plasminogen activator) and in the last recourse, invasive mechanical removal called thrombectomy [1]. Nevertheless, systemic injection of the plasminogen activator has to be in high dose, potentially toxic, due to its short half time in the bloodstream. These limitations engage teams to find innovative and targeted treatments to overcome collateral bleeding or surgical complications. Our strategy focuses on developing innovative carriers for the targeting treatment, and visualization of the blood clot. We synthesize targeting polymer microbubbles (MB) in a one-pot, scalable, and not described in the literature protocol. Our targeting agent is a sulfated polysaccharide extracted from brown algae, the fucoidan, already used in clinical trial phase IIa. It was chosen for its affinity for P-selectin, expressed protein on activated platelets and activated endothelial cells. Commercial microbubbles are used in clinics for their echogenic properties and used as contrast agents. In addition, the ultrasound insonation can also induce sonothrombolysis [2], a mechanical perturbation of the MB that can accentuate the clot disruption. In short term, the objective is to incorporate the plasminogen activator into the MB, for a complete theragnostic tool.

Experimental Methods
Microbubble synthesis is obtained via acoustic cavitation of an aqueous phase containing our targeted agent with a surfactant. The organic phase containing the monomer of isobutyl cyanoacrylate is injected into the aqueous solution at a controlled speed. The insonation is performed with the Branson Sonifier SFX 500, and during the insonation process, perfluorobutane is injected into the aqueous solution to be imprisoned inside the MBs. The obtained foam is centrifuged 3 times and filtered to 5 µm. MB characterizations were performed by size measurements with granulometry analysis on Mastersizer 3000, and concentration measurements with image analysis of calibrated counting cell with Fiji Software. Those parameters allowed us to control the shelf stability over the weeks of the MBs. Also, the morphology of the MBs was observed by Scanning Electron Microscopy (SEM). Fucoidan content was determined by a quantitative analysis with methylene blue colorimetric dosage. Targeting tests were performed ex vivo in static and fluidic conditions with human whole blood. In brief, for the static test, platelet-rich clots are obtained ex vivo by blood centrifugation and incubation at 37°C of the platelet-rich plasma. Clots are then put in contact with MBs suspension and observed by fluorescence microscopy after multiple washing. The fluidic model consists of coating microfluidic channels with collagen in order to promote platelet aggregation. Whole human blood is then injected at arterial flow speed. When platelet aggregates are formed, the channel is rinsed and the MB suspension is injected. After another rinsing, microbubble colocalization to the aggregate is observed by fluorescence microscopy. Echogenicity evaluation is performed with the comparison of commercial MBs (SonoVue) to our MBs. MBs are guided through a channel in an agar phantom setup. Signals of echogenicity and response to burst for sonothrombolysis are compared.

Page 1298 of 2028
Results and Discussion
We were able to develop an undescribed synthesis protocol for polymer MBs with acoustic cavitation reducing the time of hydrodynamic cavitation. The MBs mean size is below 6 µm and the range of production is around $10^{10}$ MBs per synthesis. Those MBs showed great shelf stability in terms of size distribution and concentration over two months. SEM images showed a good size distribution and rounded shape morphology. Fucoidan quantification reported similar incorporation to previous work in the lab from another method of MBs synthesis with around $10^{15}$ g of fucoidan per MB [3]. We are currently optimizing the targeting experiment in static and fluidic conditions but preliminary results are encouraging. Echogenic characterization preliminary experiment provided similarities with commercial contrast agent in terms of echogenicity. In order to validate these results, more synthesis conditions will be evaluated and the objective is to extend the phantom model to an ex vivo model to observe the influence of the targeted MBs with therapeutic ultrasound onto a blood clot.

Conclusion
We are thrilled to present an innovative synthesis protocol of MBS allowing echogenic and targeting properties for the treatment of thrombotic diseases. Perspectives result in the incorporation of the therapeutic agent [4] to allow its release on the targeted site and enhance thrombolysis with US insonation associated with the biochemical action of the plasminogen activator.

Enhanced Endothelization on Nanostructured 316L Stainless Steel for Cardiovascular Stent Application

**Yasar K. Erdogan**\(^1,2\), Batur Ercan\(^1,3\)

\(^1\) Middle East Technical University, Department of Biomedical Engineering, Ankara, TR; \(^2\) Isparta University of Applied Science, Department of Biomedical Engineering, Isparta, TR; \(^3\) Middle East Technical University, Department of Metallurgical and Materials Engineering, Ankara, TR; \(^4\) Middle East Technical University, BIOMATEN, METU Center of Excellence in Biomaterials and Tissue Engineering, Ankara, TR

**Introduction**

Coronary artery disease is one of the most leading causes of death in the world. 316L stainless steel was widely used to fabricate cardiovascular stents to open up clogged arteries due to its mechanical properties, corrosion resistance and acceptable biocompatibility [1]. However, its major drawback is the nickel ion release from its surfaces which may lead to toxic and allergenic effects. Additionally, the use of bare metal can lead to stent restenosis due to limited endothelization and thrombus formation. To minimize the aforementioned pitfalls of using 316L stainless steel stents surface modification techniques have been adapted in recent years [2,3,4]. In this study, we were fabricated oxide based nanostructures on 316L stainless steel via electrochemical anodization technique.

**Experimental Methods**

Prior to anodization, samples were cleaned in acetone, ethanol and deionized water for 10 min, respectively. The anodization was performed in ethylene glycol monobutyl ether solution containing 7.5 vol % perchloric acid applied potential at 15–90V voltage. Surface chemistries were examined using X-ray photoelectron spectroscopy. Roughness of the surfaces investigated using atomic force microscopy. Contact angle measurement were performed using sessile drop method of the surfaces by goniometer. The nickel ion release from surfaces were detected by ICP-MS. For cell culture experiments, HUVECs were seeded onto sterile 316L stainless steel samples at a density of 10 000 cells/cm\(^2\) and cells were cultured up to 5 days in vitro under standard cell culture conditions (37 °C and 5% CO\(_2\) atmosphere). The 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay was conducted at the 1st, 3rd and 5th days of culture to determine cellular density on the sample. For cellular imaging, HUVECs were seeded onto sterile 316L stainless steel samples at a density of 3 500 cells/cm\(^2\) and incubated at 37 °C/ 5% CO\(_2\) for 3 days. After 3 days in vitro, culture media were aspirated, and cells were fixed using a 4% paraformaldehyde solution for 20 min at room temperature. The fixed cells were permeabilized with 0.2% Triton X-100 for 30 min and blocked with 5% BSA for 30 min. When immunostaining for vinculin was complete, actin fibers were stained with red fluorescence phalloidin. Then, a 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) solution was added onto the samples. Cellular images were captured with a Zeiss confocal microscope (LSM800, Germany). Migration of HUVECs in vitro was measured using the wound healing assay. Briefly, cells were seeded in 24-well plates at a density of 1 x 10\(^5\) cells/cm\(^2\) and cultured in the 5% CO\(_2\) incubator at 37 °C overnight. Cell monolayers were then scratched using a 1000 µL sterile pipette tip. Images of the wound area were taken at 0, 4, 8 and 12 hours after the scratch with Zeiss confocal microscope. Image J software was used to measure scratch areas.

**Results and Discussion**

We successfully obtained nanostructures on the stent surfaces in two different morphologies namely nanodimples and nanopits. The feature size of these nanostructures were controlled between 20 to 300 nm in diameter. Water contact angle analysis showed that nanopit surfaces had more hydrophilic properties than nanodimple surfaces. While NP25 and NP200 nanopit surfaces had contact angles of 45.0±7.8° and 34.1±9.8°, ND25 and ND200 nanodimple surfaces had contact angles of 75.0±6.6° and 77.1±6.5°, and non-anodized surfaces had 57.7±7.1°. The surface roughness
of anodized samples were higher compared to non-anodized 316L stainless steel surfaces. The 200nm nanopit surface nanophase roughness values measured 18.6±2 nm while non-anodized surface roughness had 1.2 nm. XPS analysis results showed that nanopit samples were composed of Fe₂O₃, Cr₂O₃ and NiO while nanopit surfaces additionally had CrₓPᵧ and FeP. Furthermore, surface chemistry significantly affected nickel ion release from the surfaces and exhibited the lowest release in nanopit surfaces having 200nm diameter. In vitro tests revealed that nanostructured surfaces enhanced adhesion and proliferation of endothelial cells compared to non-anodized surface. In addition, fluorescence and scanning electron microscopy images revealed that endothelial cells were spreading more on anodized surfaces compared to non-anodized surfaces. Cellular migration experiments indicated faster endothelial cell migration on nanodimple and nanopit surfaces compared to non-anodized surface at 0, 4, 8 and 12 hr in vitro.

**Conclusion**

In this study, we were fabricated nanostructure on 316L SS by anodization technique. The nanotopography on surface influence cell-material interaction and improved hemocompatibility. Especially, nanopit surfaces having 200nm feature size is a promising candidate for rapid re-endothelialization, and minimized nickel ion release from 316L stainless steel surfaces for stent applications.

Experimental and Computational Investigation of the Performance of Braided PLLA Stents

Agnese Lucchetti¹, Ted J. Vaughan², Thomas Gries¹

¹ RWTH Aachen University, Institut für Textiltechnik, Aachen, DE; ² National University of Ireland Galway, Biomechanics Research Centre (BMEC), School of Engineering, Galway, IE

Introduction

Despite advances in stent development over the past decades, issues such as thrombosis, in-stent restenosis and vessel remodeling impairment are still associated with permanent metallic stents [1]. Bioresorbable devices have the potential to overcome these drawbacks, being in the patient just for the time needed. Braiding is a well-established technology in the stent manufacturing and brings advantages especially in terms of a superior device flexibility and a major conformability to the anatomic shape of the lesion [2]. When it comes to device development, a full understanding of the influence of each manufacturing parameter and geometrical feature is of utmost importance. In this setting, an experimental study is carried out both to understand the influence of the most significant braiding parameters on the performance of PLLA braided stents and to validate the developed computational model that will be then used not only for further device optimization but also for investigating the device performance in more complex scenarios (e.g. patient specific vessels).

Experimental Methods

Experimental study: The PLLA stents were manufactured in-house using a Steeger Braiding Machine (Körting Nachfolger Wilhelm Steeger GmbH & Co. Wuppertal, Germany). The geometrical features under analysis were the stent diameter, number and diameter of the filaments and the braiding angle (α), as summarized in Figure 1a-b. Once braided, the device structure was fixed through a heat setting process, whose optimal conditions were found to be 140 °C and 10 min. The stents were characterized by means of a radial force test, performed according to DIN EN ISO standard 25539-2-2012. More specifically, all the stents were tested at a constant temperature of 37 °C and crimped to around 50% of their initial diameter. For the 5-mm diameter stent a comparison with a nitinol (NiTi) stent as published by McKenna et al. [3] was also considered.

Computational model: The stent geometry was reconstructed with PyFormex to resemble the 4/24/70/100 stent, more specifically featuring a 4-mm diameter, 24 filaments, a 70-degree braiding angle and a 100-µm filament diameter. The Abaqus/Explicit software (Dassault Systemes Simulia, Providence, RI, USA), was employed to mimic the radial compression bench test. The device was discretized with 4896 B31 elements. The PLLA was modelled as an elastoplastic material and its mechanical properties were determined from tensile testing of filaments. Ten crimping plates were modeled as rigid bodies to resemble the radial force testing machine. These were displaced to crimp the stent by 50% and subsequently released, as to mimic the experimental test. A friction coefficient of 0.1 and 0.05 was considered for the stent self-contact and the stent-plates contact, respectively.

Results and Discussion

Experimental study: The experimental curves (Figure 2a-c) show that the radial behavior of the stents with lower braiding angle is far from the one of the NiTi stent. However, at a diameter of interest of 4 mm (dashed line in Figure 2a-c), two stents, namely 5/24/60/150 and 5/48/70/100 showed respectively a radial resistive force of 0.17 N/mm and 0.12 N/mm and a chronic outward force of 0.047 N/mm and 0.031 N/mm; therefore, higher or comparable with the NiTi device. For smaller diameters, the stents show as expected higher forces (Figure 2d), but also a higher residual elongation, up to 20%. This may be linked to the bigger influence of friction among the filaments for such small calibers.
Computational model: The model developed up to now properly catches the initial stent stiffness, while it slightly overestimates the stent radial resistive force (max. 10%) in a range of interest of 2.5-3 mm (Figure 2e). The lower hysteresis of the computational curve compared to the experimental one can be linked to the friction between the device and the plates.

Conclusion
This study showed that the mechanical performance of PLLA braided devices subjected to a radial load is in a similar range to the one of the NiTi stent for specific braided configurations. Further studies will be carried out with the aim of finding the right combination of braiding parameters and pattern to further bridge the gap between permanent and bioresorbable devices also with the help of the validated computational model.

Preliminary Trials of Idealised Crimping Test Rig for Bioresorbable Vascular Scaffolds

Jordan J. Barr, Gary Menary, Alex Lennon

Queen's University Belfast, Belfast, GB

Introduction
Coronary heart disease (CHD) is the leading cause of death worldwide\(^1\). Current treatment with metallic stents, leaves the treated vessels permanently caged and leads to long term adverse effects. Polymeric bioresorbable vascular scaffolds (BVS) are a promising alternative which negate the problem of permanent caging by being fully resorbed into the body after performing their function. Currently the polymers used in BVS are limited by their mechanical properties being lower than that of their metallic counterparts. This leads to increased BVS strut thickness and similar long term adverse events\(^2\).

Understanding and tailoring the processing steps of BVS may hold the key to solving this problem. While some of the processing steps have been heavily researched, the crimping process has been considered in much less detail. Crimping involves the radial compression of an as-cut scaffold onto a balloon catheter\(^3\). During this process the BVS undergoes significant deformation, particularly at the U-bend tips. While there is agreement that changes in morphology and molecular orientation occur due to the deformation, the conclusions drawn are conflicting with some authors attributing the lasting strength of BVS to these changes\(^3\) and others attributing it to increased localised degradation and premature failure\(^4\).

Crimping takes place within an enclosed environment and therefore analysis of the deformation occurs post-crimping. An idealised crimping test rig and method has been proposed which will replicate the crimping process and allow opportunity for analysis during crimping such as digital imaging correlation or x-ray scattering techniques. This test rig, its setup, and initial trials are the focus of the work presented here.

Experimental Methods
The crimping process has been idealised by focusing on an individual U-bend. Individual U-bend specimens were produced from Poly(l-lactide) (PLLA), PURASORB PL 38 (Corbion, Amsterdam, Netherlands). Initially, 1mm thick sheets were extruded. These were then biaxially stretched, using a custom built biaxial stretcher\(^5\) to replicate the stretch blow moulding process in BVS production, to a thickness of ~150 µm. The U-bend specimens were then laser cut from these thin sheets which are representative of current BVS strut thickness and dimensions.

The test rig, Figure 1, idealises the crimping process by imposing a displacement on the U-bend in one plane of motion. Computational modelling has shown the stresses and deformation experienced during this process to be representative of those experienced during modelling of a full crimping process. The U-bend specimens are clamped in the grips, with one stationary grip connected to a Honeywell FSG 0-5N load cell (Honeywell, Nort Carolina, USA) and one moving grip which imposes the deformation through the linear motion of a Zaber X-LSM025A motorised linear stage (Zaber, Vancouver, Canada).

Results and Discussion
Initial trials seen in Figure 2, show promising results with accurate displacements being imposed, while improvements in the laser cutting process, replication of crimping deformation and recording of load data are all currently a work-in-progress. Further modification of the rig to replicate the crimping process more fully will involve, the addition of an oven-like chamber around the specimen to maintain the temperature. With the rig fully functional, a Design of Experiments approach will be taken to compare the impact of both biaxial and crimping processing factors such as temperature, strain rate, stretch ratio and crimping rate. The incorporation Page 1307 of 2028
of DIC techniques present a challenge due to the small size of the specimens and will require work to find an appropriate speckling technique.

**Conclusion**

The idealised crimping method provides an opportunity for greater analysis of BVS during the crimping process and through this, a greater understanding which can be used to help optimise and produce more useful BVS in the future.

Small diameter artery scaffolds via additive manufacturing of thermoplastics and pro-angiogenic hydrogels

Julia Fernández-Pérez¹, Kenny van Kampen¹, Rebeca Rivero¹, Patricia Y.W. Dankers², Carlos Mota¹, Matthew B. Baker¹, Lorenzo Moroni¹

¹ Maastricht University, MERLN Institute, Maastricht, NL; ² Eindhoven University of Technology, Department of Biomedical Engineering, Eindhoven, NL

Introduction

Millions of people worldwide suffer from coronary diseases. Patients are commonly treated with a bypass using autologous tissue, usually from the saphenous vein or the internal thoracic artery. These procedures are not always possible due to insufficient tissue availability and also may induce secondary site morbidity. Currently developed tissue engineered grafts rely on lengthy culture periods, which are costly and not always off the shelf. It is for these reasons that in situ tissue engineering approaches are gaining interest. These scaffolds are intended to be implanted acellularly and encourage the body to repopulate and remodel them over time.

Experimental Methods

In this study, we have fabricated scaffolds by Additive Manufacturing of polycaprolactone (PCL), PCL-6UPy₂-urethane or polycarbonate(cyclohexyldiamide) onto a rotating mandrel as described by van Kampen et al. [1]. The tubular structures were produced with variety of fiber alignments by modifying the extruder speed. These scaffolds supported the adhesion and proliferation of HUVECs and human vascular smooth muscle cells in vitro. Cells repopulating the media layer aligned along the fibers and laid their own extracellular matrix and the intima layer consisted of a fully endothelialized lumen. To improve the mechanical properties of these constructs, an external layer was added with sine auxetic patterns, which intend to replicate the crimped collagen in the vessel wall.

Results and Discussion

Furthermore, a pro-angiogenic hydrogel was developed to emulate the adventitia layer. Two hydrogels systems have been designed: one based on alginate-norbormene using a di-thiol MMP-cleavable sequence as cross-linker and one using alginate-hydrazone and oxidized alginate. The first system is degradable by cell proteolytic activity and is composed of static covalent cross-links, while the second system exhibits viscoelastic properties due to its dynamic covalent cross-linking. Both systems were functionalized with the VEGF-mimicking QK peptide and with cell-adhesion molecules (fibronectin-derived RGD and/or laminin-derived YIGSR). The angiogenic capacities of these hydrogels was tested in 3D culture of HUVEC cells and in a rat aortic ring ex vivo model.

Conclusion

Future work will focus on combining the polymeric scaffolds with the hydrogels to obtain a multilayered construct.

Introduction

Cardiovascular diseases, which are the most common cause of death worldwide, also affect the cardiac conduction system. Dysfunctions, such as the sick sinus syndrome (SSS), require adequate treatment strategies of high relevance. Engineered cardiac tissues could offer a smart alternative to existing therapies (established electronic pacemaker) through a superior adaptation to the body, especially in infants, or when functioning as \textit{in vitro} models for drug development. 3D bioprinting of cardiomyocytes has been widely used to generate contracting cardiac patches and organoids using either isolated primary cardiomyocytes (CM) or iPSC-derived CMs \cite{1-2}. In contrast, pacemaker cells have not yet been applied for bioprinting of organoid constructs with tailored biological and mechanical properties.

Experimental Methods

Against this background, we have bioprinted 3D constructs containing fully characterized ESC-derived pacemaker cells \cite{3-4}, which were enriched with fibroblasts as a basis for future repair of SSS and drug testing applications. The cell mixture was suspended in an oxidized alginate-gelatin (ADA-GEL) hydrogel \cite{5} and 3D printed with an Allevi 1 Bioprinter (Allevi, Philadelphia, USA) into 3D scaffolds. The scaffolds were ionically and enzymatically crosslinked using CaCl\textsubscript{2} (0.1 M) solution combined with microbiological transt glutaminase (0.025 g/ml). 3D bioprinted constructs were cultivated under standard tissue culture conditions (37°C and 5 % CO\textsubscript{2}). Structural and functional measures were performed after 0, 7, 14, 21, and 28 days. We examined the integrity of our printed pacemaker constructs by analyzing the morphology and cell-material interaction (light microscopy), the expression of specific marker proteins (immunohistochemistry), the presence of ordered myofibrillar sarcomeres via second harmonic generation (SHG) imaging, as well as spontaneous contractility (beating frequency) and underlying electrophysiological mechanism via calcium imaging.

Results and Discussion

3D scaffolds containing living pacemaker cells and fibroblasts were successfully printed. Until 28 days after printing, cultivation and characterization revealed both functionality of pacemaker cells and proliferation of fibroblasts. Light microscopic video recordings with a corresponding evaluation of the beating frequency showed spontaneous contractions of pacemaker cells and clusters in a physiological range. Additionally, the flux of Ca-ions during spontaneous activity could be observed, supporting the functionality of the pacemaker cells. On the microscopic level, sarcomeric, contractile structures could be identified using SHG multiphoton imaging. A high cellular attachment within the cell biomaterial system could be achieved. Vimentin-expressing fibroblasts exhibit a typical elongated morphology, whereas troponin-positive pacemaker cell clusters showed cell protrusions and partly spindle-shaped single cells.
Conclusion
Overall, the study shows that highly specialized cardiac cells such as pacemaker cells of the sinus node can be successfully 3D printed using ADA-GEL hydrogel. This approach opens up new strategies in cardiovascular regenerative medicine with a high potential for tissue engineering of biological pacemakers and the development of advanced drug testing models.

In-Silico Assessment of the impact of material Thrombogenicity in a Left-Ventricular Assist Device

Hristo Valtchanov\textsuperscript{1}, Rosaire Mongrain\textsuperscript{1}, Renzo Cecere\textsuperscript{2}

\textsuperscript{1} Mcgill University, Mechanical Engineering, Montreal, CA; \textsuperscript{2} Mcgill University Health Centre, Cardiology, Montreal, CA

Introduction
Non-physiological flow conditions in biomedical devices with blood contacting surfaces result in blood damage in the form of hemolysis – damage to blood cells- and thrombosis – the formation of blood clots that can occlude blood flow or contribute to the risk of stroke and thromboembolism \textsuperscript{1}. A recent prospective study\textsuperscript{2} has counter-intuitively found that incorporation of hemocompatible materials in blood exposed devices has no impact on rates of thrombosis, stroke or infection, despite in-vitro evidence to the contrary\textsuperscript{3}. This study assesses the impact of hemocompatibility – measured as the rate of adhesion of activated platelets to a given biomaterial – on thrombogenicity relative to other design parameters such as flow rate, rotor speed and geometry.

Recent studies have demonstrated the ability of computational fluid dynamics to simulate the intrinsic blood coagulation process at the macroscale with high accuracy.\textsuperscript{4} The ability to assess hemocompatibility in-silico can be used to address this question by simulating conditions difficult to reproduce in a lab environment. Hence simulation is useful in assessing the practical efficacy of material choice of blood exposed devices in reducing thrombosis relative to geometry and operating conditions.

Experimental Methods
CFD simulations are executed of a left-ventricular assistive device (LVAD), in which material hemocompatibilities, flow rate and geometric features are varied in a quasi-random manner. A reduced model of the intrinsic coagulation process is incorporated following the methodology of Wu et al., \textsuperscript{5}, in which 10 Advection-Diffusion-Reaction equations are used to simulate platelets in the active/inactive, non-deposited/deposited, and stabilized states, as well as the production, usage or release of Thrombin, Prothrombin, Antithrombin, Adenosine Diphosphate, and Thromboxane. Hemocompatibility is accounted for by setting a rate of platelet deposition at the wall, which is a function of the material of the blood-exposed surface.

For the purposes of this study, a constant rate of platelet deposition is used, which is varied to represent material hemocompatibility of various materials. In addition, inflow rate, LVAD rotor speed, and geometry are varied. LVAD geometry is based on an open-hub LVAD being developed at McGill university, and geometric variations are limited to the blade angle and number of blades in the rotor section sections (which can cause large variations in wall shear-stress). Simulations are executed in an automated way using a parameterized CAD geometry. Parameter values are chosen using the SOBOL algorithm which randomly samples points in a hypercube in an equidistant manner.

Results and Discussion
Simulations are performed for mass flow rates between 1-5 L/min, rotor speeds varying between 1000-8000 RPM, and thrombogenicity ranging between nitinol (high thrombogenicity) and PVC (low thrombogenicity) [goodman]. Figure 1 shows the formation of a thrombus in a RPM case on a baseline geometry using the PVC material.

Conclusion
CFD simulations were executed in order to simulate thrombogenesis in a left-ventricular assist device. Material hemocompatibility was varied, as well as operating conditions and rotor geometry to establish sensitivity of material selection relative to other key design parameters. It was found that operating conditions played the most significant role in determining whether thrombogenesis occurred, followed by material hemocompatibility.

Nanostructured dense collagen-polyester composite hydrogels as amphiphilic platforms for drug delivery

Xiaolin Wang¹,², Olivier Ronsin³, Nicolette Farman⁴, Tristan Baumberger³, Frédéric Jaisser⁴, Thibaud Coradin¹, Christophe Helary¹

¹ Sorbonne Université, Laboratoire de la Chimie de la Matière Condensée, Paris, FR; ² Macau University of Science and Technology, School of Pharmacy and State Key - Laboratory of Quality Research in Chinese Medicine, Macao, CN; ³ Sorbonne Université, Institut des NanoSciences de Paris, Paris, FR; ⁴ Sorbonne Université, INSERM - Centre de Recherche des Cordeliers, Paris, FR

Introduction
Collagen based hydrogels are broadly used in tissue engineering as they are biocompatible, biodegradable and are the natural support of cells. In many reported cases, collagen hydrogels were fabricated from low concentrated solutions and suffered from several limitations such as poor mechanical properties and fast degradability. To circumvent these limitations, dense collagen hydrogels have been developed to increase the hydrogel stability and enhance the mechanical properties. Unfortunately, these biomaterials are poor drug delivery systems due to the poor affinity between the therapeutic molecules and the collagen network, thereby limiting their utilization to prevent infection or modulate inflammation¹. Associating collagen with biodegradable hydrophobic polyesters constitutes a promising method for the design of medicated biomaterials. Current collagen-polyester composite hydrogels consisting of pre-formed polymeric particles encapsulated within a low concentrated collagen hydrogel suffer from poor physical properties and low drug loading.

Herein, an amphiphilic composite platform associating dense collagen hydrogels (40 mg/mL) with FDA approved polyesters was developed. Polymers with different hydrophobicity (PLGA, PLA, PCL) and chain length (from 7 to 60 KDa) were tested. An original method of fabrication was disclosed based on in situ nanoprecipitation of polyesters impregnated in a pre-formed 3D dense collagen network². Physical and mechanical properties of composite hydrogels were analysed with regard to the polyester nature and chain length. In addition, their ability to deliver a lipophilic model drug (Spironolactone) in a sustained and controlled manner was also evaluated.

Experimental Methods
Dense collagen hydrogels were fabricated by placing concentrated collagen solutions at 40 mg.mL⁻¹ under ammonia vapours. After several rinses, hydrogels were dehydrated using Tetrahydrofuran (THF) baths and incubated overnight in polyester and spironolactone solutions. PLGA, PLA and PCL with different chain lengths (from 7 to 60 kDa) were used. Then, the nanoprecipitation within the collagen network was triggered by incubation in PBS (Figure 1). First, the quantity of polyesters immobilized within hydrogels and the swelling properties were assessed. Then, the ultrastructure of composites was analysed by scanning and transmission electron microscopy. Their mechanical properties were evaluated by rheology. Last, the drug release kinetic from composites was studied over one month and their cytotoxicity evaluated on fibroblasts using a live/dead assay.

Results and Discussion
The nanoprecipitation enabled the immobilization of a large amount of polyesters, reaching 50 % of the hydrogel dried weight for PLGA 60 kDa. The polymer hydrophobicity negatively impacted the nanoprecipitation whereas the long chains improved the polymer immobilization. The presence of polyesters negatively impacted the swelling properties. However, all composite hydrogels exhibited a high degree of hydration (80%). When PLGA was used, the hydrogel stiffness was increased but its deformability dropped. On the opposite, PLA or PCL did not modify the hydrogel mechanical properties compared to pure collagen. The ultrastructure analysis
revealed the presence of polydisperse nano/microparticles at the surface of collagen fibrils. These particles were smaller for PLGA and more intimately linked to collagen. These results suggest a strong interaction between PLGA and the collagen network.

Compared to pure collagen hydrogels, the drug loading in composites was 5 times higher and similar in all composites. The release kinetic of spironolactone was quasi constant for PLGA 7kDa and PCL 14 kDa over the first two weeks. Unlike pure collagen hydrogels, no burst release was detected (Figure 2B). For PLGA and PLA, the chain length negatively impacted the drug delivery. The drug release relied on diffusion for PCL and PLA whereas a combination and erosion was involved in drug release for PLGA. The released drug from composites retained its activity, thereby evidencing the absence of degradation during the composite synthesis.

Hence, the choice of polyester allows to tune the hydrogel stiffness, its deformability and the drug release kinetic of lipophilic drugs. To complete this study, cell viability experiments showed the absence of cytotoxic effect of composites hydrogels on fibroblasts and keratinocytes regardless of the polyester used.

**Conclusion**

Taken together, composite hydrogels fabricated by nanoprecipitation are promising biomaterials. The ease of fabrication, wide range of accessible compositions and positive preliminary safety evaluations of these collagen-polyesters will favour their translation into clinics in wide areas such as drug delivery and tissue engineering.

Introduction

Lung cancer is still the main cause of cancer-related deaths worldwide, making up almost 20% of all cancer deaths (GLOBOCAN, 2020). The most common type is non-small-cell lung cancer (NSCLC) and its treatment includes surgical resection, chemoradiotherapy and targeted therapy. The discovery of key oncogenic events in NSCLC patients, like the mutations on epidermal growth factor receptor (EGFR), have improved the therapeutic strategy, with the introduction of tyrosine kinase inhibitors, such as Gefitinib (GEF) (1). Nevertheless, its poor solubility in gastric fluids weakens bioavailability and therapeutic activity (2). Therefore, the development of novel GEF delivery systems to increase its bioavailability and distribution in tumor site is highly demanded.

Here, we designed an innovative strategy for GEF delivery, by functionalizing PLGA nanoparticles (NPs) with p28, a cell-penetrating peptide derived from Azurin, a bacterial protein which have both demonstrated largely their multi-targeted anticancer activity \textit{in vitro} and \textit{in vivo} (3). Additionally, their simultaneous administration with anticancer drugs increased the drug effectiveness, leading to the reduction of dose-related toxicity (4). These findings support to the design of a p28-functionalized delivery system to effectively penetrate the membranes of cancer cells while deliver GEF.

Experimental Methods

The conjugation of p28 peptide to poly(lactic-co-glycolic acid) (PLGA) polymer was performed by maleimide-thiol click chemistry and was evaluated by HPLC, before the formulation of polymeric NPs by nanoprecipitation. The nanosystems physical-chemical characteristics were evaluated by dynamic light scattering and laser doppler anemometry. The cytocompatibility of empty NPs, anticancer potential of NPs-p28-GEF and respective controls (NPs-GEF and NPs-p28) were evaluated using A549 NSCLC cells through resazurin assay. Further the cancer cells targeting ability of NPs-p28-GEF was evaluated by flow cytometry and confocal imaging. Lastly, their therapeutic potential was evaluated \textit{in vivo} using a A549 xenograft model through intravenous and subcutaneous administration.

Results and Discussion

The conjugation efficiency was around 80% and upon production, the physical-chemical characteristics of the PLGA-PEG-p28 nanoparticles were 78nm±2 for size; 0.14±0.01 for polydispersity index (PDI) and -17mV±1 for ζ-potential. Our data indicated that p28 potentiates the selective interaction of these nanosystems with lung cancer cells (active targeting). Thus, the GEF anticancer drug was encapsulated in these NPs (size: 60nm±3; PDI: 0.23±0.03; ζ-potential: -17mV±1; GEF association efficiency: 42%±2) showing a decrease in A549 cell metabolic activity around 25% compared to non-functionalized GEF encapsulated nanoparticles (size: 58nm±3; polydispersity index: 0.22±0.01; ζ-potential: -15mV±1; GEF association efficiency: 47%±1; GEF loading: 3±1). Regarding \textit{in vivo} studies, while NPs-p28 and NPs-GEF decrease A549 tumor growth in 42% and 36%, respectively, NPs-p28-GEF presented a higher
anticancer effect, by reducing the tumor burden in 58% comparing to non-treated animals, which suggest a synergistic effect of p28 and GEF.

**Conclusion**

This work supports that p28 peptide on the surface of NPs can efficiently direct target cancer cells, minimizing the cytotoxic effects on healthy tissues caused by non-specificity of drug administration alone. Importantly, this delivery system could provide a promising strategy for chemotherapy, able to inhibit lung tumor progression in vivo.

Exploiting the Chemotherapeutic and Immunomodulatory Effect of a Glioblastoma-targeted Nanodrug Using a Novel Tumor Niche-recapitulating 3D Spheroid Construct

Claudia Martins1,2,3, Catarina Barbosa1, Marco Araújo1, Maria Oliveira1, Jonathan W. Aylott3, Bruno Sarmento1,4

1 University of Porto, Institute for Research and Innovation in Health, Porto, PT; 2 University of Porto, ICBAS - Abel Salazar Institute of Biomedical Sciences, Porto, PT; 3 University of Nottingham, School of Pharmacy, Nottingham, GB; 4 CESPU, Institute of Research and Advanced Training in Health Sciences and Technologies, Gandra, PT

Introduction
Glioblastoma (GBM) is the most common and lethal type of primary brain tumor. The 5-year survival of GBM patients is still limited to a dismal 5%, highlighting the need to advance more effective GBM therapies. GBM tissue presents an abnormal expression of the L-type amino acid transporter 1 (LAT1), for which histidine (His) is an inexpensive and powerful targeting ligand [1]. Although His is expected to provide higher accumulation of drug nanoparticles (NPs) into GBM cells via LAT1 binding, consequently enhancing the anti-tumor response, it has been poorly explored in GBM-targeted therapies. Thus, this project proposes GBM-targeted, His-functionalized polymeric NPs loaded with docetaxel as a therapeutic with capacity to induce immunogenic cancer cell death [2]. On the other hand, a recent paradigm shift in the field of GBM immune environment revealed that the majority of tumor-associated macrophages in GBM are infiltrating bone marrow-derived macrophages, and not microglia [3]. Therefore, the herein project also aims at providing a first-time developed donor-isolated macrophage/GBM crosstalk 3D spheroid construct to simultaneously study drug chemotherapeutic and immunomodulatory effects.

Experimental Methods
Carbodiimide and carbamate hydrolysis chemical strategies were employed to synthesize a polymeric conjugate based on poly(lactic-co-glycolic) acid (PLGA) and His-functionalized polyethylene glycol (PEG), to serve as the NP core and shielding, respectively. The PLGA-PEG-His polymeric conjugate was characterized by various techniques such as NMR, optical contact angle measurements, FTIR and MALDI-TOF MS. The PLGA-PEG-His polymeric conjugate was further used to manufacture docetaxel-loaded NPs, through a previously established microfluidic technique of high reproducibility and easy scaling up [4]. Docetaxel-loaded PLGA-PEG-His NPs were fully characterized for physicochemical properties. Regarding the 3D spheroid construct, agarose micro-molds were used for high-throughput spheroid assembly. GBM cell binding of unloaded PLGA-PEG-His NPs was evaluated by flow cytometry in different cell lines (U251, U373, U87) to select the best cell model for the spheroid construct core. Human monocytes were isolated from healthy blood donor buffy coats provided by São João Hospital (Portugal). The 3D spheroid construct was optimized for the optimal total cell density (2500, 5000 and 1000 cells/spheroid) and tumor cell:monocyte percentage (50:50, 35:65, 20:80, 5:95), and visualized by microscopic techniques using H&E staining and immunohistochemistry. A preliminary assay was run to investigate the chemotherapeutic effect of docetaxel-loaded PLGA-PEG-His NPs compared to the free drug control.

Results and Discussion
The chemical synthesis of the PLGA-PEG-His polymeric conjugate achieved 90% conjugation efficiency, as demonstrated by NMR; optical contact angle measurements indicated an intermediate PLGA-PEG/His hydrophilicity for the conjugate; FTIR confirmed an amide formation; MALDI-TOF MS revealed an unique ionization profile for the conjugate compared to the PLGA-PEG and His controls (Fig. 1A/B, C, D and E, respectively). Docetaxel-loaded PLGA-PEG-His NPs demonstrated scale-independent 250 nm size, 0.2 polydispersity index, 70% drug entrapment.
efficiency and a controlled drug release over 48 h. The GBM cell binding of unloaded PLGA-PEG-His NPs was 2.5-times higher than non-His-functionalized NPs in all tested cell lines. Regarding the 3D spheroid construct, U251 was selected as the tumor cell model, no H&E necrosis was observed in all tested total cell densities, and only the 50:50 and 35:65 tumor cell:monocyte percentage conditions assembled into a spheroid. Immunohistochemistry revealed the spatial distribution of tumor-associated vimentin, extracellular matrix fibronectin and CD68 macrophage marker within the 3D spheroid construct (Fig. 2A). Docetaxel-loaded PLGA-PEG-His NPs drastically disturbed the morphology of the spheroid tumor core, suggesting a significantly higher level of cytotoxicity compared to the same dose of the free drug control (Fig. 2B).

Conclusion
This work has allowed the exploitation of His functionalization to synthesize cost-effective GBM-targeted NPs with capacity to undergo a significantly higher accumulation within tumor cells and disrupt the tumor core of a first-time proposed donor-isolated macrophage/GBM crosstalk 3D spheroid construct. Ongoing work is expected to open avenues regarding the immunogenic properties of the docetaxel-loaded PLGA-PEG-His by studying spheroid macrophage M1/M2 polarization.

Determination of Gentamicin Sulfate Release from the Calcium Phosphate Bone Cements

Eliza Tracuma\textsuperscript{1,2}, Janis Locs\textsuperscript{1,2}, Marite Skrinda\textsuperscript{1,2}, Dagnija Loca\textsuperscript{1,2}

\textsuperscript{1} Riga Technical University (RTU), Institute of General Chemical Engineering, Rudoffs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Faculty of Materials Science and Applied Chemistry, Riga, LV; \textsuperscript{2} Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction

Gentamicin sulphate (GENTA) is common antibiotic of choice due to its wide range of antibacterial spectrum against gram-negative and gram-positive bacteria (MIC 0.5-8 µg/mL), low level of resistance and rapid concentration-dependent bactericidal effect. Local GENTA concentration for prophylaxis against Staphylococcal species (spp.) must be in the range of 128 µg/mL to 200 µg/mL (MIC\textsubscript{90}%) [1], [2], [3]. Antibiotic loaded calcium phosphate bone cements (CPC) are widely used in orthopedic, while local antibiotic delivery helps to reduce the possible surgical site infection risk and the side effects from systemic antibiotic therapy [2]. Furthermore, the combination of CPC and antibiotics can provide dual-effect - induce bone regeneration and simultaneously prevent bacterial infections in post-surgery period. In vitro antibiotic release studies in deionized water (diH\textsubscript{2}O) from six clinically available CPC demonstrated that GENTA cumulative release varied from 36% to 85% and not all of the drug could be extracted within period of 21 days [4]. Numerous analytical methods have been developed for the determination of GENTA content in water solutions, including ultra-performance liquid chromatography equipped with evaporative light scattering detector (UPLC-ELSD), ultraviolet–visible spectroscopy (UV-VIS), mass spectrophotometry etc. [2], [5].

The aim of the current study was to prepare controlled release GENTA delivery systems based on the CPC and evaluate the GENTA release profiles within the period of 14 days. During the study two analytical methods (UV-VIS and UPLC) were developed and their applicability for the determination of GENTA release from CPC was evaluated. Moreover, influence of CPC matrix on the determination of GENTA release profiles was assessed.

Experimental Methods

Drug delivery system was prepared through mixing the α-TCP powder with GENTA containing sodium salt solution. GENTA containing cements were set for 24 h and placed into 1 mL of PBS (pH=7.4) at 37 and 100 rpm. All dissolution media (1 mL) were taken at appropriate intervals (24, 48, 120, 216 and 336 h) and used for the determination of GENTA release kinetics. GENTA release profiles from the prepared CPC were studied via UPLC-ELSD at λ=650 nm, using Aquity UPLC BEH C18 column and UV-VIS at λ=332 nm, using GENTA derivatization with o-phthalaldehyde.

Results and Discussion

Obtained results indicated that although UPLC-ELSD method is linear, accurate, precise, and robust towards the GENTA content determination in water solutions, when it comes to the analysis of GENTA content in CPC, interfering background signals twice bigger as the signal for GENTA (C\textsubscript{1}) peek were observed, thus making the analytical method not applicable for the determination of GENTA content in CPC matrix. For that reason, UV-VIS method was applied and no interfering signals coming from CPC matrix were found. The cumulative GENTA release from CPC was characterized by a burst release within the first 24 h (4.4 ± 0.2%) followed by a gradual stabilization of released GENTA (8.2 ± 0.3% (120h) and 11.7 ± 0.5% (336h)). During the research it was found that GENTA has substantial affinity to the CPC matrix, strongly influencing the active substance release into the PBS.

Conclusion

During the research it was established that UPLC/ELSD method could not be used for the characterization of GENTA release profile, if the drug is incorporated in the CPC matrix. According to the obtained results, the amount of GENTA
released from CPC, clearly exceeded the MIC for microorganisms (0.5-8 µg/mL) during the period of 14 days and released GENTA concentration showed no risk of cytotoxicity (<30 µg/mL) [1], [2], [3]. It was observed that CPC have the tendency to absorb the drug molecules, leading to presumption that only a part of the drug can be extracted from the CPC matrix, most likely due to the sulphate ion bound to the CPC via the Van der Waals interactions.

Chitosan functionalized with different ligands for the preparation of nanocarriers for active drug targeting

Marcel Popa1,2, Delia M. Rata1, Anca N. Cadinoiu1, Leonard I. Atanase1

1 Apollonia University of Iasi, Biomaterials, Iasi, RO; 2 Romanian Academy of Scientist, Bucharest, RO

Introduction
Conventional drug administration has well-known disadvantages: rapid variation of their concentration in the body or at the site of the disease, so that the duration of storage at the therapeutic level is short and requires repeated administrations, reaching high levels of concentration, can cause toxic side effects (cytotoxicity, neurotoxicity, nephrotoxicity) and fast development of cellular resistance, etc. The association of drugs especially with polymeric carriers, in nanoparticles (NPs) eliminates some of the disadvantages, ensuring a constant and longer release over time of the biologically active principle. However, even in these conditions, the systemic administration of drug carriers does not ensure the highest effectiveness due to reaching the affected areas only by passive target. Ensuring an active target is desirable and this effect can be obtained by achieving an interaction between the drug carrier and the site of the disease. Such an interaction can be performed if the receptor on the membrane of diseased cells is known, capable of recognizing a certain ligand on the surface of the drug carrier. Active drug targeting can be achieved by attaching specific ligands to the surface of nanocarriers that bind to specific molecules or cells. Generally, as specific ligands can be used: aptamers, antibodies, folic acid, and peptides.

Experimental Methods
To target respiratory disorders, CMCS was functionalized at the -COOH group by amidation with the amine group of two specific peptides, CGSPGWVRC and indolicidin (IN). The selection of the two peptides was made based on the fact that long endothelial cells have unique cell surface molecular characteristics that allow the binding of specific peptides, especially CGSPGWVRC peptides. The reaction took place first by esterification of CMCS with N-hydroxy succinimide (NHS) in the presence of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDAC) followed by amidation with the peptides. The amidation reaction was confirmed by FTIR and H-NMR spectroscopies. The peptide grafting yield, in both cases, is in the range of 1 to 10% as a higher functionalization degree is not desired because it will sterically hinder the amine groups of CS which are essential for the synthesis of the N/MPSs. For the active targeting of tumor cells, the aptamer AS1411-NH2 (Apt-NH2), recognizable by the nucleolin - receptor -, intensely expressed in the tumor cell membrane, was used as ligand. CMCS was functionalized in the presence of the EDAC / NHS system, by amidation of the amino group from the aptamer to the -COOH group from the CMCS. Schematically, the reaction is shown in fig. 1.

Results and Discussion
The structure of the aptamer-functionalized carboxymethyl chitosan (CCA) was characterized by FTIR, 1H, and 13C NMR spectroscopy. For the determination of the elemental composition of the product a scanning electron microscope equipped with an EDAX elemental analysis system has been used. It was found that in the aptamer-functionalized carboxymethyl chitosan (CCA) there are approximately 11% AS1411-NH2 aptamer, as illustrated in fig 2.

Conclusion
The obtained results prove the successful functionalization of the CMCS with different ligands which can be further use as precursors for the preparation of nanocarriers for the active drug targeting.

Introduction

Niosomes have gathered increasing interest in recent years as a self-assembled nanocarrier for transport and delivery of material to different human tissues\(^1\). The versatility of the particles associated to their stability make them an interesting choice for this purpose. Niosomes are able to encapsulate hydrophobic drugs such as epalrestat or form a nioplexe with DNA plasmids. The aim of this work was to explore the suitability of cationic niosomes for two different applications: topical ocular administration of epalrestat to counteract sorbitol accumulation in diabetic eyes\(^2\), and gene delivery towards immortalized human mesenchymal stem cells (iMSCs) for gene therapy\(^3\).

Experimental Methods

Niosomes were prepared combining Tween 60, cholesterol and DOTMA (7 and 15%) and applying a modified reverse phase evaporation method. The surfactant, helper lipid and charge modifier were dissolved in ethanol. Ethanol was removed leaving a thin film, which was subsequently hydrated with MilliQ water. Subsequently, the dispersion was sonified for 90 seconds to form niosomes. Empty niosomes can be loaded with epalrestat if it is added to the hydrating water or combined with plasmids to form nioplexes. Niosomes and their nioplexes with a reporter DNA plasmid (placZ) were characterized within a wide range of cationic lipid/DNA ratios. Transfection efficiency and cytotoxicity profiles from resulting nioplexes were evaluated in iMSCs cultures.

Results and Discussion

Niosomes loaded with epalrestat had a size of 104.5 nm, a PDI of 0.351 and a zeta potential of +15mV. The niosome size, PDI and zeta potential were stable over a month. Niosomes provided sustained release of epalrestat for several days. Empty niosomes complexed with a reporter DNA plasmid (placZ) had a size around 370 nm. Their transfection efficiency in iMSCs was comparable to the commercial reagent Lipofectamine while retaining a higher cell viability.

Conclusion

In both cases of drug delivery and gene delivery niosomes have particle size and surface charge to be considered as suitable carriers. Further experimentation will focus on permeation through ocular tissues for epalrestat loaded niosomes and the applicability of nioplexes in primary cell cultures of MSCs.

Multivalent fully biodegradable PEG-dendrimers as versatile nanotherapeutics: application in gene therapy

Victoria Leiro¹, Ana P. Spencer¹,², Natália Magalhães¹, Ana P. Pêgo¹,³

¹ i3S/INEB - Instituto de Inovação e Investigação em Saúde/Instituto de Engenharia Biomédica, Universidade do Porto, Porto, PT; ² FEUP – Faculdade de Engenharia, Universidade do Porto, Porto, PT; ³ ICBAS/FEUP, Universidade do Porto, Porto, PT

Introduction

Dendrimers are promising tools for the development of a plethora of nanotherapeutics, due to their intrinsic and unique structural characteristics: globular, well-defined, ultra-branched and controllable nanostructure, low polydispersity, and multivalency [1]. However, the repeated administration of non-degradable dendrimers can lead to toxicity due to their bioaccumulation [2]. In addition, in drug delivery applications, such as gene therapy, carrier stability can result in low biological performance due to an insufficient intracellular cargo (nucleic acid) release. Thus, biodegradable dendrimers have been eagerly awaited [3,4]. Here, we present a novel family of versatile, biosafe, water-soluble, and fully biodegradable PEG-dendritic nanosystems [5], which overcomes the limitations of the most used dendrimers, advancing the current state of the art of dendritic delivery systems and therapeutics. These new dendrimers display the possibility of multifunctionalization at both their dendritic arms and PEG end. Moreover, in this work, their function to serve as nucleic acid (siRNA) vectors for gene therapy is also thoroughly explored in several cell lines, including in hard-to-transfect neuronal cells even when in full tissue explants (dorsal root ganglia) [5b].

Experimental Methods

Fully biodegradable (fb) PEG-dendrimers were synthesized and later decorated at their arms, by click chemistry, with different amine groups. Moreover, these were further functionalized with a fluorescent tag (Cy5.5) at their PEG end, through a reactive functional group at their PEG end. All dendrimers and conjugates were characterized by NMR and FTIR.

siRNA dendriplexes were prepared at different N/P ratios (from 5 to 80). siRNA complexation ability of dendrimers was assessed by SybrGold® exclusion assay. The dendriplexes were characterized regarding size, polydispersion index (PdI) and zeta potential by dynamic light scattering, and their morphology was studied by transmission electron microscopy. Moreover, their ability to protect siRNA from endonuclease degradation was evaluated by polyacrylamide gel retention assay. Relative metabolic activity (resazurin), as well as haemolysis and coagulation assays in the presence of dendrimers and dendriplexes were evaluated in U2OS and ND7/23, and red blood cells, respectively. Cellular association/uptake and silencing assays were carried out in U2OS and ND7/23 cells expressing the fusion protein eGFP-Luciferase and evaluated by flow cytometry. Furthermore, their capacity to transfect embryonic dorsal root ganglion (DRG) explants was studied using confocal microscopy.

Results and Discussion

Generation 3 of fb PEG-dendrimers were successfully synthesized, characterized, and functionalized with: i) different amine moieties at their dendritic arms to allow the nucleic acid complexation; and ii) a fluorescent tag at the PEG end in order to be able to track their biological pathway by fluorescence techniques. This strategy ensures the suitable exposure of the corresponding PEG end-linked molecule to the surface of the dendritic nanosystems, and it is extrapolatable to many other molecules, such as targeting moieties. The developed amine-terminated dendrimers efficiently complexed and protected siRNA in dendriplexes showing sizes, PdI’s, surface charge and morphologies very suitable for cellular uptake, no toxicity in several cells and primary
neuronal cultures, and non-thrombogenic and haemocompatible character. Moreover, these fb nanosystems were successfully cell-internalized, including in hard-to-transfect neuronal cells even when in full tissue explants (dorsal root ganglia) (Figure 1). Importantly, full biodegradability was found crucial for an efficient nucleic acid intracellular release and attainment of excellent transfection efficiencies.

Conclusion

New versatile, biocompatible and fully biodegradable PEG-dendrimers, as well as their bio-function as nucleic acid vectors are presented. They allowed an efficient complexation and protection of siRNA, as well as a successful siRNA transfection in different mammalian cells, including hard-to-transfect primary neuronal cultures. Our fb dendritic nanosystems can be efficiently functionalized with different ligands at both their PEG end and dendritic arms, thus the present study puts forward then as versatile and targeted vectors for further developments in nanotheranostics.

Polyethylene glycol based-hydrogel synthesis and characterization for anti-inflammatory drug delivery

Sidzigui Ouedraogo¹, Arnaud Ponche¹, Laurent Pieuchot¹, Mathilde Grosjean², Benjamin Nottelet², Noëlle Mathieu³, Karine Anselme¹

¹ Université de Haute Alsace, Institut de Science des Matériaux de Mulhouse (IS2M), UMR 7361, Mulhouse, FR; ² Université de Montpellier, Institut des Biomolécules Max Mousseron (IBMM), UMR 5247, Montpellier, FR; ³ Institut de Radioprotection et de Sûreté Nucléaire (IRSN), Laboratoire de radiobiologie des expositions médicales (LRMed), Paris, FR

Introduction
Radiotherapy of abdomino-pelvic tumors induces in 20% of patient’s late side effects involving a chronic inflammation. This is accompanied by the depletion of the mucus layer and bacterial permeability [1]. No curative treatments are available. In the aim to provide a therapeutic solution to this inflammation, we develop a biodegradable self-rolled patch that could be applied locally by colonoscopy without surgery. This innovative biomaterial is based on the combination of hydrogel and elastomeric layers. The association of two different layers confers tunable mechanical and bio-resorption properties to the patch and allows the unidirectional release of anti-inflammatory drugs (AI): Budesonide and Prednisolone toward the ulcerated zone after its unrolling. Targeting anti-inflammatory drugs selectively to the inflamed zone may improve therapeutic outcomes and minimize systemic toxicity. Polyethylene glycol-based (PEG) hydrogels are choice biomaterials as scaffolds for drug delivery carries [2]. However, long-term drug release from PEG-based hydrogels remains challenging. Understanding the relationship between mesh size (ξ) and precursor solution composition is critical for the design of drug delivery hydrogel. Here we report a PEG-based hydrogel synthesis and nanostructure characterization to achieve long-term and efficient release of Prednisolone for the development of self-rolled patches.

Experimental Methods
An efficient solvent free microwave-assisted method is used to synthesize Poly(ethylene glycol) diméthacrylate (PEGDM) [3]. Proton nuclear magnetic resonance spectroscopy (H-NMR) is conducted to assess the efficiency of functionalization. Hydrogels are then formulated by photo-reticulation of the synthesized product (cure process parameters: UV (365 nm, 90µW/cm², 20min) in water with photo initiator Irgacure 2959). Particular attention is paid to modifying the molecular weight of PEG (6000 Da and 20,000 Da) and the concentration of PEGDM hydrogels to study the effects of these parameters on the nanostructure and the behavior of the hydrogels. For each molecular weight of PEG, three modalities of concentrations (10%, 30% and 50%) are selected. Equilibrium swelling ratios (Qs) of PEG-based hydrogels composition is measured and used in estimating the equilibrium polymer volume fraction (v²s) and mesh size (ξ) with equilibrium swelling theory at 37°C [4] [5]. To assess drug release, the formulated hydrogels are first loaded in concentrated drug solutions for AI impregnation. Then, loaded hydrogels are soaked in fresh PBS at 37°C for in vitro drugs release. The amount of Prednisolone release was quantified by Reverse Phase – Hight Performance Liquid Chromatography (RP-HPLC) coupled to UV light detection.

Results and Discussion
H-NMR analyses validate a simple, efficient, and fast method for the functionalization of PEG with methacrylate moieties with a chemical yield of more than 91% for the two sizes of linear PEG (6 and 20 kDa). Analysis of experimental data of the six formulated PEGDM hydrogels show a correlation between the mesh size of a swollen cross-linked network and its equilibrium polymer volume fraction (Figure 1) as established by Peppas and al. [5] on poly(vinyl alcohol) and poly(2-hydroxy ethyl methacrylate) networks.

Page 1331 of 2028
Formed hydrogels ensure an efficient AI encapsulation, with no chemical modification, and a release over seven days. Increasing hydrogel molecular weight improves the total amount of Prednisolone released (Figure 2).

**Conclusion**
Six different formulations of PEG-based hydrogels were synthesized and explored. The photo-crosslinked hydrogel synthesis protocol is validated.

This preliminary study provides a basis for the design of star-shaped block copolymer degradable hydrogels. The setting of the optimal mesh size is under study. Likewise, the work presented in this document will be also compared with the polymer-budesonide formulation.

Development of Fibrin Matrices for Sustained Drug Delivery

Karina Egle\textsuperscript{1,3}, Ingus Skadins\textsuperscript{2}, Arita Dubnika\textsuperscript{1,3}

\textsuperscript{1} Riga Technical University, Institute of General Chemical Engineering, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre, Riga, LV; \textsuperscript{2} Riga Stradins University, Department of Biology and Microbiology, Riga, LV; \textsuperscript{3} Headquarters at Riga Technical University, Baltic Biomaterials Centre of Excellence, Riga, LV

Introduction
Fibrin acts as a local reservoir for growth factors and as a provisional matrix to attract cells that support the regenerative process [1]. Commercially available fibrin matrices have an advantage of a simplified method for fibrinogen activation, bypassing the clotting cascade. Usually, a dual syringe applicator to combine fibrinogen solution with a thrombin-calcium chloride (CaCl\textsubscript{2}) solution is used [2]. Previous studies have not shown antibacterial efficacy for commercially available fibrin matrices. Infections are known to be a common phenomenon, so antibiotics are needed to reduce them. Because the resulting fibrin matrix is a good environment for microbial growth, the addition of antibiotics to one of the components of fibrin matrice has been shown to reduce postoperative infections [3]. The aim of this study was to find suitable parameters for obtaining a fibrin matrix that would retain its shape and cross-links over time. Also to study the effect of preparation technology on the properties of fibrin matrices and their ability to provide drug delivery. Two types of antibiotics were used in this study.

Experimental Methods
Samples were prepared from thrombin (from Bovine plasma), fibrinogen (from Bovine plasma) and 40 mM CaCl\textsubscript{2}. The 2-syringe method was used for uniform mixing. In order to find the most suitable preparation technology, the given samples were prepared using 3 methods:

\textit{Method 1} - Fibrinogen was mixed separately in a syringe with 1 mL CaCl\textsubscript{2} solution and in a second syringe thrombin with 1 mL CaCl\textsubscript{2} solution.

\textit{Method 2} - 1 mL of CaCl\textsubscript{2} was added to the fibrinogen to form a suspension 1. In another syringe, 1 mL of H\textsubscript{2}O was added to the thrombin to form a suspension 2.

\textit{Method 3} - Fibrinogen was mixed with 2 mL of CaCl\textsubscript{2} to form suspension 1 in a syringe. The thrombin weighed in the second syringe was then added to suspension 1, and the contents of the two syringes were mixed together. In all methods, the two substances were mixed together to obtain a homogeneous mass.

As for the drug, during preparation, it is added to fibrinogen and then mixed with thrombin-CaCl\textsubscript{2}. As drugs Vancomycin hydrochloride (V-HCl) (as modular material) and Clindamycin phosphate (CLP) were used. Samples were compared by gel fraction, drug release, swelling, and microstructure.

Results and Discussion
Less CaCl\textsubscript{2} solution in the sample provides more cross-linked sample and prevents it from losing shape over time. Examining the phase composition of the fibrin matrices, it was observed that the amount of added CaCl\textsubscript{2} is completely eliminated and does not form a separate intense peak in the sample. The gel fraction of V-HCl / fibrin matrices is 84.01 ± 0.54 %, which is higher than for CLP / fibrin matrices (72.84 ± 1.23 %) and for fibrin matrices without drugs (76.72 ± 0.91 %).

The swelling results showed that for drug-free fibrin matrices and CLP / fibrin samples, equilibrium was reached after 1.5 hours, while for V-HCl / fibrin matrices it was observed after 2.5 h. This confirms that the V-HCl / fibrin matrix samples are best cross-linked and does not allow water to disrupt the cross-links between fibrin matrix components. Also the release kinetics from samples with V-HCl and CLP were tested and results were compared. The release of
V-HCl from fibrin matrices was monitored for 312 hours (13 days). The results show that 77% of the total V-HCl was released during this time.

Conclusion
To obtain a fibrin matrice, CaCl₂ must be added first to the thrombin and then mixed with fibrinogen to form a homogeneous mass. V-HCl / fibrin matrices have the highest gel fraction, as in this case V-HCl acts as a crosslinking agent that improves crosslinking of the samples, but weakens CLP.

Poly(sebacic acid) as a carrier of azithromycin delivered via inhalation for the treatment of bacterial lung infections

Introduction

Conventional therapy methods of pulmonary bacterial infections – oral or intravenous administration of antibiotics – are not always effective due to limited drug delivery to the lower respiratory tract. Moreover, such treatment requires high doses of drugs that may cause side effects and the development of antibiotic resistance. One of the possible ways to solve these problems is to use biodegradable microparticles with a short degradation time as inhaled antibiotic delivery systems [1]. Poly(sebacic acid) (PSA) is considered material for such purposes thanks to its controllable degradation kinetics. This work aimed to obtain PSA microparticles (MP) with a diameter in the range of 1-5 µm, i.e. the optimal size for pulmonary administration via inhalation [2] loaded with azithromycin (AZ), i.e. the antibiotic used in the treatment of pulmonary infections. The second goal was to evaluate the encapsulation efficacy of AZ, characterize surface and microstructural properties of MP as well as to assess their compatibility with human lung epithelial cells.

Experimental Methods

PSA was obtained from sebacic acid via polycondensation. MP were manufactured using solid-in-oil-in-water (S/O/W) emulsification, where S: AZ in a different weight ratio to PSA; O: PSA dissolved in dichloromethane (DCM); W: water solution of poly(vinyl alcohol) (PVA). AZ was dispersed in PSA solution using ultrasounds. MP were obtained by adding the oil phase to the water phase and evaporation of the organic solvent under constant stirring. Then, MP were washed in UHQ-water to get rid of PVA residues, and freeze-dried. MP were observed using both optical and scanning electron microscopes (SEM) to assess their microstructure. Diameter size (Z-ave), polydispersity index (PdI), and zeta potential (ζ) were characterized via dynamic light scattering (DLS), while AZ encapsulation efficacy by using high-performance liquid chromatography (HPLC). Biocompatibility was evaluated using AlamarBlue assay and live/dead fluorescent staining on human lung epithelial cells (A549 and BEAS/2B) after 24 h contact with MP dispersed in Dulbecco modified Eagle’s medium (DMEM) at different concentrations.

Results and Discussion

Obtained MP were round and of regular shape. Their surface was smooth even at high magnification (fig. 1). The Z-ave were in the range of 1.46-2.45 µm, PdI was on average 0.3, and ζ value varied between -15.5 and -6.3 mV. Obtained values showed no correlation with AZ concentration.

The average sizes of MP may vary due to the limited repeatability of the emulsification method. However, Z-ave of all of the obtained MP were within the range of 1-5 µm, meeting the condition of an appropriate size for inhalation, as shown in fig. 1. Satisfactory drug loading was also obtained.

In vitro tests of PSA microparticles without the addition of AZ showed (fig. 2) that, depending on the type of cells, the MP are not cytotoxic at low concentrations: ≤ 100 µg/ml (A549) and ≤ 50 µg/ml (BEAS-2B). The LD50 (the dose causing 50% mortality) of MP for A549 and BEAS/2B cells was 359 µg/ml and 149 µg/ml, respectively.

Conclusion

The results of this study show the potential of PSA as a material for inhalable drug carriers in the treatment of pulmonary bacterial infections. Chosen manufacturing parameters allow obtaining uniform MP of sizes within the...
range required for inhalation. Regular shape and low roughness may suggest no progressive degradation in the process of MP formation. Manufactured MP were also cytocompatible with model epithelial lung cells, suggesting their potential usefulness as pulmonary drug delivery systems. Further studies will focus on evaluating the degradation of PSA matrix, drug release kinetics, and assessment of antimicrobial properties of the system.

Electrospun brinzolamide carrier – potential antiglaucoma drug delivery platform

Olga Cegielska¹, Paweł Sajkiewicz¹, Maciej Sierakowski²

¹ Institute of Fundamental Technological Research Polish Academy of Sciences, Laboratory of Polymers and Biomaterials, Warsaw, PL; ² Cardinal Stefan Wyszyński University in Warsaw, Institute of Biological Sciences, Warsaw, PL

Introduction
Pharmacological treatment of glaucoma is based on aqueous solutions and suspensions. Their precorneal residence time is very short, which results in low drug bioavailability and makes frequent dosing obligatory. The drug spreading over the eye is partially absorbed to the bloodstream, which further reduces the drug rate absorbed at the destination site [1].

In the last few years attention has been drawn to the potential nanofibers in ophthalmology [2,3]. Nanofibers are well known for providing sustained and controlled delivery of active ingredients [4]. Non-woven of any shape can be put near the pupil. When made of proper materials, they can be less prone to clearance and provide more localized delivery than traditional formulations [3].

An electrospun delivery system of poorly soluble antiglaucoma drug brinzolamide (BRZ) based on mucoadhesive hydroxypropyl cellulose (HPC), polycaprolactone (PCL) and beta-cyclodextrin (β-CD) has been formed. Cyclodextrins improve water solubility of hydrophobic ingredients, increasing its permeability to target tissues [5]. In combination with hydrophilic and hydrophobic polymer, a sustained drug delivery is expected to be achieved. To evaluate the drug delivery system potential basic studies of the nanofibers, complexation ability between cyclodextrin and brinzolamide, and permeability of brinzolamide through lamb corneas were performed.

Experimental Methods
HPC/PCL/β-CD/BRZ nanofibers have been formed via electrospinning from hexafluoroisopropanol solutions. Their morphology was studied using scanning electron microscope (SEM). Phase solubility study was performed on a series of aqueous solutions. Additional samples containing HPC beside BRZ and β-CD were prepared to evaluate HPC influence on complexation. After incubation in elevated temperature the samples were filtered and brinzolamide amount was measured using high performance liquid chromatography (HPLC).

Supramolecular structure study of the complex was performed using Fourier transform infrared spectroscopy with attenuated total reflection sampling technique (ATR FTIR) in search of changes in spectra compared to pure components indicating interaction between them.

Brinzolamide permeation from the nanofibers through lamb corneas was studied using Franz diffusion cells. Corneas with nanofibrous samples on top were mounted on acceptor chambers filled with phosphate buffered saline (PBS). Donor chambers were put on top and the cells were put in water baths on heated magnetic stirrers. At predetermined time points samples were collected and replaced with pure PBS. Commercial brinzolamide solution was tested for a reference; 15 repetitions were made for each delivery platform to obtain reliable data. Brinzolamide content in the samples was measured using HPLC.

Results and Discussion
Proper morphology fibers with a diameter from several dozen nm up to about 1 µm were obtained using selected processing/materials parameters.
Cyclodextrins increased brinzolamide solubility in PBS, although above a certain β-CD/BRZ ratio BRZ solubility started to decrease, probably due to complexes aggregation. HPC significantly increased brinzolamide solubility. The complex spectrum was similar to the pure β-CD spectrum; among others the peak corresponding to OH stretching vibration was narrowed and shifted, which is interpreted as evidence of a successful complexation. Permeation of BRZ from the nanofibers was slow and sustained. There was no burst release. Permeation profiles of BRZ from the nanofibers and commercial solution were similar. Considering large drug loss from the later and significantly reduced loss expected with the nanofibers, the system potential for a more effective prolonged delivery is very high.

**Conclusion**

Complexation takes place between β-CD and BRZ, favored by HPC. Effective gradual BRZ permeation from the nanofibers through animal corneas is achieved. In further study mucoadhesion of the nanofibers will be evaluated.

Quantitative assessment of the comparative nanoparticle-uptake efficiency in a range of biological fluids.

Tiago Santos1,3, Pedro L. Granja1,3, Zsombor Lacza2, Peter Hamar2

1 Universidade do Porto, Instituto de Investigação e Inovação em Saúde (i3S), Porto, PT; 2 Semmelweis, Department of Orthopaedics, Budapest, HU; 3 Universidade do Porto, Instituto de Engenharia Biomédica (INEB), Porto, PT

Introduction
Nanoparticles (NPs) potentially provide a powerful tool for specific treatments of diseases, acting as a drug delivery transport. However, a deep understanding and control of how NPs interact with biological systems is a key driver to assure the safe implementation of nanomedicine [1, 2]. The overall idea of this work was to provide new leads in the development of such a field, finding tools for various biomedical applications. What the biological cell actually "sees" when interacting with a nanoparticle will influence the mechanism of internalization. Thus, whether the cell is presented with the bare particle or the particle dispersed in a biological medium, thus covered by a protein corona, results in different uptake behaviour [3, 4].

Experimental Methods
For this project, multiple cell lines were used and the ultimate goal was to control and quantify uptake of a series of negatively charged carboxylate modified polystyrene of different sizes (20, 40, 100, 200, 500 and 1000 nm), understanding the endocytic pathways required for NPs internalization and their final sub-cellular destination, they were dispersed in different biological fluids (no serum, fetal bovine serum, human albumin, SPRF).

Results and Discussion
Although the depletion of serum during the exposure to NPs is quite accepted to lead to enhanced NPs deposition on the cell layer resulting in increased cell uptake, we have in our possession outstanding preliminary results that shows that serum fraction of platelet-rich fibrin (SPRF), presents an outstanding potential as source of proteins (for larger NPs-corbora complex). Indeed, our results show an increase on the NP uptake when compared to same-sized NPs in the serum free condition. Truly, from our knowledge this has never been previously described, therefore understanding the reasons for this abnormal uptake behaviour will lead to a better understanding on the mechanistic of endocytosis and consequently, to a better control and precise drug delivery. Also, in terms of the proteome profiler analysis, data from the serum of interest (SPRF) showed interesting differences in terms of pro and anti-inflammatory regulatory responses in which we intend to go deeper, in order to initially investigate what are the differences between the sera and therefore be able to explain the abnormal uptake behaviour mentioned in Fig 1.

Conclusion
We found that internalization of NPs is highly size-dependent for all cell lines studied, with the different cell types showing very different uptake efficiencies for the same materials. Moreover, our studies showed that, in a physiologically relevant environment, highly complex protein coronas are established and modulate biological effects at the nanoparticle-cell interface in an innovative way (Fig 1), which has important implications for nanomedicine.

Multifunctional ready-to-use starPEG-heparin cryogels for the sustained delivery of signaling proteins

Jana Sievers¹, Ralf Zimmermann¹, Jens Friedrichs¹, Dagmar Pette¹, Yanuar D. Limasale¹, Carsten Werner¹,², Petra B. Welzel¹

¹ Leibniz-Institut für Polymerforschung Dresden e.V, Dresden, DE; ² Technische Universität Dresden, Center for Regenerative Therapies Dresden, Dresden, DE

Introduction
Efficient, safe and spatiotemporally controlled delivery of signaling proteins, while avoiding adverse effects is a key factor for various biomedical applications, such as in vitro and in vivo tissue engineering or drug delivery. Besides conventional hydrogel-based systems, macroporous cryogels have gained increasing attention due to their attractive material properties, including injectability and effective supply of the cells with nutrients and oxygens. However, most of the reported cryogel systems, neither allow a sustained protein release, nor tuning of the release properties independently of other cell-instructive material properties or ‘off-the-shelf’ usability. Moreover, a detailed understanding of the implication of the cryogels’ macroporous architecture on signaling protein release is still missing.

To address these challenges, in this work a ready-to-use starPEG-heparin cryogel system, containing different amounts of the protein-affine heparin component, was developed and thoroughly investigated.

Experimental Methods
In extension to our previous work [1], a set of multifunctional cryogel scaffolds were prepared by covalently crosslinking end-functionalized multi-armed polyethylene glycols (starPEG) and the natural glycosaminoglycan heparin. For the evaluation of signaling protein release, both experimental analyses based on enzyme-linked immunosorbent assay and mathematical modeling based on a reaction-diffusion model were applied. A detailed characterization of the global and local material properties of the different cryogel scaffolds was performed using methods, such as scanning electron microscopy, atomic force microscopy-based nanoindentation and uniaxial compression measurements. Beyond that, signaling protein and cell adhesion-peptide pre-functionalized cryogels were prepared utilizing an additional lyophilization step and tested for their storability and ready-to-use potential. Therefore, the bioactivity of the loaded signaling proteins was investigated in in vitro neuronal differentiation experiments.

Results and Discussion
The potential of the developed cryogel system for systematically tunable long-term delivery of different signaling proteins is shown. We demonstrate that by varying the heparin concentration of the macroporous cryogels, a fine-tuning of the protein release kinetics was made possible, while keeping the structural and mechanical properties of the scaffolds constant. The experimental and theoretical analysis of the signaling protein delivery allowed us – for the first time – to show the impact of the unique macroporous cryogel structure on protein release, leading to local differences in protein concentration. These findings are truly relevant for the application scenario, as they enable better control over the specific signaling protein concentrations that cells within the cryogels or in their surrounding will be exposed to. As a proof-of-concept for their ready-to-use potential, the pre-functionalized cryogels, prior stored in the dehydrated state, were demonstrated to induce the neuronal differentiation of colonizing pheochromocytoma cells, thus confirming the bioactivity of the loaded proteins.

Conclusion
The here developed tunable starPEG-heparin cryogel system overcomes otherwise reported limitations of cryogels, i.e. too-rapid release, limited loading capacity, and insufficient control over the release characteristics. Together with
the ease of handling and mechanical stability, this makes our multifunctional cryogel system attractive as easily storable and applicable systems for precision delivery of signaling proteins in therapeutic in vivo or high-throughput in vitro applications.

Introduction
Infection as well as disturbed tissue regeneration after trauma are still challenging problems in surgery. Biomaterials as carriers for antibacterial as well as tissue inducing factors are needed to fight bacterial infection and on the other hand to induce tissue regeneration. Many materials exist, that could be used as carrier, but collagen is one of the most abundant proteins in the body and therefore a suitable biomaterial for Drug Delivery. However its stability is weak. Therefore, due to its weak stiffness and huge swelling degree the treatment with Rose Bengal and green light might improve the mechanical properties. A problem that might occur is that such a photochemical crosslinking could affect the activity of adsorbed biomolecules as well as drugs. To investigate the influence of RBX treatment, BMP-2, SDF 1α and Vancomycin were coated on two collagen scaffolds (Atelocollagen and Collagen Solutions) with subsequent light treatment and activity testing.

Experimental Methods
Collagen scaffolds were coated with BMP-2, SDF 1α and Vancomycin by adsorption and treated with rose bengal and green light. Scaffolds were incubated for different time points and release of bioactive molecules measured by specific ELISAs. The functionality of released BMP-2 and SDF-1 was tested on human osteoblasts and HUVEC, respectively, by viability assays. In case of BMP-2 the functional activity was also tested by the alkaline phosphatase activity (ALP). In case of SDF-1 migration assays were performed to demonstrate the still present chemotactic effect of SDF-1 after treatment with RBX.

or Vancomycin the coated collagens were investigated regarding their bacterial growth-limiting effect on Staphylococcus aureus.

Results and Discussion
Continuous release of bioactive molecules could be shown over 24 hours. This release was hardly effected by rose bengal crosslinking. Comparable to this results no effects on the inhibition capacity of bacterial growth was detected when collagen scaffolds coated with Vancomycin with or without following RBX treatment. Proliferation on both tested collagensheets increased after SDF-1 (HUVECs) or BMP-2 (human osteoblasts) relase. Although RBX treatment reduced this effect, it was still significantly higher when compared to original sheets without growth factors. Whereas humane osteoblasts showed a significant higher ALP activity on Collagen Solutions with BMP-2 (with or without RBX treatment) no differences were measured on Atelocollagen. Additionally no significant differences in the used concentrations (100 and 500 ng) were measured after RBX treatment. HUVECs showed a higher migration when tested with SDF 1α containing collagen solution scaffolds. Although this effect was again a little bit reduced after RBX treatment, it was still significantly higher when compared to non treated sheets. The SDF-1 effect on atelo collagen sheets was much less. This is the first study using human cells with RBX treated collagen sheets and demonstrating the functionality of bound growth factors after RBX treatment. We could show that the effect of RBX not only depends on each molecule or drug used but also on the scaffold. We detected differences in the effects of growth factors when bound to and released from collagen solution or
atelocollagen. For this reason it is important to evaluate the influence of the photochemical crosslinking method for each application. In this context the bioactivity of biomolecules was influenced by this treatment.

**Conclusion**

The use of RBX for crosslinking is a useful tool to improve the mechanical properties of collagen for Drug Delivery. It depends on the scaffold used whether the bound growth factor keeps its functionality. However, when using the "right" scaffold, this method can be further developed for creating laminates with different loadings for application in the treatment of open fractures after trauma.

Phytotherapeutic hybrid scaffold via combined 3D printing and electrospinning for antibacterial wound dressing

Irem Unalan, Aldo R. Boccaccini

Friedrich-Alexander-University Erlangen-Nuremberg, Institute of Biomaterials, Department of Materials Science and Engineering, Erlangen, DE

Introduction
Recently, a new family of hybrid scaffolds, which are fabricated via a combination of 3D printing and electrospinning techniques, have been prepared, which exhibit enhanced mechanical properties, biological activities, and extracellular matrix (ECM)-like three-dimensional (3D) structures for tissue engineering applications [1,2]. In this approach, electrospun nanofibers are included to support cell attachment while the scaffold structure is designed to mimic the natural ECM by 3D printed struts. In the present study, hybrid scaffolds further developed to provide biological functions and antibacterial activity to avoid the increasing prevalence of bacterial infections. In this regard, phytotherapeutics [3] such as essential oils (EOs) are considered alternative natural antibacterial agents to overcome the potential drawbacks of standard antibiotics [3].

Experimental Methods
This study's objective was to develop new strategies to fabricate phytotherapeutic containing hybrid scaffolds using a combination of 3D printing and electrospinning as a novel antibacterial wound dressing. In this study, firstly, polycaprolactone (PCL) struts were fabricated successfully by 3D printing. Then, EO-loaded PCL-gelatin (GEL) electrospun nanofibers were deposited on the printed PCL struts' surface. The physical and mechanical properties, total phenol content, antibacterial, the antioxidant and biological activity of the hybrid scaffolds were evaluated.

Results and Discussion
SEM images illustrated that the hybrid scaffold's morphology was uniform, bead-free nanofibers and a unit layer structure consisting of interconnected pores of ~410 μm size formed by the printed PCL structure. Also, our investigations indicated that hybrid scaffolds did not have cytotoxic effects on normal human dermal fibroblast (NHDF) and keratinocyte (HaCat) cells. On the other hand, the hybrid scaffolds exhibited antibacterial properties against S. aureus (gram-positive), and E. coli (gram-negative).

Conclusion
In conclusion, the novel family of phytotherapeutic hybrid scaffolds may have potential in wound healing applications and can be considered as a promising biomaterial for avoiding bacterial infections without using antibiotics.

Localized delivery of antibiotics through 3D core/shell hydrogel scaffolds to treat/prevent infections and promote healing of a chronic skin burn wound

Ashwini Rahul Akkineni¹, Janina Spangenberg¹, Michael Geissler¹,³, Hubert Buechner², Anja Lode¹, Michael Gelinsky¹

¹ Technische Universität Dresden, Medical Faculty Carl Gustav Carus of TU Dresden, Dresden, DE; ² Heraeus Medical GmbH, Wehrheim, DE; ³ Technische Universität Dresden, Institute of Natural Materials Technology, Dresden, DE

Introduction
Chronic skin wounds, as result of burns, are often prone to infections. Invasive bacterial infections caused by Staphylococcus aureus (gram positive), Pseudomonas aeruginosa and Acinetobacter (gram negative) at the wound site are found to be leading cause of death in burn patients. Additionally, development of antibiotic resistant bacteria such as methicillin-resistant Staphylococcus aureus (MRSA) in recent decades had further complicated treatment of skin wound infections caused by burns [1].

Current clinical care of infected chronic burn wounds include systemic and topical treatments for managing pain and infection at the injury site along with facilitating skin regeneration by excision and grafting (with allografts or skin substitutes). Traditional, systemic administration of antibiotics is usually associated with inadequate local availability of the drug, thus not being effective in deterring aggressive infections. Whereas inhibitory concentration of antibiotics can be achieved by topical application - leading to effective management of the infection. However multiple applications are needed to maintain a minimum inhibitory concentration to completely eradicate the infection and its recurrence. To overcome these challenges, our current work explores the many capabilities of 3D core/shell bioprinting to locally deliver desired concentrations of antibiotics through 3D bioprinted hydrogel scaffolds.

Experimental Methods
High viscous ink alginate/methylcellulose (ALG/MC [2]) and alginate/methylcellulose/laponite (ALG/MC/LAP [3]) along with low concentrated alginate (3% w/w) were used as shell and core parts, respectively. The core ink was loaded with 10 mg/ml antibiotics (Vancomycin, Clindamycin and Gentamicin). Scaffolds consisting of individual antibiotics were fabricated using core/shell 3D extrusion printing technique [4]. Release of the antibiotics was quantified by a semi-quantitative method i.e. agar diffusion assays. Briefly, antibiotic loaded scaffolds were incubated in 0.9% saline solution at 37°C. At specific time intervals (2 h, 6 h, 1, 2, 3 & 7 days) the release solution was collected and 20 µl each were added onto a sample carrier. The sample carrier was placed on an agar plate previously colonized with S. aureus, and incubated at 36°C for 18 h. The released antibiotic would diffuse into the surrounding agar creating a zone of inhibition (ZOI) as the bacteria are killed by the antibiotic around the sample carrier. The ZOI was found to be directly proportional to the amount of antibiotic in the release solution, hence a standard curve was developed by plotting area of ZOI for known antibiotic concentrations which was used to quantify the antibiotic concentration in the release solutions.

Results and Discussion
Antibiotics loaded hydrogel scaffolds were successfully fabricated by core/shell3D extrusion printing technique (Fig. 1A-C). Over a period of 7 days, all the antibiotics were released in biologically active form. It appears that the cumulative release of Vancomycin was highest compared to Clindamycin and Gentamicin. The release of Vancomycin and Clindamycin was sustained and significantly lower when ALG/MC/LAP ink was used to fabricate
the scaffolds. A complete arrest of Gentamicin release was observed for ALG/MC/LAP scaffolds. Furthermore, by changing the core and shell dimensions, it was shown that release kinetics of antibiotics can be varied.

**Conclusion**

In our current work, we could successfully print 3D core/shell hydrogel scaffolds with various antibiotics loaded in the core. Their release in inhibitory concentrations was observed till 7 days, indicating sustained release characteristics. Inclusion of the nanoclay laponite in inks further significantly reduced the burst release of loaded antibiotics. Furthermore, release kinetics could also be tuned by simply changing the dimensions of the printing needles. It can be envisioned that such a versatile delivery system could potentially open new strategies to treat skin burn or wound infections.

Evaluation of the co-adjuvant antimicrobial effect of lyocell/silver knitted fabrics modified with Nisin Z

Tânia D. Tavares1, André Catarino1, Carla Silva2, Joana C. Antunes1, Helena P. Felgueiras1

1 University of Minho, Centre for Textile Science and Technology, Guimarães, PT; 2 University of Minho, Centre of Biological Engineering, Braga, PT

Introduction
The resistance of bacteria to traditional antibiotics is raising a serious global public health problem with huge economic and societal consequences. Antimicrobial peptides (AMPs) have been raising great interest as alternatives to antibiotics. Nisin Z belongs to the lantibiotics class of AMPs and is produced by the non-pathogenic bacteria Lactococcus lactis. This AMP has a significant antibacterial activity against Gram-positive bacteria [1]; however, its activity against Gram-negative bacteria is limited and can be improved with the addition of the non-antibiotic chelating agent ethylenediaminetetraacetic acid (EDTA), known to assist in cell permeabilization [2]. Nisin Z has been mostly studied for food preservation applications, with very little research being done on its potential for biomedicine. Lyocell is the only regenerated cellulosic fiber known as green and renewable that resorts to commercial eco-friendly manufacturing processes. The combination of lyocell and silver, recognized for its antibacterial effectiveness, in textile dressings, has been shown effective against bacteria colonizing chronic wounds [3]. The purpose of this work is the functionalization of silver-enriched lyocell knitted fabrics with Nisin Z, in the presence and absence of EDTA, against two of the most common Gram-negative bacteria present in chronic wounds, Escherichia coli and Pseudomonas aeruginosa.

Experimental Methods
MIC of Nisin Z-EDTA against E. coli (ATCC 25922) and P. aeruginosa (ATCC 25853) was assessed by the broth microdilution method [4]. Testing started with Nisin Z at 4 mg/mL and EDTA at 200 µM, both prepared in distilled water (dH2O). Nisin Z was serial diluted (1:2) in Mueller Hinton Broth (MHB) to a final volume of 25 µL. EDTA was used at equal volume and combined with the peptide. Finally, 50 µL of the bacteria suspensions prepared at 2×10⁷ CFUs/mL in MHB were added. Free Nisin Z, free EDTA, agent-free bacteria suspensions and culture media were used as controls. Samples were incubated for 24 h at 37ºC and 120 rpm. MIC was established as the concentration at which bacteria did not show any growth.

Lyocell spun yarns with 150 dtex and silver-plated polyamide multifilament yarns with 33-44 dtex were used to produce seamless weft fabrics via knitting machine MERZ model MBS, with a E28 gauge, diameter of 33.02 cm and 1152 latch needles. Lyocell (control) and lyocell/silver-plated fabrics were engineered. Fabrics were characterized via bright field microscopy (fabric pattern) and Fourier-transform infrared spectroscopy (FTIR, chemical structure). Nisin Z with and without EDTA addition was immobilized onto the engineered fabrics at 2×MIC via dip coating. Fabrics were immersed for 72 h at 120 rpm in the Nisin Z or Nisin Z-EDTA solutions for complete saturation. Loading amount was verified by UV-visible spectroscopy. Weakly bonded molecules were eliminated with dH2O washes. Kirby-Bauer diffusion testing and time-kill kinetics studies, up to 24 h of incubation, were conducted with the two microbial cells in MHB.

Results and Discussion
MICs for Nisin Z-EDTA against E. coli and P. aeruginosa were determined at 31.25 and 62.5 µg/mL, respectively; without EDTA, Nisin Z only exhibited activity against E. coli, and at 250 µg/mL. As seen, the activity of Nisin Z against Gram-negative bacteria is limited, particularly against P. aeruginosa, requiring EDTA to destabilize the outer bacterial membrane and facilitate peptide permeabilization [2].

Page 1350 of 2028
Seamless fabrics with a defect-free and uniform pattern were successfully produced from lyocell and lyocell/silver-plated yarns. Here, silver was used as an additive with the goal of preventing cell overexposure to its ions and, consequently, cytotoxic effects (considering the purpose of the final application). Cellulose characteristic chemical groups were detected via FTIR, confirming the fabric composition and presence of free -OH groups. Binding with Nisin Z and EDTA via hydrogen bonding was confirmed as well by UV-vis spectroscopy. The antimicrobial potential of the modified fabrics was also verified. Diffusion of the functionalized active cues against the two microbial cells was observed in the lyocell-based fabrics, with a formation of a halo. Yet, their combination with silver was more effective (halo 2x larger). Similar observations were made via time-kill kinetics studies, with Nisin Z-loaded lyocell/silver fabrics being quicker in acting against the selected microorganisms. EDTA was seen to play a determinant role against *P. aeruginosa*.

**Conclusion**

Data revealed that the addition of EDTA with Nisin Z is essential to improve its activity against Gram-negative bacteria. Overall, the potential of these fabrics and peptide to work in synergy for prospective wound dressing applications was demonstrated.

New gels preparation based on peptide-peptide co-assembly

Alexandra Croitoriu, Loredana E. Niță, Alexandru Serban, Alina G. Rusu

Petru Poni Institute of Macromolecular Chemistry, Iasi, Romania, Department of Natural Polymers, Bioactive and Biocompatible Materials, Iasi, RO

Introduction
Low molecular weight gelling agents (LMWG) are small molecules that can associate following a hierarchical process of self-assembly forming 3D networks generated by non-covalent interactions. Different molecular entities, such as organic molecules, proteins, peptides and DNA, have the ability to create complex structural systems through spontaneous diffusion and specific association between molecules, dictated by non-covalent interactions. The versatility of the amino-acid structures provides flexibility in the design of the peptide chains. Peptides can perform specific biological functions due to their structure and ability to assemble. Among the multiple self-assembled peptide hydrogels reported to date, phenylalanine-derived nanostructures provide efficient aromatic core self-assembly. Spontaneous self-assemblies in aqueous solution consist of peptide nanotubes from individual entities with unique properties and the technique approached was that of the pH switch. Taking into account these aspects, this study aims to prepare different gels by co-assembly of peptides derived from phenylalanine with other peptides. The final purpose is to obtain structures with double function: capacity for hydrogelation and antimicrobial character.

Experimental Methods
The technique approached was that of pH switch. Thus, peptide (Fmoc-Ph-Ph) was dissolved in a NaOH solution. In the next step, HCl or citric acid was added until the pH is neutralized. In parallel another peptide (Fmoc-Lys) was dissolved following the same procedure. The two peptides were mixed by using two approaches: in the first approach the solution of peptide was mixed immediately after the preparation. In the second approaches the peptides solution was mixing after 30 minutes (to allow time for the formation of the self-assembly process to begin and then to start the co-assembly process) (Figure 1).

Results and Discussion
The ability to self-assemble of phenyl peptide, as well as to co-assemble with other peptides was evaluated by combining different characterization techniques such as FT-IR, SEM microscopy. The gels obtained by the use of peptide as LMWGs, show stability, withstanding the vial inversion test (Figure 2).

Conclusion
The study results evidenced the dependence of the hydrogel formation on more than only one single factor. The self-assembly process of peptides derived from phenylalanine was generated by the hydrophobic π-π interactions of the fluorenyl moieties, and hydrogen bonds from the carbonyl group. The co-assembly process was evidenced by FT-IR spectroscopy and SEM microscopy. All resulted data support the formation of inter- and intra-molecular physical bonds that ensure the formation of fibrils and their organization in the 3D network. The swelling studies confirmed the superabsorbent nature of the prepared hydrogels, and recommend the systems for incorporation into the network matrix of drugs by diffusion process.

Infection-resistant medical device technologies from sustainable sources

Zili Ji, Nicola Irwin, Colin McCoy, Eneko Larraneta, Louise Carson

Introduction
Infection caused by bacterial colonization is the most common and serious challenge associated with biomedical devices, which harms patients' health and poses a significant financial burden to healthcare systems. Lignin is a low cost, readily available naturally occurring material which has shown great prospects in its antimicrobial activity 1. In addition, hydrogel polymer systems have been investigated as coating materials due to their reported biocompatibility 2, and their low friction surfaces can efficiently decrease the trauma caused by the devices during insertion, and removal from the body. It is therefore of great interest to develop lignin-loaded hydrogel systems that would combine the benefits offered by hydrogels and lignin to use as efficient anti-infective coating materials for the surface of biomedical devices. The aim of this study is to investigate the anti-infective properties of lignin-loaded hydrogels as candidate antibacterial coating materials for medical devices. The antibacterial properties of lignin-loaded hydrogels were compared with those which loaded with tetracycline hydrochloride, a widely used broad spectrum antibiotic.

Experimental Methods
A series of lignin-loaded (0, 1, 5 and 10 wt%) hydroxyethylmethacrylate-co-methacrylic acid copolymer systems were prepared by free radical polymerization. Some of the copolymers were additionally loaded with tetracycline hydrochloride (TET) to evaluate their drug loading and drug release ability, and also indicates antibacterial property of lignin as comparison. Lignin-loaded polymers were compared using Fourier Transform Infrared Spectroscopy (FTIR), scanning electron microscopy (SEM), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC) and static contact angle measurement. Equilibrium swelling analysis and in vitro pH-mediated drug release were also performed. Antibacterial properties of the polymers, TET-loaded polymers and silicone discs, as controls, were assessed in zone of inhibition (ZOI) test and bacterial adherence test incubated with Proteus mirabilis ATCC 51286 and Staphylococcus aureus ATCC 29213. Minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) tests of TET against P. mirabilis and S. aureus were also performed.

Results and Discussion
ATR-FTIR analysis confirmed polymerization of the polymers. From SEM results, lignin-loaded copolymers demonstrated relatively even surfaces in comparison with silicone. DSC and TGA results show that lignin-loaded polymers degraded at higher temperature, which indicates their better thermal stability. The water contact angle of the copolymers was measured as within the range of 50°-75°. The copolymers exhibited pH-dependent swelling behaviors, and their water content plateaued by 48 h. In pH 9 buffers, the swelling rates of all the polymers and amount of released lignin of lignin-loaded polymers were much higher than those in pH 6 buffers. Zone of Inhibition test results indicated that the presence of TET significantly increased the zone size against both bacteria. The average zone diameter against S. aureus was 2 cm, while against P. mirabilis the zone diameter was approximately 0.4 cm. No clear zones were shown in the non-TET-loaded group. The MIC value of TET against S. aureus was tested to be 0.63 mg·L⁻¹ and for P. mirabilis was 78 mg·L⁻¹. The TET-loaded samples successfully reduced the bacterial adherence of S. aureus to below the limit of detection (LOD) after 4h and 24h incubation. Similarly, lignin-loaded polymers significantly decreased the relative bacterial adherence to below the LOD after 24 h incubation. Lignin-loaded polymers reduced planktonic cells and bacterial adhesion as TET-loaded samples after 24 h incubation.
Conclusion

The surface properties of the copolymers confirm their potential to be used as candidate hydrophilic coating materials for urinary catheters. The highly thermal stable copolymers reveal their potential for sustained release of loaded drug to urinary tract and indicate their ability to tolerate typical physical sterilization methods. The copolymers will also be stable during storage and under less risk during fabrication. Their pH-mediated swelling behaviors can be used as a factor to predict the drug release patterns of drug-loaded copolymers in urinary tract under infected and normal conditions. The finding of microbiological assessments indicated that released lignin possesses the ability to kill planktonic \textit{S. aureus} cells and inhibit the bacterial adhesion on the polymer surfaces. This work suggests that lignin-loaded polymers can be used as alternative biomedical device coating materials to reduce the device related infections in a low cost, sustainable and greener way.

Introduction
Chronic wounds such as diabetic ulcers represent a major healthcare problem. Infection by antibiotic-resistant bacteria contributes greatly to wound chronicity and is responsible for 33,000 estimated deaths per year in the European Union. Current treatments based on iodine and silver antiseptics or topical and oral antibiotics are inefficient, toxic, or may induce resistance. Therefore, alternatives are urgently needed. Antimicrobial peptides (AMP) are a promising alternative, as they act through non-specific mechanisms and cause virtually no resistance. In this work, we developed AMP-grafted poly(D,L-lactide-co-glycolide-polyethylene glycol (PLGA-PEG) nanoparticles. AMP grafting will increase stability, local concentration and infection targeting due to AMP cationic character. MSI-78(4-20) was used as active peptide. This short AMP is a cost-effective and highly selective compound, which maintains activity when grafted to polymer surfaces¹².

Experimental Methods
MSI-78(4-20)-PLGA-PEG NPs composed of PLGA-PEG and PLGA-PEG-maleimide (PLGA-PEG-Mal) were produced by nanoprecipitation and functionalized with cysteine-modified MSI-78(4-20) through a thiol-maleimide Michael Addition reaction. The obtained NPs were characterized in respect to their size distribution, zeta potential and AMP grafting through AMP quantification using the fluorescamine assay, Fourier-transform infrared spectroscopy (FTIR) and nuclear magnetic resonance (NMR). Antimicrobial activity was assessed against Pseudomonas aeruginosa and Staphylococcus aureus, two of the most common pathogens in chronic wounds using minimal inhibitory and bactericidal concentration (MIC and MBC) assays.

Results and Discussion
NPs with approximately 100nm in size did not change significantly upon AMP covalent binding, while an increase in surface charge from -2.8mV ± 0.8 to 8.6mV ± 1.8 was observed. FTIR showed the characteristic peaks of the AMP and NMR displayed a significant decrease of the Mal peak, confirming covalent tethering. AMP maintained antimicrobial activity when bound to the NPs with a MIC and MBC of 8-16 mg/mL and 16-32 mg/mL, respectively against P. aeruginosa, and 32-64 mg/mL and 64->64 mg/mL against S. aureus.

Conclusion
The AMP MSI-78(4-20) was successfully grafted onto the surface of PLGA-PEG NPs maintaining antimicrobial activity against P. aeruginosa and S. aureus. These data support that the formulation may be useful for future treatment of infected chronic wounds.

The authors also acknowledge the support of BN - Biointerfaces and Nanotechnology i3S Scientific Platform were FTIR and DLS were performed.

Zeta-potential of AMP-PLGA-PEG NPs

AMP-PLGA-PEG NPs were produced using different percentages of PLGA-PEG-Mal (10%, 20% and 40%). Surface charge increases with increased amounts of PLGA-PEG-Mal suggesting an increase in functionalization. The adsorption control sample (40%AMPads) also presents an increase in charge suggesting that a small portion of the peptide may not be covalently linked, however, results for this sample are highly inconsistent, demonstrating that covalent binding is a better strategy than adsorption.

1H NMR spectra (400 MHz, CDCl3) of AMP-PLGA-PEG-NPs

AMP signals from the peptide could not be detected in the 1H-NMR spectrum (neither in CDCl3 (C) nor in DMSO-d6), due to the very small amounts of peptide linked. However, it was possible to observe the disappearance of the signal corresponding to the maleimide protons of the NP (6.75 ppm, identified with a red rectangle), which indirectly indicates the conjugation of AMP to the NPs.

Design of multi-functional PVC coating addressing the polymicrobial nature of Ventilator-Associated Pneumonia

Tânia Grainha, Diana Alves, Eugénia Nogueira, Maria O. Pereira

University of Minho, Centre of Biological Engineering, Braga, PT

Introduction
Ventilator-associated pneumonia (VAP) is a common nosocomial infection and presents a serious concern due to the high mortality and morbidity rates associated [1]. The presence of the endotracheal tube (ETT) is a risk factor for developing VAP because its surface is prone to microbial adhesion. Microbial adhesion to surfaces and consequent biofilm formation remains one of the greatest current challenges in healthcare, when microorganisms are able to reach the surface of medical devices, such as ETT, becoming the focus of persistent infections [2]. Studies have demonstrated that most biofilms associated with VAP are composed by polymicrobial communities. In general, mixed bacterial and bacterial-fungal biofilms are more resistant to antibiotic treatment than the corresponding individual biofilms. Thus, aggressive and extended antibiotic therapies may be needed to control VAP. The major concern related with this approach is the development of resistance towards antibiotics.

An alternative to deal with VAP relies, therefore, on the use of preventive measures. Given the recognized role of ETT on VAP development, one promising approach is to prevent ETT colonization through the modification of the surface materials used to design these medical devices [3].

This work aims to develop an effective strategy to fight VAP, targeting its polymicrobial nature. Accordingly, the goal is to functionalize poly(vinyl) chloride (PVC) surfaces using a polydopamine (pDA)-based strategy, in order to prevent the adhesion and biofilm formation of three important VAP-related pathogens: Pseudomonas aeruginosa, Staphylococcus aureus and Candida albicans. For that, different compounds were individually tested against single-species biofilms encompassing these pathogens.

Different compounds were firstly screened in order to characterize its antimicrobial action towards the three pathogens. The most promising were further used to functionalize PVC following two approaches: direct incorporation on the surface and indirectly through the attachment of compound-loaded liposomes. This latter strategy is being explored as an attempt to achieve a more controlled drug release, reduce the dosages and minimize eventual side effects caused by the antimicrobials. The final goal is to engage, individually or in dual or even triple combinations, the most promising compounds in the design of a broad-spectrum antimicrobial surface. This safe-by-design multi-functional surface will be tested against single-, dual- and triple-species biofilms.

Experimental Methods
PVC surfaces were functionalized with Farnesol, Ciprofloxacin and Amphotericin B using the pDA approach. Briefly, each antimicrobial compound was firstly dissolved with dopamine, being the PVC coupons immersed in the final solution. Dopamine polarization allowed antimicrobials incorporation throughout the thickness of the pDA film formed. The antimicrobial capability of the polydopamine-mediated antimicrobial PVC surfaces was tested against P. aeruginosa, S. aureus and C. albicans, the most prominent VAP-related pathogens, inspecting different concentrations of each one of the antimicrobial compounds. After a contact of 24 h, the number of viable cells adhered to the surfaces was enumerated.

Ciprofloxacin and Amphotericin were also encapsulated in liposomes and the antibiofilm potential of these liposomal formulations were inspected so far for single-species biofilms.

Results and Discussion
Farnesol, Ciprofloxacin and Amphotericin B were successfully immobilized onto PVC surfaces using pDA-based strategy and these modified surfaces displayed anti-biofilm potential. Farnesol was able to reduce S. aureus biofilm formation leading to more than 5-log₁₀ CFU reduction while Amphotericin B was effective against C. albicans ceasing its growth. Moreover, Ciprofloxacin displayed promising results by inhibiting both P. aeruginosa and S. aureus single-species biofilms, reaching more than 6-log₁₀ CFU reduction and total eradication, respectively. Ciprofloxacin and Amphotericin B were effectively encapsulated in liposomes and these antimicrobials-loaded nanocarriers showed promising results by reducing biofilm formation. Liposomal Ciprofloxacin reduced biofilm forming ability of S. aureus and P. aeruginosa while liposomal Amphotericin B reduced C. albicans biofilm formation. Although preliminary, both liposomal formulations demonstrated potential to be further used in the functionalization of PVC surfaces.

Conclusion
In conclusion, dopamine chemistry was successfully applied in the functionalization of PVC surfaces. Immobilization of Farnesol, Ciprofloxacin and Amphotericin B proved to be a promising approach to be further applied in the fight of VAP once they displayed high antimicrobial activity against single-species biofilms. The following steps will include the binding of the compounds in dual and triple combinations for broadening the antimicrobial spectrum of the polydopamine modified PVC and the study of its performance towards multi-species biofilms.

Investigation of Antimicrobial Coatings for Endotracheal Tubes to Prevent Ventilator-Associated Pneumonia

Jia Li, Matthew Wylie, Nicola Irwin, Louise Carson, David Jones, Colin McCoy

Queen's University Belfast, School of Pharmacy, Belfast, GB

Introduction
Ventilator-associated pneumonia is a major type of hospital-acquired infection and is a frequent cause of mortality and morbidity in Intensive Care Units (1). Endotracheal tubes help patients breathe but can also lead to infection due to the bacterial biofilm formed on the surface (2). This study describes development of a strategy for coating of endotracheal tubes to delay or prevent biofilm formation.

Experimental Methods
Copolymer hydrogels were polymerized from 2-hydroxyethyl methacrylate (HEMA) and methacrylic acid (MAA) in different proportions (80:20 and 70:30%w/w), as reservoir coatings. Two different antibiotics, gentamicin and levofloxacin, were loaded into the coatings by immersed in gentamicin solution (50mg/ml) and levofloxacin solution (10mg/ml) for 48 hours. Copolymers loaded with gentamicin and levofloxacin were characterised in terms of drug release and resistance to microbial adherence.

Results and Discussion
The release of gentamicin and levofloxacin from the hydrogels were rapid, with 50% release occurring within the first 5 hours. Both coatings loaded with gentamicin and levofloxacin displayed anti-adherence properties against Staphylococcus aureus (ATCC29213) and Pseudomonas aeruginosa (LMG679) that both hydrogels were able to produce a 100% reduction in adherence over 24 hours (Figure 1).

Conclusion
Coatings for endotracheal tubes loaded with gentamicin or levofloxacin displayed good short-term microbial anti-adherent properties which can provide a platform to reduce the incidence of ventilator-associated pneumonia.

New natural solvent improves beta-lactam antibiotic efficacy

Belén Olivares¹,², Bernardo J. Morales³, Fabián A. Martínez⁴, Paola R. Campodónico¹, Marcelo Ezquer¹

¹ Universidad del Desarrollo, Instituto de Ciencias e Innovación en Medicina, Santiago, CL; ² Universidad Nacional de Cuyo, Programa de Doctorado en Biología, Mendoza, AR; ³ Universidad Pedro de Valdivia, Facultad de Ciencias de la Salud, Santiago, CL; ⁴ Universidad de Santiago de Chile, Laboratorio de Resonancia Magnética Nuclear, Santiago, CL; ⁵ Universidad del Desarrollo, Instituto de Ciencias e Innovación en Medicina, Santiago, CL; ⁶ Universidad Nacional de Cuyo., Programa de Doctorado en Biología, Mendoza, AR

Introduction

World Health Organization declared bacterial infections by resistant pathogens a global crisis and place it among its priority lines of research. The aim of the present work is to improve the antibacterial efficacy of available molecules. We focus on beta-lactam antibiotics, a very useful therapeutic class of antibiotics, but unstable in the aqueous solvents of conventional formulations. That condition represents a clinical problem leading to therapeutic failure and antimicrobial resistance. We designed a new vehicle based on a natural deep eutectic solvent consisting on betaine and urea (BU). BU is capable of improving the stability of some beta-lactams including imipenem (IMP) the most unstable of the beta-lactam family. The main goal of the present work is to evaluate the therapeutic efficacy, the kinetics of release of IMP dissolved in BU, and evaluate the in vitro toxicological and immunogenic profile of the new solvent. Furthermore we studied the protective mechanism of the effect observed.

Experimental Methods

Killing curves of Pseudomonas aeruginosa incubated at 37°C, with IMP dissolved in BU in comparison with its aqueous solutions. Viability measures were made counting bacteria by flow cytometry using SytoBC®/propidium iodide. The kinetic of IMP release was evaluated using a diffusional test based on a bicameral devise model and data were analyzed applying Peppas Krosmayer equation. Cytotoxicity was evaluated measuring viability of primary fibroblasts cultures exposed to BU. The immunogenicity was evaluated through a human monocytic cell line THP-1 model measuring the expression of TNF and IL-6 using lipopolysaccharides as a proinflammatory positive control. The mechanism of intermolecular interaction was studied by selective NOESY H¹ - H¹ Nuclear Magnetic Resonance (NMR) applied to IMP-BU solution.

Results and Discussion

IMP-BU reduced the P. aeruginosa counting units forty times compared to IMP aqueous solution (mean and SEM 1.87x10⁷ ±3.91x 10⁶ and 7.5x10⁸ ± 3x10⁷ respectively) in 24 hours. The value of the diffusional coefficient obtained (n=1,01) indicates a case II release, consisting in a linear and progressive kinetic release. On the other hand, the cytotoxicity assay of BU showed an IC50 of 59.4 mg/ml,wich is higher than the reported for others solvents of this class. Furthermore the proinflammatory citokines expression levels indicates no inmunogenic response of BU. Finally the NMR analysis indicated especific interactions between de drug and the molecules of the solvent.

Conclusion

BU could represent a new biosafe funcional excipient to maintain IMP stability and therefore improve its efficacy.

PolyVax: Polymeric Nanoparticles as mRNA vaccines for prophylaxis and cancer therapeutics

Cristina Fornaguera, Coral Garcia-Fernandez, Laura Olmo, Marta Díaz-Caballero, Marta Guerra-Rebollo, Salvador Borrós

Institut Quimic Sarria (IQS) - Ramon Llull University (URL), Grup d'Enginyeria de Materials (Gemat), Barcelona, ES

Introduction
Vaccination has been one of the main success of modern society, remarkably improving the human beings’ half-life thanks to the eradication of many infectious diseases. Traditional vaccines were composed of entire or fractions of the infectious agent. However, they account with unsolvable disadvantages, such as safety issues and low immunogenic potential that requires the addition of adjuvants. In this context, the use of mRNA for immunizing purposes has shown an enhanced performance, as demonstrated by the very fast approval of two mRNA vaccines preventing SARS-CoV-2 infection. Beyond success in preventing viral infection, mRNA has also spread the use of vaccination for therapeutic cancer applications, and currently, the bibliography demonstrating research studies using mRNA vaccines is huge. Nevertheless, the tech transfer is still limited. In this context, PolyVax aims to solve current issues of mRNA vaccines by the development of a mRNA vaccine based on proprietary patented polymeric nanoparticles, with demonstrated safety, efficacy and selectivity to immune target cells.

Experimental Methods
Nanoparticles with a selective transfection to dendritic cells, encapsulating spike antigen epitopes or tumor associated antigens mRNA were synthesized and lyophilized by a simple, scalable and GMPzable process. Their safety and efficacy were tested in vitro and in vivo. Biodistribution of different routes of administration and specific immune response generation was tested in healthy mice.

Results and Discussion
Based on our experience of biomaterials engineering, we developed a library of oligopeptide-end modified poly (beta aminoesters) (OM-pBAE) by two-step Michael addition of primary amines to acrylates, followed by oligopeptides end capping. These proprietary OM-pBAE demonstrated high efficiency on the encapsulation of various mRNA encoding for different proteins (antigenic and reporter), by electrostatic interaction between the cationic polymers and the anionic nucleic acid, for the formation of small nanometric (<180nm) nanoparticles, able to be freeze-died without losing their integrity and functionality for, at least, 9 months. By the selection of the appropriate oligopeptide composition, we found a formulation that selectively targets dendritic cells after parenteral administration. In addition, this formulation is able to promote dendritic cells maturation and to generate a specific immune response against SARS-CoV-2 encoded spike antigens and against tumor-associated antigens in mice. In addition, tech transfer studies demonstrated the capability to produce the vaccine in an easy to scale up and under GMP procedure.

Conclusion
In conclusion, we have been able to design a platform for the production of mRNA vaccine based on polymeric nanoparticles able to overcome the main limitations that traditional vaccines present.

Functional composite biomaterials based on iron nanoparticle-loaded hydrogels for 3D biofabrication

Christoph Rehbock, Yaya Li, Stephan Barcikowski

University of Duisburg-Essen, Essen, DE

Introduction
Nanocomposites constitute an interesting class of materials for tissue engineering, where the embedding of nanoparticles into a biocompatible polymer adds novel functionality and hence, improves viability and proliferation of relevant adhered cells. Our group has developed an elegant method for the fabrication of nanocomposites based on laser ablation in liquids in polymer and monomer solutions, yielding nanocomposites with outstanding purity and biocompatibility [1]. In previous works we could already demonstrate improved cytocompatibility of these materials through two separate pathways I) local changes in surface charge and stiffness [2] and II) Release of metal ions [3].

Experimental Methods
Nanoparticles were implemented into the hydrogel by an in situ embedding procedure using laser ablation in liquids. The obtained hydrogels were characterized using surface zeta-potential measurements, TEM and confocal microscopy. Contact angles were measured with the captive bubble method to probe the hydrophilicity of the composites. Ion release from the composites was measured by ICP-MS analysis. Protein adsorption was determined by quantification of residual proteins in supernatants via UV-Vis spectroscopy. Suitability for 3D additive manufacturing was demonstrated using a microextrusion-based compact 3D-printer.

Results and Discussion
In our most recent work we focused on alginate and PEG hydrogel-based biomaterials loaded with iron nanoparticles and examined the mechanism of metal ion release from these biomaterials. We show that the nanoparticles were evenly distributed in the gel matrix and hydrophilicity and surface charge were increased. We identified a unique release behavior of iron ions from alginate-based composites, primarily driven by oxide solubility and interactions between iron ions and the alginate hydrogel matrix. Furthermore, we could find a significantly enhanced adhesion of model serum proteins to the biomaterial surface, which, interestingly already occurs at very low nanoparticle loadings (< 0.1 wt%). This seems to indicate that a mechanism based on locally elevated iron ion concentrations is responsible for the enhanced biocompatibility of these nanoparticle-loaded biomaterials. [4] We further verified the suitability of these materials for 3D bioprinting applications where the nanoparticles had no adverse effects on printability. [3] [4] These findings were complemented by recent examinations with hematopoietic stem and progenitor cells in 2D and 3D culture. Here we found a significant influence of iron nanoparticles in the biomaterial on the early stage of in vitro erythropoiesis relevant for applications in in vitro blood farming.[5]

Conclusion
Our findings demonstrate that the loading of hydrogel-based bioinks with a few ppm of soluble metal nanoparticles can have a pronounced impact on biocompatibility. Interestingly, we could further demonstrate that the commonly used combination of iron nanoparticles with an alginate matrix shows a unique iron ion release behavior, which could deepen our understanding of future biomaterial-cell interactions. Further initial 3D-printing experiments with these newly developed, nanoparticle-spiked bioinks demonstrate their further usefulness for example in tissue engineering applications.

Introduction

World Health Organization (WHO) has classified pulmonary infections as one of the main diseases affecting the human race and therefore important efforts must be consecrated to their prevention, diagnosis and treatment. Pneumonia is an inflammatory condition of the lung (alveoli) and it is caused by infection with viruses, bacteria, parasites or fungi. Although oral or injectable drugs against bacterial pulmonary infections are effective, the treatment has to be administered as combination therapy in high drug doses for long durations in order to maintain an optimum therapeutic level. As pulmonary infections are often persistent and recurrent, a rise in drug-resistant strains of infectious organisms, such as \textit{Streptococcus pneumoniae}, poses great challenges in the treatment of pneumonia in the clinical practice. In order to overcome this inconvenient, a potential therapeutic approach is to target the delivery of drugs directly to the site of infection.

Experimental Methods

An UltraTurrax homogenizer was used for the preparation of a water-in-oil emulsion. The esterification of the carboxylic groups of CMCS with the hydroxyl groups of PVA and amidation of the remaining amino groups CMCS with its carboxylic groups was carried out in the presence of DMT-MM, as an activating agent. Nano/microspheres were separated by centrifugation, purified by successive washings and freeze dried. The following parameters were taken into account: CMCS/PVA/DMT-MM weight ratio (w/w), concentration of polymer solutions (%) (w/v), emulsification and condensation reaction time, hydrodynamic regime.

FTIR spectroscopy was used to confirm the reaction between PVA/CMCS in the presence of DMT-MM. N/MPs diameter/morphology was evaluated by DLS, TEM and SEM. Particles stability was studied measuring the Zeta potential (ZP) in buffer solution (PBS) at pH 7.4. SEM-EDAX elemental analysis was used in order to determine the elemental composition of N/MPs. The swelling degree in solutions that mimic biological fluids was evaluated by a gravimetric method.

Results and Discussion

A widely accepted theory in the literature states that for efficient lung deposition, the carrier’s size should be in the range of 1–5 μm. Smaller particles (<1 μm) are likely to be absorbed quickly from the airways and this poses a risk of systemic toxicity. Moreover, 80% of these smaller particles are exhaled without being deposited due to their low inertia. In contrast, larger particles (>5 μm) are cleared by the mucociliary clearance mechanism. Therefore, a particle size in the range of 1–5 μm is required to achieve efficient pulmonary drug delivery via inhalation route.

In view of the above, the main objective of this study is related to the preparation of nano/microparticles (N/MPs), based on carboxymethyl chitosan (CMCS) and poly(vinyl alcohol) (PVA). The mechanical properties brought by the PVA and the mucoadhesive properties of the CMCS represent a viable combination for the preparation of porous N/MPs. These N/MPs were prepared by a condensation reaction of the polymers in the aqueous phase of a water-in-oil emulsion (polymer’s aqueous solution dispersed in ethyl acetate), as illustrated in the following Fig 1: The size of the obtained particle was in the submicronic range, as a function of the molar mass of PVA. The FTIR and EDAX analysis has confirmed the presence of both PVA and chitosan in the composition of the particles. The ZP values confirmed the high stability of these particles in an aqueous medium.

Conclusion
Based on the obtained results, these biocompatible particles are suitable for the loading of specific drugs in view of the potential treatment of pulmonary diseases by a pulmonary inhalation method.

Understanding the influence of nanogels’ structure on protein corona formation

Federico Traldi, Anjumanara B. Arefa, Arianna Fornili, Marina Resmini

Queen Mary University of London, School of Biological and Chemical Sciences, London, GB

Introduction
The use of nanomaterials as drug delivery systems and diagnostic tools has attracted considerable interest from scientists in the last decades. However, the limited knowledge of the behaviour of nano-systems in biological media and their interactions with biomolecules is hindering their application in clinical settings. The formation of “protein corona” has been linked to a significant, and still vastly unpredictable, change in the behaviour of many nanoparticle systems both in vitro and in vivo, posing significant obstacles to the rational design of nanomaterials. There is a clear need to understand how the physical-chemical properties of nanoparticles affect their interactions with proteins and how the chemical structure can be used to tailor this behaviour.

Experimental Methods
In the present work, we investigated how morphological and chemical properties of polymeric nanogels affect their interactions with proteins. Nanogels are attractive drug delivery platforms thanks to their high colloidal stability, bioavailability, and the stimuli responsive properties that can be introduced by using specific monomers. However, few studies have attempted to elucidate the relationship between the structure of nanogels and protein corona formation. A series of acrylamide-based nanogels were synthesised using high dilution radical polymerisation. Nanogels surface charge was modified by the addition of charged co-monomers such as acrylic acid and the crosslinker methylenebisacrylamide was added to the formulation in concentrations of 5, 10 and 20 molar%. The impact of these parameters on the affinity of nanogels for model proteins such as lysozyme was investigated using a combination of techniques such as dynamic light scattering and spectrophotometry. Experimental investigation was complemented with the computational analysis of protein affinities for functional groups responsible for the protein-nanogel interactions.

Results and Discussion
Our findings suggest that both structural and morphological properties of nanogels significantly affect their ability to interact with the tested proteins. Although protein corona of nanogels was found to be more sensibly affected by the nanogel surface charge, more subtle changes in the matrix were also able to significantly alter the affinity of nanogels for the proteins.

Conclusion
These data improve our understanding of the correlation between nanogels chemical composition and protein corona formation and may enable a more rational design of drug delivery systems.

Biocompatibility assessment of magnetoelectric cobalt ferrite CFO-BCZT nanoparticles for non-invasive deep brain stimulation

Maurizio Gulino,1,2 Donghoon Kim3, Xiangzhong Chen3, Qiao Tang3, Sofia D. Santos2, Salvador Pané3, Ana P. Pêgo1,4

1 i3S/INEB - Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Porto, Portugal, Porto, PT; 2 FEUP - Faculdade de Engenharia, Universidade do Porto, Porto, Portugal, Porto, PT; 3 Multi-Scale Robotics Lab (MSRL), Institute of Robotics and Intelligent Systems (IRIS), ETH Zurich, Zurich, Switzerland, Zurich, CH; 4 ICBAS/FEUP - Universidade do Porto, Porto, Portugal, Porto, PT

Introduction
Magnetoelectric nanoparticles are arising an increasing interest as innovative nanomaterials capable of effectively modulating neural circuits in vivo with high precision and minimal invasiveness compared to traditional brain stimulation devices (Guduru et al., 2015; Nguyen et al., 2020; Singer et al., 2020). Due to the recent burst of this new class of materials, few studies have been conducted to assess their biocompatibility and the impact on neuronal and glial cells.

Here, we explored rodent primary astrocytes and microglia to assess the biocompatibility of a piezoelectric ceramic composite with evidenced potential as implant material.

Experimental Methods

Functional multiferroic core-shell cobalt ferrite (CFO) nanoparticles coated with calcium/zirconium-doped barium titanate (CFO-BCZT) were synthesized with hydrothermal and sol-gel processes. Single crystalline cubic CFO core was prepared with hydrothermal method. Then BCZT shell was coated on CFO core particles using sol-gel method. Magnetoelectric properties of CFO-BCZT core-shell nanoparticles have been studied using magnetic field-assisted piezoresponse force microscopy.

The cellular responses of CFO-BCZT nanoparticles were evaluated through cytotoxicity assay, microscopy analysis and cellular uptake. Uncoated CFO nanoparticles were used as reference for the corresponding coated sample.

Results and Discussion

Crystallinity of the CFO and CFO-BCZT nanoparticles have been assessed with X-ray diffraction. Both particles showed no impurities nor secondary phase. Piezoresponse Force Microscopy scan of CFO-BCZT core-shell nanoparticles indicates that CFO-BCZT has magnetoelectric coupling, which is caused by the magnetic field induced interfacial strain between CFO and BCZT.

We show that while astrocytes viability was not affected after NPs exposure at different concentrations for 24 hours, primary microglia viability was compromised by CFO nanoparticles. As hypothesized by us, the coating decreased such effect in cells exposed to CFO-BCZT nanoparticles. Prussian blue staining revealed that CFO-BCZT nanoparticles are less internalized by microglia compared to CFO, suggesting that the BCZT shell makes the NPs less prone to microglia phagocytic activity.

Conclusion

In conclusion, these data indicate that CFO-BCZT nanoparticles not only exhibit magnetoelectric coupling effect, but they are also more biocompatible compared to uncoated ones. This sets the exploration of CFO-BCZT nanoparticles as a promising solution to overcome the current limitations of traditional deep brain stimulation systems.

Novel application of hot stage polarized light microscopy for the production of nanostructured lipid carriers via warm microemulsion templates

Felipe M. Gonzalez-Fernandez1,2, Sara Nicoli1, Paolo Gasco2, Silvia Pescina1

1 Parma University, Food and Drug Department, Parma, IT; 2 Nanovector Srl, Turin, IT

Introduction
Nanostructured lipid carriers (NLC) are lipid-based nanocarriers (< 200 nm) composed of both liquid and solid lipids, stabilized with surfactant(s) and dispersed in an aqueous media. Their range of applications is wide since they are mainly composed of highly biocompatible lipids, enhancing drug apparent solubility in water, protecting it from degradation phenomena and overall improving targeted drug delivery. Amongst the diverse production methods, a simple and easily up-scalable approach is the redispersion in cold aqueous media (~ 4 ºC) of warm oil-in-water microemulsions, i.e., self-assembled, thermodynamically stable, isotropic transparent liquids [1]. Quick identification of surfactants-lipids-water combinations that lead to microemulsions at temperatures generally above the solid lipid melting point (65-70 ºC) is a crucial step in this method. Depending on the relative proportions between components, different systems can be observed: some structures can be macroscopically assessed, while other require microscopic assessment. Previous research on the use of polarized light microscopy for the evaluation of microemulsions is available in the literature but only at room temperature [2]. Hot stage microscopy, already used in different fields, allows to heat and cool the samples in a staggered manner or maintain at a fixed temperature to evaluate their temperature behaviour [3].

In this work we report a novel application of hot stage polarized light microscopy for the characterization and identification of warm microemulsion templates for the production of NLC.

Experimental Methods
Pseudoternary phase diagrams were constructed for lipid/surfactant/water mixtures consisting of triacetin (oil), monostearin (solid lipid) and tyloxapol (surfactant) mixtures using a water titration technique. Briefly, initial mixtures containing only lipids and surfactant having relative proportions ranging from 9:1 to 1:9 were accurately weighted in transparent glass vials. Oil to solid lipid proportion was held at a constant 2:3 ratio. The mixtures were heated at 65 ºC under magnetic agitation. Aliquots of 10% ultra-pure deionized water were progressively added and the macroscopically appearance after stabilization was noted and classified. Lipid-water and surfactant-water mixtures were also analysed as control.

An optical polarizing light microscope (Nikon Optiphot 2 POL, Nikon, USA) coupled to a stage temperature microscope controller (TP 93 Linkam Scientific Inst., Miami, USA) was used to analyse the 120 different excipient combinations. A drop of warm sample was deposited on microscope slides placing a cover glass. Samples were positioned on the hot stage preheated at 65 ºC and observed under cross-polarized immediately, minimizing any possible evaporation. Photomicrographs at 400x magnification were taken.

Results and Discussion
The pseudoternary phase behaviour of the triacetin/monostearin-tyloxapol-water system was macroscopically and microscopically assessed at 65 ºC. Macroscopically, a large region containing mixtures that appear transparent to the naked eye was quickly identified, especially with increasing tyloxapol concentrations. Water addition resulted in loss of transparency, specially at high triacetin/monostearin proportions leading to coarse macroemulsions or, in some cases, phase separation.
Microscopically, the method allowed to further characterise the large transparent region previously observed, detecting both anisotropic and isotropic structures, being only the latter of interest for our application. Low water concentrations of 10 and 20% of water showed intense birefringence mainly explained by high monostearin concentration. Isotropy was observed for all samples containing lipid-surfactant ratios of 2:8 and 1:9 with independence of the percentage of water. Further anisotropic structures compatible with liquid crystal mesophases were also observed but only further characterization by other techniques (i.e. small-angle X-ray scattering) could adequately corroborate their structure.

Lipid-water and surfactant-water controls were also in close agreement with previously reported data [4]. In the case of monostearin, anisotropy compatible with a liquid-crystalline lamellar mesophase could be observed until water percentages of 50%. In the case of the tyloxapol-water mixtures, at all water concentrations a dark field was observed.

**Conclusion**

The novel method based on hot stage polarising light microscopy quickly and efficiently allowed to detect isotropic microemulsions, simplifying the development of nanostructured lipid carriers based on triacetin/monostearin-tyloxapol-water mixtures. Further research, by redispersion of the isotropic structures in cold aqueous media could help confirm the usefulness of this approach for a more efficient NLC production.

SNAP loading on carbon nanotubes

Fatemeh Kabirian¹, Petra Mela², Ruth Heying³

1 KU Leuven, Department of Cardiovascular Sciences/Cardiovascular Developmental Biology, Leuven, BE; ² Technical University of Munich, Munich, Medical Materials and Implants, Department of Mechanical Engineering and Munich School of BioEngineering, Munich, DE; ³ KU Leuven, Department of Cardiovascular Sciences/Cardiovascular Developmental Biology, Leuven, BE

Introduction
Nanocarriers such as carbon nanotubes are appropriate candidates for drug delivery applications. Due to the nanoscale, they have a high surface area and they can store higher concentration of drug molecules such as a nitric oxide donor which could be used to overcome the limitations of current approaches such as burst release.

Experimental Methods
S-nitroso-N-acetyl-D-penicillamine (SNAP, C7H12N2O4S) as a nitric oxide donor was synthesized. Before formation of SNAP crystals, 25 mg of Multiwalled carbon nanotubes were immersed in 1 ml of SNAP solution for 24h at 4°C. After washing with ice cooled MQ water, the loaded MWCNTs were dried in a lyophilyzer. The amount of nitrogen was measured by performing CHNS analysis.

Results and Discussion
Immersion of MWCNTs inside the SNAP solution resulted in 2.3±0.26% nitrogen content in the loaded MWCNTs.

Conclusion
SNAP can be loaded on MWCNTs which can be promising for the development of medical devices with antibacterial properties.

Acknowledgement
The authors greatly acknowledge the FWO Vlaanderen for the postdoctoral grant (1291021N) given to Fatemeh Kabirian to support this study.
Loading of SNAP on carbon nanotubes
Comparison of two types of mesoporous silica nanoparticles loaded with gentamicin to overcome antibiotic resistance and inhibit bacterial biofilm formation

Nassim Chekireb\textsuperscript{1,2}, Jean-Sebastien Thomann\textsuperscript{2}, Anna Belcarz\textsuperscript{3}, Agata Przekora-Kuśmierz\textsuperscript{3}, Grazyna Ginalsak\textsuperscript{3}, David Duday\textsuperscript{2}

\textsuperscript{1} Université Sorbonne Paris Nord, Bobigny, FR; \textsuperscript{2} Luxembourg Institute of Science and Technology, Esch-sur-Alzette, LU; \textsuperscript{3} Medical University of Lublin, Lublin, PL

Introduction
Gentamicin is an antibiotic broadly used because it has the ability to treat different types of infections. However, after oral administration, the bioavailability of gentamicin is low and cell penetration is poor. In addition, the internalized gentamicin molecules expulsed from cells with efflux pumps or degraded by specific enzymes, resulting in a decrease of the activity sought. In case of parenteral administration, gentamicin is rapidly eliminated by glomerular filtration, and then passes to the renal cortex. Therefore, administration of repeated doses leads to renal accumulation and nephrotoxicity \cite{1}. Bacterial resistance to antibiotics, including gentamicin, is a serious threat for Health \cite{2}. It is therefore essential to find new ways of delivering antibiotics to decrease the appearance of bacterial resistance. A better control of antibiotic release through nanocarriers like amorphous mesoporous silica nanoparticles (AMSNPs) is one promising approach to limit this bacterial resistance phenomenon. The literature shows the advantages of using locally delivered antibiotics including the delivery of a high concentration of antibiotics to a localized area without systemic involvement and minimal risk of developing bacterial resistance \cite{2-3}. The aim of the present work is the use of 2 advanced synthetic strategies to obtain AMSNPs able to efficiently carry a drug such as gentamicin and their effects on the eukaryotic cell viability and growth inhibition of 4 reference bacterial strains

Experimental Methods
The AMSNPs was synthesized using sol-gel approach, the gentamicin loading was carried out by precipitation in ethanol. The morphology of AMSNPs was performed by scanning transmission electron microscope (STEM), the size and zeta potential were determined by Malvern zeta sizer. the demonstration of the presence of gentamicin on silica was established by FTIR. The AMSNPs cytotoxicity against mouse preosteoblasts was evaluated by colorimetric MTT assay. Antimicrobial efficiency was evaluated on 4 reference bacterial strains

Results and Discussion
The two types of particles have different morphology in terms of size varying from 70 nm to 110 nm, specific surface area from 494 m\textsuperscript{2}/g to 1031 m\textsuperscript{2}/g and pore size from 2.3 nm to 18 nm. Stellate silica nanoparticles are less cytotoxic than wormhole silica nanoparticles. The MIC and MBC values for both type of silica nanoparticles have shown bactericidal activity for all strains and bacteriostatic activity for S. aureus

Conclusion
Overall, this study demonstrates that both types of nanoparticles loaded with gentamicin are not cytotoxic on bon cells and efficient for bringing gentamicin into bacterial cells.

Drug delivery for neural stem cell proliferation

Eirini Epitropaki, Yujie Xie, Amanda K. Pearce, Rachel K. O'Reilly

University of Birmingham, Chemistry, BIRMINGHAM, GB

Introduction
Neurodegenerative diseases such as ischemic stroke, Alzheimer’s, and Parkinson’s can cause cellular loss, which can be tackled with the use of neural stem cells (NSCs). To promote stem cell differentiation into functional neurons, nanomedicine as a non-invasive method presents an opportunity to enable delivery of differentiating agents, while preserving the blood and brain barrier (BBB). In order for nanoparticles to achieve efficient delivery to the central nervous system (CNS), numerous physicochemical parameters must be examined. Size, morphology, and surface charge of the nanoparticles are the key parameters that determine delivery efficacy. Based on the above, the current work aimed to produce amphiphilic nanoparticles with various corona chemistries, different sizes, and biodegradable nature, in order to explore the above parameters. Different morphologies such as diamond platelets and molecular caterpillars were formed by exploiting the core crystallinity using the crystallization driven self-assembly (CDSA) technique. As the particles are developed as an intravenous carrier, the interaction between the self-assemblies and protein models must be investigated. The effect of the surface charge was explored by introducing the nanoparticles in various biological environments such as salts, cell culture medium, fish water, and model protein solutions and monitor the interactions occurring.

Experimental Methods
1. For the Synthesis of the particles, a combination of ROP (for the hydrophobic core) and RAFT (for the hydrophilic corona) polymerization was used.
2. The incorporation of the fluorophore was conducted through a Mitsunobu reaction.
3. The self-assembly took place using the flash nanoprecipitation technique (Dissolution of polymer into good solvent and direct introduction to an aquatic or biologically relevant medium while stirring intensely)
4. For the development of different morphologies, crystallization-driven self-assembly (CDSA) technique was utilized. (Dissolution of polymer into θ solvent, heating up the system and then let it cool down in order to crystallize)
5. The self-assemblies and their interactions with biological media were examined thoroughly by DLS, AFM, and confocal measurements.

Results and Discussion
• Diblock copolymers with versatile corona chemistries were easily developed through simple techniques.
• By utilizing the ratio between the hydrophobic core and hydrophilic corona, as well as the corona chemistry and the length of the semi-crystalline PLLA, different morphologies were obtained.
• The positively charged self-assemblies indicated a stable solution for 24 hours at 36.5 °C. The particles were examined in various biologically relevant mediums, where they indicated a smaller particle size of 68 nm in a PBS solution. The observed result can be explained due to the stabilization of the charges in PBS solution hence the smaller population.
• The protein corona was examined with a 4 mg/ml BSA solution, which was used as the model protein. DLS and zeta potential measurements verify the electrostatic interactions between the negatively charged BSA protein and the positively charged particles. Various layers of BSA appeared to have deposited on top of the particles creating a cluster of 1μm, as it was observed through AFM. Lastly, the correlation of the fluorescent channels
through confocal proves the interaction between the protein and the nanoparticles and verifies the protein corona formation.

Conclusion

- A library of diblock copolymers was synthesized with positive and neutral corona chemistries, with amorphous and crystalline core, and with an incorporated fluorescent ACM probe.
- Various morphologies acquired through CDSA like diamond platelets, diamonds with tails, and molecular caterpillars depending on their corona chemistry and ratio.
- Stability in body temperature of the catanionic corona particles over time was demonstrated.
- Stability of the aforementioned particles in various biologically relevant mediums, such as salts, cell culture medium, and fish water was examined.
- Electrostatic interactions of the negatively charged BSA protein with the positively charged particles were verified by DLS, AFM, and confocal measurements.

**In-vitro cell responses to strontium/magnesium-doped calcium phosphate nanoparticles**

**Shabnam Hosseini, Kathrin Kostka, Matthias Eppe**

*Duisburg-Essen University, Chemistry, Essen, DE*

**Introduction**

Bone is an inorganic–bioorganic composite material consisting mainly collagen and calcium phosphate. Its structure, surface roughness, chemistry, and mechanical properties of biomaterials biological matter are fascinating for many researchers.[1, 2] Calcium phosphate nanoparticles (CaP) are well known as highly biocompatible and biodegradable inorganic composite for bone regeneration.[3] On the other hand, strontium (Sr) and magnesium (Mg) are assumed to enhance the formation of bone. The substitution of strontium and magnesium into hydroxyapatite instead of calcium is an effective way to enhance the biological properties of calcium phosphate-based biomaterials.[4, 5]

**Experimental Methods**

Here, strontium-doped calcium phosphate (SrCaP) and magnesium-doped calcium phosphate (MgCaP) nanoparticles with different molar contents of 5, 10, 15, and 20% were prepared separately by precipitation from aqueous solutions as dispersed nanoparticles. The nanoparticles were characterized by dynamic light scattering (DLS), zeta potential measurements, scanning electron microscopy (SEM), atomic absorption spectrometry (AAS), X-ray powder diffraction (XRD), thermogravimetric analysis (TGA), and energy-dispersive X-ray spectroscopy (EDX). Furthermore, *in-vitro* cell culture studies as a viability test (MTT) and uptake investigation in the three different cell lines HeLa, MG63, and MC3T3 were carried out.

**Results and Discussion**

The resulting nanoparticles were monodisperse with well-controlled size (about 100 nm), morphology, and composition. The nanoparticles were well taken up by HeLa, MG63 and MC3T3 cell lines together with a low cytotoxicity.

**Conclusion**

The nanoparticles can either be used in dispersion or added to a calcium phosphate paste for injection into bone defects.

\(^1\) University of Porto, i3S, Porto, PT; \(^2\) University of Porto, Faculty of Pharmacy, Porto, PT; \(^3\) Universidade de Lisboa, Faculty of Pharmacy, Lisboa, PT; \(^4\) Instituto Universitário de Ciências da Saúde (CESPU), Instituto de Investigação e Formação Avançada em Ciências e Tecnologias da Saúde, Gandra, PT

Introduction

Diabetes mellitus (DM) is one of the biggest health problems nowadays, as 463 million individuals suffer from DM worldwide and this number is expected to rise [1]. Type 1 DM (T1DM) is a chronic auto-immune disease characterized by insulin insufficient secretion due to β-cells destruction [1]. Since T1DM is not preventable and most of the cases are diagnosed after massive β-cells destruction [2], definitive cure consists in replacing the destroyed pancreas [3]. However, the number of available pancreas or islets is limited, in addition to the need of a lifelong immunosuppression therapy. In this work it is proposed an innovative biomimetic pancreas, comprising differentiated induced pluripotent stem cells (iPSCs) into functional insulin-producing cells, immobilized in a biofunctional matrix and glucose-responsive nanoparticles (NPs) encapsulating a GLP-1 analogue. The sensitiveness to glucose will be accomplished by the incorporation of the enzyme glucose oxidase (GOx) in the system. In the presence of high levels of glucose, GOx degrades it into gluconic acid, decreasing the surrounding pH (\(\sim 5\)). pH-sensitive engineered NPs will respond to the decrease of the environmental pH by releasing their cargo.

Experimental Methods

pH-sensitive NPs based on hybrid PLGA/polymethacrylates matrices were produced by a modified solvent emulsification-evaporation method based on double emulsion technique [4] to encapsulate GLP-1 analogue exenatide or semaglutide. Association efficiency (AE) and drug loading (DL) were determined by HPLC. Exenatide and semaglutide in vitro release profiles were assessed at different pH (5 and 7.4) and secondary structure stability after release was confirmed by circular dichroism. Human WLS-4D1 induced PSCs (hiPSCs) were differentiated into insulin-producing cells [5]. iPSCs differentiation was assessed at different stages by flow cytometry through the expression of different cell markers. The capacity of differentiated cells to produce insulin was assessed by glucose-stimulated insulin secretion (GSIS) assay.

Results and Discussion

Different NPs formulations showed a monodisperse population (PdI <0.160) with an average size ranging from 120 to 150 nm and zeta potential (ZP) around 30-40 mV for higher polymethacrylates ratios, decreasing up to -7 mV for higher PLGA proportions. Two GLP-1 analogues were encapsulated (exenatide and semaglutide) using different DL (between 5\% and 15\%). For exenatide-loaded NPs, AE values ranged from 34 \% to 49 \%, while for semaglutide-loaded NPs, AE was close to 50 \%, depending on PLGA/polymethacrylates ratios. NPs showed a pH-dependent in vitro release profile, despite showing a burst release of around 40 \% at pH 7.4 and 60\%-70\% at pH 5 after 5 minutes, depending on the peptide. Besides, both exenatide and semaglutide maintained its secondary structure after 48h of in vitro release. hiPSCs were successfully differentiated into insulin-producing cells and GSIS assay showed that cells were capable of responding to high and low levels of glucose in the media, releasing different amounts of insulin.

Conclusion

Highly-loaded glucose-responsive NPs were successfully produced. Additionally, insulin-producing cells differentiated from hiPSCs were effectively differentiated and responsive to glucose, showing its potential to be used in the artificial pancreas system as a diabetes therapy. Ongoing work is focused on encapsulation of the nanosystem
in alginate microparticles and co-encapsulation of this nano-in-micro system with differentiated pancreatic cells in an alginate-based 3D scaffold.

Superparamagnetic and bioactive nanoparticles for bone cancer treatment

Florestan Vergnaud¹, Xavier Kesse¹, Francis Perton³, Sylvie Begin-Colin³, Damien Mertz³, Stéphane Descamps², Charlotte Vichery¹, Jean-Marie Nedelec¹

¹ Université Clermont Auvergne, Clermont Auvergne INP, CNRS, ICCF, Clermont-Ferrand, FR; ² Université Clermont Auvergne, CHU Clermont-Ferrand, Clermont Auvergne INP, CNRS, ICCF, Clermont-Ferrand, FR; ³ Université de Strasbourg, Institut de Physique et Chimie des Matériaux de Strasbourg (IPCMS), UMR-7504 CNRS, Strasbourg, FR

Introduction
Most patients who develop primary bone tumors require a surgical intervention. In this respect, the design of a multifunctional material, used as a bone substitute, is of high clinical interest to simultaneously treat cancer and promote bone regeneration. Bioactive glass (BG) nanoparticles are a promising material for bone tissue regeneration thanks to their ability to dissolve when immersed in body fluids and precipitate into hydroxyapatite, a crystalline phase with a composition close to the one of bones mineral part.¹² By coupling the high bioactivity of large specific surface area bioactive glass with the heating ability of iron oxide nanoparticles under an alternating magnetic field (AMF),³ such multifunctional material could be used to selectively destroy remaining or resurging cancer cells (magnetic hyperthermia) before promoting bone regeneration.

Experimental Methods
In this scope, core-shell heterostructures consisting of superparamagnetic iron oxide nanoparticles surrounded by BG shells have been synthesized using a sol-gel synthesis protocol previously optimized in the group,⁴ and characterized. Their physicochemical properties such as morphology, specific surface area and composition, have been evaluated using transmission electron microscopy (TEM), X-Ray Diffraction, infrared spectrometry, N2 sorptometry, and inductively coupled plasma-atomic emission spectroscopy (ICP-AES). Their heating ability was studied by calorimetry under AMF with multiple field parameters, and the hydroxyapatite growth kinetics was assessed after immersion in Simulated Body Fluid (SBF) at 37°C. Furthermore, in vitro cytotoxicity tests were performed on human mesenchymal stem cells (MTT tests).

Results and Discussion
As shown in Figure 1, non-agglomerated heterostructured nanoparticles have been obtained, with a large proportion of particles with only one magnetic NP as a core. These γ-Fe₂O₃@SiO₂-CaO core-shell nanoparticles show good heating ability, with a temperature increase of 4 °C within 3 min under clinically relevant magnetic field parameters (157 kHz, 23.9 kA/m, figure 2), corresponding to a heating power (Specific Absorption Rate, SAR) of about 200 W/gFe. Hydroxyapatite was observed (XRD, FTIR) after 7 days of immersion in SBF, showing an effective mineralization process, and cytocompatibility has been demonstrated up to 7 days.

Conclusion
These results suggest that γ-Fe₂O₃@SiO₂-CaO heterostructures are a promising biomaterial to fill bone defects resulting from bone tumor resection, as they have the ability to both help bone tissue repair and act as thermoseeds for cancer therapy.

Introduction

Metal ions, depending on their properties, present the potential to affect the porosity and biocompatibility of MSNs (MSNs). The positive effect of doping MSNs with calcium (Ca) ions has already been thoroughly evaluated. Cerium (Ce) ions are reported to have antibacterial, antioxidant, angiogenic, anti-inflammatory and antimicrobial properties [1]. These properties are some of the prerequisites to achieve tissue regeneration. It has already been argued that the addition of Ca to MSNs could improve the bioactivity of these materials. In the present study the effect of Ce addition in calcium doped MSNs on their bioactivity and biological behavior (cell proliferation, antibacterial properties and reactive oxygen species (ROS) production) was evaluated.

Experimental Methods

Mesoporous, MCM-41 type, silicate nanoparticles were synthesized with either neat siliceous walls (undoped group) or doped with Ca and Ce ions (doped group) at Ce concentrations of 1%, 2.5%, and 5%. The synthesis was performed by the method of synergistic self-organization via sol-gel reaction. The structural and porous characteristics of MSNs were determined by X-ray Diffraction Analysis and Brunauer-Emmett-Teller (BET) porosimetry, respectively. The in vitro apatite forming ability of the synthesized MSNs was evaluated by immersion in conventional simulated body fluid (c-SBF) under renewal conditions. The cytotoxicity test was performed by the biochemical method of water-soluble salt of MTT tetrazole [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]. Indirect "MTT assay" with eluates of the tested MSNs in different concentrations (12.5, 60, 125, 250 μg/ml) was performed 1, 3, 5, and 7 days after incubation with human gingival fibroblasts. For the detection of intracellular reactive oxygen species (ROS) levels, we employed the cell-permeable ROS-sensitive probe H₂DCFDA on culture medium received from both cell and bacterial cultures. Measurement of fluorescence was achieved using excitation wavelength 480-520 nm and emission wavelength 570-600 nm. Oxidation of H₂DCFDA 20 μM (incubated for 1 h) in cells treated with different concentrations of MSNs was monitored by measurement of the fluorescence in 96-well black-walled microplates. For investigation of antibacterial properties, bacterial cultures of Escherichia coli O157:H7 NCTC 12079, Staphylococcus aureus ATCC 6538, and Pseudomonas aeruginosa (clinical isolate) were used. Bacterial cultures were prepared by inoculating 10 mL NB with an isolated colony from an agar plate. After 24 h incubation at 37°C, 100 μL of broth culture was inoculated into 10 mL fresh NB and incubated under the same conditions.

Results and Discussion

All MSNs presented non cytotoxic behavior at all tested concentrations. At day 1 an upregulation in mitochondrial activity and ROS production was observed for all tested materials comparative to undoped MSNs. At day 3, statistically significant positive effect on cell viability was observed for cerium-doped MSNs (p < 0.001) but with a basal production of ROS. Enhanced cell proliferation with basal production of ROS was also observed at day 5 for all the tested MSNs (p< 0.001). Finally, at day 7 cell proliferation was promoted significantly in the cases of SiCaCe1 and SiCaCe2.5 MSNs (p<0.05). Cerium can change its oxidation states (Ce⁴⁺ and Ce³⁺) in physiological fluids, condition that can modulate ROS production [1]. Excessive ROS production has been reported as a dominating factor
in cell toxicity and it constitutes an effective mechanism for antibacterial activity properties [2]. In this study, the antibacterial assay revealed that the MSNs had only a slight inhibitory effect on Staphylococcus aureus and Pseudomonas aeruginosa, which agrees with the high fibroblast proliferation rates. Apparently, either the dissolution of cerium ions from the synthesized MSNs is limited, not reaching the necessary level for a strict antibacterial effect or other equilibrium mechanisms exist between ROS generation and degradation that need further clarification. Finally, the FTIR spectra revealed the deposition of apatite after only 1 day immersion in SBF, as confirmed by the shifting of the wide peak at 900–1200 cm⁻¹ to lower wave numbers, as well as the appearance of the two bands at 610 - 600 and 560 - 550 cm⁻¹ attributed to the bending vibration of the (PO₄)³⁻ bond.

**Conclusion**

Bioactive and biocompatible Ce-doped mesoporous MCM-41 nanoparticles were synthesized through the sol gel method. Their limited antibacterial activity under the tested concentrations was correlated with a progressive reduction of ROS, which however, was associated with a significant upregulation of cell proliferation, verifying the potential use of these materials in various dental and biomedical applications. Future work will be focused on direct cytotoxicity and antibacterial testing and the study of their drug loading and release profiles.

Establishing a Multiplex Protein-Based Assay as a Tool for Screening Osteogenic Properties of Calcium Phosphate Biomaterials

**Maria José R. Eischen-Loges**, Zeinab Tahmasebi Birgani, Yousra Alaoui Selsouli, Hoon S. Rho, Lars Eijssen, Vanessa LaPointe, Pamela Habibović

1 Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL; 2 Maastricht University, Department of Bioinformatics - BiGaT, NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht, NL; 3 Maastricht University, Department of Psychiatry and Neuropsychology, MHeNs School for Mental Health and Neuroscience, Maastricht, NL

**Introduction**

The intrinsic self-healing capacity of bone tissue often falls short in case of large, critical-sized defects. To aid regeneration of such large defects, autologous bone grafts are still considered the gold standard treatment. Nevertheless, the use of autografts has noteworthy drawbacks, such as limited availability, the need for a second surgical intervention and donor site morbidity. This has led to a large demand for inexpensive, off-the-shelf-available and preferably synthetic bone graft substitutes. Calcium phosphate–based biomaterials are widely used in bone regeneration applications. Nevertheless, their properties and clinical performance are in general inferior to those of autologous bone grafts. Hence, there is a need for further improvement. An important reason that has hindered the optimization of synthetic bone graft substitutes, including calcium phosphates, is a lack of reliable in vitro screening methods for biomaterials. Here, we present a multiplex protein assay as a tool for screening the osteogenic properties of biomaterials, calcium phosphates in particular, and for predicting their success in promoting osteogenic differentiation of human mesenchymal stem cells (hMSCs).

**Experimental Methods**

In order to establish the osteogenic differentiation program of hMSCs, the cells were cultured in basic medium and osteogenic medium with or without the addition of BMP-2, in basic medium supplemented with Ca²⁺ or PO₄³⁻, or on a calcium phosphate coating. A multiplex protein assay to detect analytes related to bone formation and resorption, angiogenesis, and immunomodulation was performed at multiple time points. Osteogenic differentiation was confirmed by conventional methods such as an alkaline phosphatase assay and qPCR, and extracellular matrix mineralization by Alizarin red staining. The protein profiles will be correlated to the results of osteogenic differentiation using a statistical model to determine a descriptive panel of markers. As the next step in the process of establishing a screening tool, a medium-throughput calcium phosphate library was generated by coating cell culture plates with a thin layer of calcium phosphates, doped with a range of inorganic additives at varying concentrations. HMSCs were cultured on the coatings to perform a multiplex protein assay, as well as conventional assays for data validation.

**Results and Discussion**

The multiplex analysis of differentiating hMSCs over time identified differentially expressed proteins as markers for osteogenic differentiation (Figure 1). Mineral deposition as an indicator for osteogenic differentiation and extracellular matrix mineralization was observed in hMSCs cultured in osteogenic medium, osteogenic medium supplemented with BMP-2, basic medium supplemented with Ca²⁺ or PO₄³⁻, and on a calcium phosphate coating at day 28 (Figure 2A). This observation was supported by an alkaline phosphatase activity assay. This enzyme is involved in mineral deposition and its activity was increased early on in basic medium supplemented with Ca²⁺ or PO₄³⁻, and on a calcium phosphate coating. In addition, an increase in ALP activity levels over time was also observed in osteogenic medium and osteogenic medium supplemented with BMP-2 (Figure 2B).

**Conclusion**

Page 1391 of 2028
Here, we presented our efforts towards developing a high-throughput screening tool based on protein multiplex for evaluating the osteogenic properties of calcium phosphate–based biomaterials.

High-throughput Screening to Elucidate Biomaterial-induced Fibrosis

Torben A.B. van der Boon

University Medical Center Groningen, Department of Biomedical Engineering, Research Institute W.J. Kolff, Groningen, NL

Introduction
Nowadays, it is becoming common knowledge that the human body, its tissues and cells react to biophysical and biochemical cues located on biomaterial surfaces.[1] Identifying how these parameters influence cellular behavior is of crucial importance and will aid us in the further development of medical implant technology. Unfortunately, in many studies attempting to identify these physicochemical properties’ influence on cell behavior, investigation of individual properties is the conventional method, leaving out a significant number of other variables which are encountered in vivo, which is where cells always interact with multiple cues simultaneously.[2] We are developing an orthogonal double gradient platform which allows us to investigate just such complex situations in a high-throughput screening (HTS) fashion. The platform grants us the power to screen the cell response towards thousands of these combined parameters in single cell experiments, which will result in the optimization of material properties to enhance biomaterial and implant function. Currently, we are in the final platform optimization stage, after which we will screen silicone rubber’s susceptibility to fibrosis and scar tissue formation.

Experimental Methods
PDMS double orthogonal gradients (DOGs) are prepared by sequential imprinting – and shielded air plasma oxidation treatments in accordance with previously published methodology.[3-5] Primary human dermal fibroblasts will be cultured on the DOGs for 7 days and stained for early fibrosis biomarkers (Collagen-II and α-SMA).

Results and Discussion
Every imaginable position on the orthogonal double gradient surfaces has a unique combination of three surface parameters, possessing ‘real’, clinically relevant values. This allows us to investigate a virtually unlimited amount of different parameter combinations, within their respective ranges, on single substrates. Wavy topography gradients range from \( \lambda = 1.5 \, \mu m - 12 \, \mu m \) and \( A = 50nm - 1.5 \, \mu m \), the smallest wavelengths corresponding with the smallest amplitudes going from small to big, in a coupled fashion. Stiffness gradients range in Young’s Modulus from \( \sim 50 - 500 \, MPa \), and ‘wettability’ gradients from \( 5 - 90 ^\circ \) in water contact angle (WCA). As a ‘proof of concept’, we cultured hBM-MSCs on the platforms for 24 h, imaged the cells via automated fluorescence microscopy and identified the cell response with respect to cell density, cell spreading, and nucleus area. We have found that the synergistic effect of abovementioned parameter combinations all influence cell behavior in a different manner with regard to these relatively ‘simple’ assessable characteristics. Our next steps involve the translation of ‘hotspots’ or regions of interest (ROI) to homogeneous parameter substrates, as a last verification step in the optimization process, as well as the screening of biomaterial susceptibility to fibrosis and scar tissue formation.

Conclusion
The highly efficient cell screening tool we have created with our DOG platform allows us to screen cell response to combined physical parameter influence in a high-throughput fashion, investigating thousands of different parameter combinations in single cell experiments. It will serve its purpose to facilitate enhanced biomaterial development.
High-throughput screening approach. Different physicochemical biomaterial properties influence cell behavior in a complex manner. The screening platforms enable all parameter combinations to be present within a gradient-like range. The influence on, in this example ‘Cell density’, is identified via fluorescence immune-staining and semi-automated imaging and analysis.

High-resolution quantitative analysis of proteins distribution involved in cells focal adhesions formation to electrospun polymers fibers

Krzysztof Berniak, Daniel Ura, Piotr Szewczyk, Joanna Karbowniczek, Urszula Stachewicz

AGH University of Science and Technology, Faculty of Metals Engineering and Industrial Computer Science, Cracow, PL

Introduction
The study of interactions between human cells and polymers fibers is one of the most crucial elements in assessing new materials' biocompatibility in medicine and bioengineering. Poly(methyl methacrylate) (PMMA) is a commonly used polymer in biomaterials with a very high degree of biocompatibility with human cells [1]. The electrospun PMMA fibers have already been used for cell dynamics studies for tissue engineering [2]. The cell culture studies indicate the stretching of cells along the fibers, creating adhesion sites through which they temporarily connect to them [3]. These molecular structures consist of a series of proteins, including paxillin and vinculin. Immunofluorescence labeled of proteins provides vast amounts of information about the localization of these proteins at the points of cell contact with the scaffold. Within this study, we show the analysis of cell adhesion sides with PMMA fibers deposited on glass using two types of cells: osteoblasts and fibroblasts. To assess potential correlations between the distribution of focal adhesions in two different types of cells to electrospun PMMA fibers, a quantitative analysis of localizations of particular protein foci in 3D multicolor microscopy images is required. We show the potential application of high-resolution confocal microscopy with Airyscan2 to study cell-matrix interaction on electrospun polymer fibers.

Experimental Methods
To obtain a 12 wt. % solution, poly(methyl methacrylate) (PMMA, Mw=350 000 g·mol⁻¹, Sigma Aldrich, UK) was dissolved in N, N-dimethylformamide (DMF, Sigma Aldrich, UK). The solution was stirred at 700 rpm for two h on a hot plate set at 55°C (IKA RCT basic, Germany). PMMA fibers were produced via electrospinning using the apparatus EC-DIG with climate control (IME Technologies, the Netherlands) at T= 25°C and RH=40 %. A voltage of 12 kV was applied to the needle, kept at a distance of 15 cm from the grounded drum rotating at 2000 rpm. The flow rate was set to 4 ml·min⁻¹. The samples were directly deposited 10×10 glass slides.

Human osteoblast-like cell line MG63 and fibroblasts NIH 3T3 cell line were cultured in DMEM supplemented with 10% addition FBS, 2% antibiotics (penicillin/streptomycin), 1% amino acids and 1% L-glutamine under standard conditions, i.e. at T = 37 °C, RH = 95% and 5% of CO₂.

After three days of cell growth, samples of the PMMA scaffolds were fixed with 4% paraformaldehyde for 15 min. Fixed cells were permeabilized with 0.1% Triton X-100 in PBS for 5 min at T= 22oC and then incubated in a blocking solution (3% BSA in PBS). To visualize actin filaments, cells were incubated for one hour at T= 22oC with Alexa Fluor™ 633 Phalloidin. Nuclear DNA was stained with DAPI for 5 min. Selected proteins involving in focal adhesion (vinculin and paxillin) were labeled by immunofluorescence. Multicolor 3D microscopy images of cells connecting to PMMA fibers were acquired using high-resolution microscopy with the concept Airyscan2 (Zeiss LSM 900), and the image analysis was performed by using ImageJ.

Results and Discussion
Within this study, we have verified the cell's connection to PMMA fibers and glass, showing the distinct changes in paxillin and vinculin distribution. It was possible due to the imaging with the high-resolution Airyscan2 confocal microscopy technique. Both human osteoblast MG-63 and murine fibroblast NIH 3T3 cells show a high affinity for PMMA fibers. They tended to be spread along fibers. However, they also create numerous connections with each
other (Figure 1). High-resolution imaging of paxillin and vinculin shows a significant difference in the distribution of both proteins in the contact cell surface to PMMA fibers and the glass for both cell lines. It indicates that the cell uses a different mechanism when creating attachment sites to PMMA than to glass. The nature and density of such foci formation correlate with the properties of the surface scaffold on which the cells are grown.

**Conclusion**

The application of the high-resolution confocal microscopy with Airyscan2 allowed to register the places of cell adhesion to polymer fibers with very high resolution. It allowed observing changes in the spatial distribution of proteins involved in forming focal adhesion of cells to the PMMA fiber and the glass.

Effect of silver ion incorporation into a bioactive glass surface on the adsorption of albumin

Jacopo Barberi¹, Andrea M. Giovannozzi², Luisa Mandrile², Marta Miola¹, Alessandra Vitale¹, Lucia Napione¹, Silvia Spriano¹

¹ Politecnico di Torino, DISAT, TO - Torino, IT; ² National Institute of Metrology, Quantum Metrology and Nanotechnologies Division, TO - Torino, IT

Introduction

Nowadays, bacterial infection is one of the major causes for orthopedic implants failure. While it is well known how to manufacture materials that are able to stimulate osseointegration and to firmly bond with the bone, the fight against pathogenic microorganisms is carried on mainly by antibiotics, with consequent problems of poorly localized actions and antibiotic-resistance. Therefore, novel antibacterial strategies have been deeply researched. Among those, incorporation of silver in biomaterials, such as bioactive glasses, is acknowledged as an effective way to reduce bacteria proliferation. Osseointegration of biomaterials is dependent on the surface properties of the implants and on the interactions with the biological environment. In particular, a protein layer is formed on the surface within minutes after the contact between the surface and the biological fluids and it will dictate how the cells will respond to the implanted foreign body. As consequence, it is important to understand how antibacterial modifications of bioactive materials affect their interactions with proteins. In this work, the adsorption of albumin was investigated onto a silica-based bioactive glass where silver ions were incorporated through ionic exchange (Ag-SBA2) in order to understand eventual differences with the untreated surface (SBA2)[1].

Experimental Methods

SBA2 bioactive glass (mol %: 48% SiO₂, 18% Na₂O, 30% CaO, 3% P₂O₅, 0.43% B₂O₃, 0.57% Al₂O₃) was prepared via precursors melting and casting, cut into disks and grinded (up to 1000 grit). Ag-SBA2 was prepared by soaking glass slices for 1h in 0.03M AgNO₃ solution. Protein adsorption was obtained by soaking the samples for 2h at 37°C in albumin solution in PBS, in near physiological conditions (20 mg/ml, pH 7.4). The glass substrates were characterized in terms of topography and roughness (SEM, AFM and confocal microscopy), chemical composition (EDS and XPS), surface charge and potential (solid surface zeta potential, Kelvin Probe Force Microscopy (KPFM)) and surface energy (contact angle, Owens-Wendt method). The adsorbed proteins were quantified by using different methods (BCA assay, fluorescent proteins and XPS) and the BSA layer was also imaged (fluorescent microscopy and KPFM). Substrate-protein interactions and albumin conformation were investigated, too (solid surface zeta potential and ATR-FTIR).

Results and Discussion

After silver incorporation, confirmed by chemical analysis, the surface properties of Ag-SBA2 were mostly similar to the undoped glass. In particular, topography and roughness were unchanged during soaking in the silver solution, as expected. Wettability and surface free energy, both the dispersive and polar components, were also similar between the two substrates. Instead, zeta potential titration curve showed that the incorporation of Ag³⁺ ions increased the surface potential, in particular around physiological pH (7.4).

Quantification of adsorbed BSA showed that both surfaces adsorb a similar amount of albumin, with a little higher amount on Ag-SBA2. This can be possibly related to a couple of different factors: the high affinity of silver for proteins and the presence of a more positive charge on the surface, which is able to attract the negatively charged albumin. On both surfaces, albumin forms a complete and homogeneous layer, as detected by imaging techniques. Adsorption of proteins was confirmed also by zeta potential measurement on the surfaces, with a shift of the IEP of both glasses.
towards the IEP of albumin. Thanks to ATR-FTIR measurement, it was found that albumin retains more its native conformation on the undoped glass with respect to the silver containing glass, where a more disordered structure was found. This fact can be ascribed to a greater interaction between the proteins and the doped surface, due to the presence of metal ions and more positive charges.

**Conclusion**

In conclusion, even though the incorporation of silver ions in a bioactive glass surface does not affect surface properties that are usually addressed as pivotal in protein adsorption, such as roughness and surface energy, the presence of a more positive charge on the surface of the glass and affinity of proteins towards metallic ions seems to be enough to increase adsorption of albumin and strength of the protein-biomaterial interaction. The increased interaction with proteins may be beneficial for the cells response to antibacterial silver containing materials.

**Introduction**

Zinc is an essential trace element that plays a pivotal role in bone metabolism and remodeling. Additionally, Zn can promote osteogenesis and mineralization in osteoblastic cells as well as inhibit osteoclastogenesis [1]. This ion is associated with antioxidant and anti-inflammatory functions as it can inhibit the NF-κB pathway activation [2]. As a result, this compound has great potential for the development of biomaterials for tissue regeneration.

In this study, we developed new Zn-doped sol-gel coatings to bioactivate titanium implants and characterized their physicochemical, proteomic, and biological features to evaluate the role of Zn ions in bone healing.

**Experimental Methods**

The sol-gel method was employed to synthesize Zn-doped coatings to be applied onto Ti discs. The sol-gel reactions were carried out through methyltrimethoxysilane and tetraethyl-orthosilicate precursors. Acidified water (0.1 M HNO₃) was used to hydrolyze these precursors. Increasing amounts of ZnCl₂ (0.5, 1, 1.5 % wt) were added to the mixtures. The coatings were applied by dip-coating and samples were cured at 80°C for 2 h. The samples were physicochemically characterized through SEM, FTIR, ²⁹Si-NMR, hydrolytic degradation, Zn²⁺ release, contact angle, and roughness measurements. Proteomic assays were carried out to evaluate the effect of Zn on protein adsorption. Samples were incubated for 3 h with human serum. Afterwards, the proteins adsorbed onto the coatings were eluted and analyzed through nLC-MS/MS. The osteogenic potential was tested *in vitro* with MC3T3-E1 by evaluation of cytotoxicity, proliferation, ALP activity, and the gene expression of ALP, RUNX2, RANKL, RANK, and iNOS by RT-PCR. The inflammatory potential was assessed by RT-PCR gene expression (TNF-α, IL-1β, TGF-β, and IL-4) and by ELISA (TNF-α) in RAW264.7 macrophages.

**Results and Discussion**

The Zn-enriched biomaterials were successfully obtained and applied as coatings. Chemical characterization revealed no effects on the silica network condensation by the addition of Zn. All coatings showed a similar morphology and roughness. However, the composition with Zn displayed higher contact angle values and thus a more hydrophobic behavior than the coating without Zn. A controlled degradation and Zn²⁺ release were obtained. As more ZnCl₂ was added to the sol-gel network, more degradation and Zn liberation were achieved.

Regarding the *in vitro* analyses, the materials were not cytotoxic. In addition, an increased expression of ALP, TGF-β, RANK, and RUNX2 osteogenic markers was measured for the Zn-doped coatings. A higher gene expression of IL-1β and TNF-α proinflammatory markers was detected by incubating the Zn-enriched samples with macrophages. At the same time, the expression of TGF-β and IL-4, anti-inflammatory markers, also increased. In Fig. 1, the ELISA assay showed a decreased secretion of TNF-α cytokine for the coatings with 0.5 and 1 % wt ZnCl₂, demonstrating a dose-dependent anti-inflammatory potential of this compound.

Proteomic results showed changes in the protein layer composition adsorbed onto the coatings with Zn respect to the protein layer formed onto the control surface. These differential proteins were associated with immune, coagulative and regenerative functions. Complement system proteins C1S, CO3, CO4A, and CO9 were found more adsorbed onto the materials with Zn. However, in parallel, VTNC, IC1, FHR1, and CLUS proteins, which can inhibit
this pathway and are related to anti-inflammatory functions were also found more adhered onto them. The increased affinity of these proteins for the Zn-enriched surfaces could explain the immunological activity detected by RT-PCR as well as the reduction in the secretion of TNF-α. Moreover, PLF4, PROC, and IPSP proteins, which are linked to blood coagulation, increased their affinity to the Zn-containing coatings. On the other hand, VTNc, TITIN, and CXCL7 proteins were also found more adsorbed onto the materials with Zn. CXCL7 can improve the recruitment of human mesenchymal stem cells. TITIN can improve osteoblast proliferation, while VTNC is involved in the promotion of osteogenic differentiation of mesenchymal stem cells. Thus, these protein adsorption patterns can explain the observed osteogenic responses.

Conclusion
These new Zn-doped coatings present an interesting alternative to improve the bone tissue regeneration process. The incorporation of ZnCl₂ in the sol-gel network improved their osteogenic potential in a Zn dose-dependent manner and showed an anti-inflammatory effect. In addition, the cellular responses can be correlated with the effect of this divalent cation in protein adsorption onto the biomaterial surfaces.

Progenitor cells derived from healthy and osteoarthritic human cartilage have potential for cartilage tissue engineering

Margot Rikkers¹, Jasmijn Korpershoek¹, Riccardo Levato¹,², Jos Malda¹,², Lucienne Vonk¹,³

¹ University Medical Center Utrecht, Department of Orthopaedics, Utrecht, NL; ² Utrecht University, Department of Clinical Sciences, Utrecht, NL; ³ CO.DON AG, Teltow, DE

Introduction

Articular cartilage-derived progenitor cells (ACPCs) are a potential new cell source for cartilage tissue engineering. Unlike mesenchymal stromal cells (MSCs), ACPCs do not have the tendency to undergo terminal hypertrophic differentiation. This study aims to isolate and characterize ACPCs from human hyaline cartilage. ACPCs derived from healthy and osteoarthritic cartilage are compared. In addition, the potential to use ACPCs for cartilage tissue engineering and clinical application is assessed.

Experimental Methods

Cells were isolated from macroscopically healthy (n = 6, age 46 – 49) and osteoarthritic (n = 6, age 55 - 79) human knee cartilage. Subsequently, ACPCs were isolated from the total cell population by clonal growth after differential adhesion to fibronectin. MSCs were isolated from human bone marrow by plastic adherence after separating the mononuclear fraction using a Ficoll-paque density gradient. Healthy and osteoarthritic ACPCs were characterized by cell surface marker expression, growth kinetics, colony-forming efficiency, and multilineage differentiation. The populations were compared to full-depth chondrocytes derived from the same donors. Finally, ACPCs were cultured in 3D pellets under chondrogenic culture conditions to investigate neo-cartilage formation.

Results and Discussion

Healthy and osteoarthritic ACPCs were successfully isolated and differentiated into the adipogenic and chondrogenic lineage, but failed to produce calcified matrix when exposed to osteogenic induction media. Full-depth chondrocytes derived from the same donors were able to produce calcified matrix upon induction of osteogenic differentiation. ACPCs proliferated faster compared to chondrocytes. Both ACPC populations, as well as full-depth chondrocytes met the criteria for cell surface marker expression to define MSCs as determined by flow cytometry. Cartilage-like matrix production was successful in ACPC pellet cultures, and healthy ACPC pellets had reduced expression of hypertrophic marker type X collagen.

Conclusion

In conclusion, this study provides further insight into the ACPC population which is present in both healthy and osteoarthritic human articular cartilage. The populations show similarities to MSCs, yet ACPCs did not produce calcified matrix under well-established osteogenic and mineralization culture conditions. Furthermore, extensive culture-expansion potential of ACPCs makes these cells an ideal cell type for cartilage tissue engineering and possibly for clinical application.

Investigating the impact of Ti$_3$C$_2$Tx (MXene) within the capsular bag on the development of posterior capsular opacification

Grace Cooksley$^1$, Marcus Dymond$^1$, Yury Gogotsi$^3$, Joseph Lacey$^2$, Susan Sandeman$^1$

Introduction

Posterior capsular opacification (PCO) is the most common complication arising from the corrective surgery used to treat cataract patients. A cataract forms due to the aggregation of protein over the crystalline lens of the eye and is the leading cause of avoidable blindness globally. Despite the success of the corrective surgery in restoring visual acuity, patients implanted with an artificial intraocular lens (IOL) no longer have accommodative function and risk developing PCO; a secondary cataract formed of residual lens epithelial cells (LEC) within the capsular bag that have proliferated, differentiated and migrated over the visual axis.

The two-dimensional transition metal carbides and/or nitrides (MXenes) have been investigated for biomedical applications, specifically ophthalmic devices, due to their unique combination of conductivity, hydrophilicity, flexibility, and transparency. Ward et al., (2020) used Ti$_3$C$_2$Tx in an adjustable focus lens model to provide changes in dioptric range for an accommodative IOL design. However, the benefit of providing accommodation using Ti$_3$C$_2$Tx could increase the risk of developing PCO, resulting in further postoperative treatment for patients. MXenes have yet to be investigated with regards to their impact on the developmental pathways of PCO. The aim of this study was to investigate the effects of MXene on LEC behaviour linked to the development of PCO. The study focussed on the initial wound healing response following cataract surgery. Interleukin-1 beta (IL-1$\beta$) instigates inflammatory cytokine interleukin (IL)-6 and IL-8 mediated wound healing response following cataract surgery. Excess stimulation promotes inflammation and subsequent developmental pathways of PCO. It was hypothesised that Ti$_3$C$_2$Tx would suppress activation of this inflammatory cytokine cascade using a human lens epithelial in vitro model of inflammatory cytokine activation.

Experimental Methods

Delaminated Ti$_3$C$_2$Tx, MXene was synthesised using the MILD method and characterised using dynamic light scattering and UV-spectroscopy. Coatings of Ti$_3$C$_2$Tx were spin-coated onto the IOL optic (Ossila Spin Coater). The wettability of IOL material and coatings were characterised using contact angle analyser (OCA 15plus, Dataphysics). The viability of human lens epithelial cells (HLE-B3) grown on hydrophobic and hydrophilic IOLs (Rayner Intraocular Lenses Ltd., Worthing, UK) and Ti$_3$C$_2$Tx-coated hydrophobic IOLs was characterised using Live/Dead™ stain, MTS and LDH assay. Expression of IL-6 and IL-8 by HLE-B3 cells incubated on the IOL types was quantified using enzyme-linked immunosorbent assay (ELISA). Cytokine expression was further investigated using an in vitro model of HLE-B3 cells incubated with Ti$_3$C$_2$Tx colloidal solution to determine the impact of Ti$_3$C$_2$Tx on the wound-healing response of HLE-B3 cells. The study also investigated the ability of Ti$_3$C$_2$Tx to suppress cytokine expression, by treating HLE-B3 with Ti$_3$C$_2$Tx colloidal solution after priming with proinflammatory cytokine IL-1$\beta$.

Results and Discussion

Dynamic light scattering and UV-spectroscopy confirmed the synthesis of Ti$_3$C$_2$Tx colloidal solution with an average particle dispersant index of 0.244 and flake size of 472 d nm. Contact angle analysis showed the presence of Ti$_3$C$_2$Tx coatings increased the wettability of the hydrophobic lenses. There was no significant difference in cell viability between HLE-B3 cells grown on the hydrophobic, hydrophilic, and Ti$_3$C$_2$Tx-coated hydrophobic IOLs. Moreover, the
expression of IL-6 and IL-8 did not significantly differ between the IOL types. On direct contact with Ti3C2Tx colloidal solution, HLE-B3 cells did not express IL-6 and IL-8. After priming of HLE-B3 with IL-1β, post-treatment of Ti3C2Tx suppressed all expression of IL-6 and IL-8 after only 1-hour exposure. This work demonstrated that intraocular lens material and the addition of Ti3C2Tx coatings did not impact cell viability between the IOL types. Moreover, this work showed the presence of Ti3C2Tx colloidal solution does not induce cytokine expression but, suppresses IL-6 and IL-8 expression by HLE-B3 cells, suggesting a potential role of Ti3C2Tx in cytokine adsorption.

**Conclusion**

Ti3C2Tx MXene does not influence cell viability and does not induce the expression of IL-6 and IL-8, suggesting the presence of Ti3C2Tx within the capsular bag post-cataract surgery will not promote inflammatory pathways leading to PCO development. Further work will include investigating the impact of Ti3C2Tx on the epithelial-mesenchymal transition (EMT) pathway, an established fundamental pathway in PCO development, by migration assays and the development of an *in vitro* transwell insert model of inflammation using a co-culture of HLE-B3 cells and THP-1 monocytes.

Introduction
Aging is a high-risk factor for the development of osteoporosis. Osteoporotic fractures (also called fragility fractures) are an important cause of disability and loss of life quality, with an economic impact on the health care systems. Mesenchymal stem/stromal cells (MSCs) are key players in bone regeneration/repair. Engineering MSC can be a strategy to promote commitment into the osteogenic lineage and accelerate bone healing. Non-coding RNAs (ncRNAs) are a large class of transcripts that do not encode for proteins, but can be used as tools to mediate bone homeostasis and regeneration/repair, and control MSC and pre-osteoblasts differentiation, proliferation, and extracellular matrix (ECM) composition, among other mechanisms. The aim of this study is to: 1) investigate the role of the long ncRNA H19 on the ECM proteins secreted by MSCs derived from osteoporotic patients; and 2) explore how H19-engineered MSC-derived ECM can modulate cell behaviour.

Experimental Methods
MSCs were isolated from the bone marrow of osteoporotic patients that underwent total hip arthroplasty following a fragility fracture. Cells were cultured under basal or osteogenic-inducing stimuli. H19 and ECM components expression was quantified by RT-qPCR. siRNA was used to knockdown H19 levels (siH19), by transfection. A scrambled sequence was used as control. The effect on osteogenic differentiation and ECM production was evaluated by ALP and calcium deposits histochemical staining. Protein was extracted at day 10 of differentiation using an ECM enrichment protocol. Mass spectrometry-based proteomic analysis was performed to investigate proteins and pathways targeted by H19, in particular those associated with the ECM. Protein identification was performed against entries from the UniProt database with Sequest HT search engine. Then, the ECM produced by siH19-engineered MSCs was decellularized an repopulated with MSCs and pre-adipocytes (differentiated for 10 days under adipogenic conditions), which were cultured on top of the decellularized matrix. The effect of the matrix on the MSCs or pre-adipocytes behaviour was tested by RT-qPCR for MSC lineage specific markers, and by resazurin assays.

Results and Discussion
H19 knockdown in hMSCs led to a decrease in the expression of several ECM components including COL1A1, COL1A2 and COL3A1. It also caused a decrease of osteogenic differentiation markers, including RUNX2 and ALP. Mineralization was impaired when H19 levels were decreased, compared with control. High-throughput analysis showed that distinct ECM proteins were modulated by H19, including COL1A1, FBN1 and VTN. Naïve MSC cultured on top of the decellularized matrix secreted by siH19-MSCs show a tendency to differentiate toward adipogenesis in detriment of osteogenesis. The expression levels of CEBPB (adipogenic marker) were increased, while RUNX2 (osteogenic marker) was decreased in MSCs cultured on top of siH19-MSCs derived matrices, compared with control-MSC derived matrices. Furthermore, metabolic activity was inhibited when MSCs were cultured in the siH19-MSCs decellularized matrices. In agreement with these results, CEBPB was overexpressed when pre-adipocytes were cultured in the matrices produced by hMSCs depleted in H19.

Conclusion
Page 1406 of 2028
Inhibition of H19 in MSC-derived osteoblasts changes ECM components and mineralization. Furthermore, the ECM secreted by siH19-MSCs guides the effect on cell proliferation and osteogenic/adipogenic differentiation. In conclusion, this study shows that modulation of the long ncRNA H19 impact levels of ECM components, which consequently influences cell behaviour.

Introduction
The lifespan and performance of an implant is largely dependent on our body's immune response. Chronic inflammation, encapsulation by fibrotic tissue, and aseptic loosening reduce the durability of many implant materials and cause severe pain in patients. Mainly responsible for these reactions are monocyte-derived macrophages (MDMs), phagocytic cells of our innate immune system. MDMs strongly adhere to material surfaces and orchestrate many downstream events of inflammation and healing. However, the macrophage response can be modulated by surface characteristics such as topography or E-modulus of biomaterials and implants. Existing methods that comprehensively analyze the molecular response of these cells towards an implant are invasive and in most cases marker-based. Aggressive treatments to detach adherent cells, such as scraping or digestion with enzymes, alter cell surface proteins, impair cell viability and ultimately limit the ability to accurately characterize adherent cells.

Experimental Methods
Raman microspectroscopy (RM) is a marker-independent, non-invasive method that allows the analysis of cells and tissues without the need for staining or processing. Using spectral imaging, biochemical components such as proteins, lipids and nucleic acids in single cells can be visualized, making it an ideal method to reveal differences in the biochemical composition of macrophages.

Results and Discussion
In the present study, we analyzed human MDMs in suspension by RM, revealing that especially lipid composition significantly differs in M0 (resting), M1 (IFNg/ LPS), M2a (IL-4/ IL-13) and M2c (IL-10) MDM phenotypes. To track similar biochemical alterations without potent activators such as LPS, interferons or cytokines, we cultured MDMs on titanium disks with varying surface topographies. While classical methods like cytokine expression or surface antigen analysis did not show significant differences between the samples, RM identified changes in biochemistry and lipid composition.

Conclusion
Our data shows that Raman microspectroscopy and Raman imaging allow an improved and more detailed classification of MDM response to environmental triggers such as implant material topographies or biochemical composition, providing unique insight into the activation spectrum of macrophages.

Development of a Virus-Like Particle platform for the control of cell fate

Thomas Dos santos, Tatiana Petithory, Isabelle Brigaud, Karine Anselme, Laurent Pieuchot

Université de Haute Alsace, IS2M, Mulhouse, FR

Introduction
During evolution, living organisms have developed different proteins capable of self-assembly into 3D objects with specific functions such as viral capsids or components of cell cytoskeleton. The coat protein forming the capsid of many viruses can be produced through heterologous expression systems and form auto-assembled noninfectious nanoparticles named Virus-like Particles. VLPs form repetitive and well-defined architectures that can be used as an antigen-presenting platform for the designs of new vaccines.

Here we present the development of the VLPs from the RNA bacteriophage AP205 as a genetically modified platform to control cell adhesion and fate. AP205 particles are formed from 180 copies of a coat protein. The assembled particles are very robust and tolerate insertion of small sequences into N- and C- termini that will be exposed at the particle surface.

Experimental Methods
Using cloning techniques, we fused a short adhesion peptide (RGD) to the C-terminus of the coat protein. The resulting fusion protein was then expressed in a bacterial system and purified by affinity and size exclusion chromatography. Negative staining transmission electron microscopy and DLS analysis assessed the presence of particles consistent in size with the VLPs. Immunostaining and confocal microscopy allowed us to determine the adhesion properties of our particles by measuring the spreading of cells.

Results and Discussion
Adsorption of RGD containing particles on PDMS surfaces allows mouse cells C2C12 to adhere. Regulation of the stoichiometry and concentration of RGD-particles provide control of cell spreading and cell density on culture surface. These results show that recombinant VLP-RGDs can be used to control cell adhesion. With the same methods, we were able to produce particles expressing differentiation peptides.

Conclusion
We are currently working on the osteoinductive and myoinductive properties of our new particles. We expect to use AP205 VLPs as a general modular platform to finely control cell fate.
Innovative phosphate-based bioresorbable and antibacterial bioglasses

Introduction
Infectious diseases are one of the most important causes of death in the World. The constant use of antibiotics has led to the development of new very resistant bacterial strains, which are a threat for public health. For this reason, noticeable efforts from different scientific fields have been devoted to achieve solutions that might contribute to attenuate this problem. In this context, research on new antibacterial materials has become a current and important goal in materials science. Several metals are well-known in literature for their antibacterial properties, both because of direct contact with the surface and the release of ions into the solution (indirect contact). Among these metals, the most extensively used in different applications are silver and copper. They show a broad spectrum of action against bacteria both upon exposure to surfaces and ions in solution. The advantage of copper resides in its lower toxicity to mammalian cells than silver. Indeed, Cu\textsuperscript{2+} ions in small quantity facilitate the activity of different enzymes and help cross-linking of collagen and elastin of bones, whereas in high concentration it can inhibit osteoblast proliferation. Therefore, it is crucial to control copper concentration for biomedical applications.

The aim of this work is to evaluate the antibacterial effects and the biocompatibility of undoped (CPG) and Cu\textsuperscript{2+}-doped calcium-phosphate glasses (CPG_Cu) which have shown in previous studies interesting degradative, mechanical and optical properties to be used in biophotonic and medical applications.

Experimental Methods
CPG and CPG_Cu were analyzed with inductively coupled plasma – optical emission spectroscopy (ICP-OES) to evaluate their content of Ca, P, Na, Mg, B, Si and Cu. The antimicrobial effect of CPGs against four of the most common causing-infections bacteria, namely Staphylococcus aureus ATCC 25923, Escherichia coli ATCC 25922, Pseudomonas aeruginosa PAO1 and Klebsiella pneumoniae were investigated; the biocompatibility was performed using NIH-3T3 cells. These viability assays in both bacteria (after 24h) and eukaryotic cells (after 24 and 48h) were evaluated through the quantitative 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) test, which was performed in both direct and indirect contact and measures dehydrogenase activity as an indicator of the metabolic state. Moreover, we investigated the viability of adherent cells with MTT and confirmed it with scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM).

Results and Discussion
The obtained results demonstrated the promising antibacterial properties of Cu\textsuperscript{2+}-doped CPG with respect to undoped CPG, in particular against Gram-negative bacteria. The particular efficacy against E. coli, P. aeruginosa and K. pneumoniae is due to the different composition of bacterial surface. The preliminary quantitative and qualitative (SEM and CLSM) studies performed using 3T3 cells showed that CPG and CPG_Cu were not toxic.

Conclusion
The results suggested that the tested bioresorbable bioglasses showed biocompatible and antibacterial properties useful for medical applications.

**Bacterial colonization of oxygen-functionalized graphenic surfaces**

**Wojciech Pajerski**, Joanna Duch, Monika Golda-Cepa, Dorota Ochonska, Monika Brzychczy-Wloch, Andrzej Kotarba

1 Jagiellonian University, Faculty of Chemistry, Krakow, PL; 2 University of Gdansk, Faculty of Chemistry, Gdansk, PL; 3 Jagiellonian University Medical College, Department of Molecular Medical Microbiology, Chair of Microbiology, Faculty of Medicine, Krakow, PL

**Introduction**

The graphene family nanomaterials are an exciting promise in biomedical applications such as tissue engineering, bone regeneration, stem cells differentiation, bio-imaging, and photothermal therapy [1]. The specific properties of graphene-based biomaterials, which play a pivotal role in regenerative medicine applications include: electrical conductivity, good mechanical properties, large surface area, and tunable surface functionalities [2]. Although, carbon biomaterials are extensively studied in recent years, interactions at biointerfaces between bacteria and carbon surfaces are still far from in-depth understanding. The major issue concerning the use of graphene-based biomaterials is the infection risk and subsequent complications causing additional treatment and higher mortality.

The aim of the study was to identify the key factors mediating the bacteria adhesion to oxygen-functionalized graphenic surfaces. The investigations were focused on the initial step of bacteria colonization, which is crucial for infection and biofilm formation.

**Experimental Methods**

In this work, we have investigated the effect of oxygen plasma functionalization of model graphenic sheets (introduction of oxygen functional groups) on changes in work function (WF), surface free energy (SFE), wettability, and bacterial adhesion. The oxygen plasma parameters were precisely adjusted (exposure time: <20 min, generator power: <60 W, oxygen pressure: 0.3 mbar) to limit the modifications to the surface without changes in the bulk structure of the material. The investigated graphenic surfaces were thoroughly characterized by SEM, RS, XPS, TG/DTA, contact angle, work function measurements, and bacterial adhesion tests.

**Results and Discussion**

The effect of oxygen functional groups introduced to graphenic surfaces on bacterial adhesion was evaluated for a series of microorganisms: *Staphylococcus epidermidis, Staphylococcus aureus, Pseudomonas aeruginosa, Escherichia coli*. The modification of graphenic surfaces was accomplished by the application of low-temperature oxygen plasma treatment while adjusting the parameters for control surface modification (number of surface functional groups) without changing the bulk structure of the material. The obtained results clearly show that key factors of bacterial colonization are the surface work function (electrodonor properties) and the zeta potential (surface charge) of bacterial cells. The lowest colonization rate was observed for lower work function graphenic material (4.4 eV) and for bacteria with the lowest zeta potential (*E. coli*). The results were rationalized in terms of total interaction energy with the main contribution from electrostatic forces at the graphenic sheet-bacterial cell interface (Fig. 1).

**Conclusion**

It was found that even the short time of oxygen plasma modification (a few seconds) increases significantly hydrophilicity, surface free energy, and work function of graphenic materials. The changes in surface chemistry, and bacterial surface charge substantially influence the bacterial adhesion. The strong relationship between work function value and bacterial adhesion was observed for several pathogenic bacterial strains: the lower work function value,
the lower colonization rate. Additionally, the low zeta potential inhibits the bacterial colonization rate of graphenic surfaces. The results pointed out the work function lowering of the graphenic biomaterial surface as a rational strategy for the infection risk limitation.

Diabetic environment alters the adhesion behaviour of Staphylococcus aureus to the Ti6Al4V surface

Maria Fernandez-Grajera1,2,3, Miguel A. Pacha-Olivenza1,2,3, M. Luisa Gonzalez-Martin1,2,3, Amparo M. Gallardo-Moreno1,2,3

Introduction
The titanium alloy Ti6Al4V is a biomaterial with good mechanical properties and great biocompatibility, but one of the biggest drawbacks is infectious processes. Diabetes is a disease with a very high incidence in the elderly population. In this age group it is also common to find patients with bone replacements such as hip or knee implants usually made of titanium and its alloys. The presence of glucose and ketone bodies in cases of poorly controlled diabetes significantly alters the incidence of infections in these patients. The reasons are unclear, but diabetes has been linked to different physiological processes such as inflammatory reactions, poor vascularisation or neutrophilic chemotaxis. However, there has been little work on analysing the effect of a diabetic environment on the bacterial adhesion behaviour to biomaterial surfaces from the bacterial approaching to the surface to long adhesion times using a dynamic model. This work will evaluate the adhesive behaviour of Staphylococcus aureus to Ti6Al4V surfaces under flow with and without diabetic supplements, including different concentrations of glucose and ketone bodies.

Experimental Methods
25 mm Ti6Al4V disks were mirror polished. The strains selected have been S. aureus ATCC 29213, a gram-positive bacterium with opportunistic behaviour. Bacterial growth was carried out with different diabetic conditions, including the individual action of glucose and ketone bodies and their combined action. Bacterial adhesion experiments were performed in a laminar flow chamber, where bacteria were allowed to adhere to Ti6Al4V in a suspension of phosphate buffer saline (PBS) supplemented with the same diabetic components as those used in the growth media. The contact was allowed for 5h at a temperature of 37°C. During this time a series of live photographs were recorded and then analysed to quantify bacterial adhesion. Experiments were carried out by triplicate.

Results and Discussion
The results show that the different concentrations of diabetic components in the culture media modify the adhesion dynamics of S. aureus. In particular, the supplementation with glucose leads to an increase in the number of the final adhered bacteria, but not in the initial adhesion dynamics. However, the different concentrations of ketone bodies cause changes not only in the initial adhesion rates but also in the final coverage of the Ti6Al4V surface. Under a more realistic environment of poorly controlled diabetes, the mixture of supplements indicates the dominant role of hyperglycaemia in the adhesion rate, being the largest of all treatments. Likewise, a significant increase in the bacterial aggregation over time was observed, ketoacidosis being the dominant parameter for this behaviour.

Conclusion
This study reveals the role of hyperglycaemia and ketoacidosis in the initial adhesion process of bacteria to the titanium surface. While hyperglycaemia seems to be more associated with an increase in the final number of bacteria, ketoacidosis causes bacterial aggregation and affects both the initial stages of adhesion and the final coating of the surface.

Introduction

Multiple Sclerosis (MS) is the leading cause of nontraumatic neurologic disability in young adults in many countries. In the acute phase of the disease, the primary pathological hallmark is the presence of focal inflammatory lesions, characterized by demyelination but relative preservation of axons. These lesions evolve into chronic active lesions with complete demyelination, formation of an astroglial scar and extensive inflammation. Astrocytes have been for long assigned a role as bystanders during demyelination. Although recent finds suggest that these cells are highly active participants in MS lesions’ development, their role during MS progress is still poorly understood. Astrocytes change their phenotype from quiescent to reactive with differentially expression of reactive genes (e.g., Glial fibrillary acidic protein (GFAP) and Lcn2) and extracellular matrix proteins (e.g., collagen IV, fibronectin), which strongly modify the properties of the lesion environment. Our working hypothesis is that the alterations in the matrix caused by reactive astrocytes negatively impact the formation of new myelin sheaths after demyelination. Currently there is no suitable in vitro model that can recreate all features of astrogliosis. Thus, there is a need for the development of new methodologies to study this phenomenon.

In this work we present a three-dimensional (3D) tissue-engineered model to study astrocyte reactivity. In order to reconstruct a more physiologically relevant environment, astrocytes were embedded within modified alginate matrices. Alginate was chosen due to its compatibility with mammalian cell culturing, possibility of introducing modifications in its the structure to increase biological responses and tunable mechanical properties.

Experimental Methods

1% (wt/v) alginate hydrogels were produced by mixing non-modified high molecular weight alginate with alginate modified with the cell adhesive peptide RGD (GGGGRGDSP) and oxidized alginate (theoretical oxidation of 10% (m/m)) with engrafted matrix metalloproteinase sensitive peptide PVGLIG (GGYGPV↓LIGGK). Final concentration of RGD and PVGLIG was set to 40 μM and 400 μM, respectively (Alg Mod). Non-modified alginate was used as a control (Alg HMW). Primary rat cortical astrocytes (P1-P2 pups) were embedded in hydrogels and maintained in culture for 7 days. A pro-inflammatory stimulus (LPS/IFNg) for 72h was used to induce an astrogliosis-like phenotype. To promote alginate hydrogels mechanical properties changes, an external BaCl₂ (50 mM) bath was performed (15 min, 37°C) at 24h post cell seeding. The mechanical properties of hydrogels were measured by rheology. Astrocytic phenotype was evaluated by gene expression and 3D image analysis using the IMARIS software and glial fibrillary acidic protein (GFAP) as the astrogliosis marker.

Results and Discussion

Astrocytes embedded in Alg Mod extend more and longer cellular processes and acquire an overall more complex morphology, when compared to astrocytes grown in Alg HMW. This is in line with a more physiologically relevant extracellular environment being achieved with the introduction of modifications into the hydrogel. Treatment with LPS/IFNg did not alter metabolic activity of cells and increased the expression of the Lcn2 and CollIV genes (after 72h of treatment), with cellular morphology remaining relatively unchanged. Preliminary results suggest...
that mechanical properties of the hydrogel are not altered in the presence of the stimulus. These results are indicative of an astrogliosis-like phenotype being achieved. After submitting cell-laden hydrogels to an external BaCl₂, matrices became stiffer (G* increased from 21.22 Pa to 144.03 Pa) and approximately 45% smaller in size. Preliminary results suggest that cell metabolic activity and viability was affected by this process, but cellular morphology remains unchanged.

**Conclusion**

In this work we present a 3D cell culture method to study astrocyte reactivity and response to biochemical and mechanical stimuli. Modifications introduced in alginate hydrogels allowed astrocytes to acquire a more complex morphology in line with what happens *in vivo*. Treatment with LPS/IFNγ did not alter metabolic activity and induced an increase in expression of *Lcn2* and *ColIV* while the morphology remained relatively unchanged. Finally, using BaCl₂ we were able to increase astrocyte-laden alginate hydrogels’ stiffness (G*), with preliminary results suggesting a negative impact on cells’ metabolic activity and viability but with morphology remaining normal. In the future we will use this 3D culture system to combine these two types of stimuli (biochemical and mechanical) and characterize astrocytic response, shedding light into the complex world of mechanobiology of the glial scar and its impact on demyelinating conditions.

Spatial topological confinement dictates the effective growth and differentiation of neural stem cells

Jagoda Litowczenko¹, Barbara M. Maciejewska¹, Jacek K. Wychowaniec¹,2

¹ Adam Mickiewicz University in Poznan, NanoBioMedical Centre, Poznań, PL; ² University College Dublin, School of Chemistry, Dublin, IE

Introduction
According to World Health Organization (WHO) neurological disorders are a leading cause of disability and the second leading cause of death worldwide, affecting 276 million and 11.6% of global disability-adjusted life years (DALYs) in 2016. Particularly challenging is the limited capacity for the repair of mature nervous system, which to this day remains a significant clinical challenge and hurdle for patients [1]. This is in part due to the lack of understanding of neural tissue re-growth development. Tissue engineering approaches are able to overcome those challenges by combining cell therapies with advanced biomaterials to restore tissue homeostasis and proper functions. Specifically, spatiotemporal guidance of axon outgrowth was found crucial for the re-wiring of neural tissue damage resulting either from traumatic injuries or progressive diseases [2]. Nerve cells are particularly susceptible to the surface stiffness and topography. In our recent studies we observed that both topographical cues and stiffness promotes morphological changes in the cells of neuronal origin [3]. Graphene-based materials due to their mechanical strength, conductivity and/or available surface for bio-functionalization are also largely exploited as scaffolds that regulate cell behaviour, including proliferation, differentiation in order to promote specific tissue regeneration [4]. Recently we also showed that surface roughness of rGO scaffolds plays a crucial role in cell attachment and proliferation [5]. Therefore strategies involving manipulation of topography, stiffness, as well as surface chemistry, are being explored to engineer guidance conduits with precise ability to direct behavior of neural stems cells.

Experimental Methods
Here we studied material neural stem cells (NSCs) interactions; in particular, we investigated the alignment and differentiation of NSCs on a series of groove-patterns made of silicon, as well as of composite graphene-based matrices, prepared by photolithography and soft lithography methods. Spatial dimensions of fabricated matrices were varied from across nano- to micro-length-scales to investigate the effects on the biological outcome of cultured cells up to 21 days. Immunocytochemistry, and detailed proteomic analysis were performed to elucidate the underlying cellular mechanisms.

Results and Discussion
We demonstrated that groove patterns topography have a strong impact not only on cell alignment and neurite outgrowth but also on differentiation of NSCs. Our results point out to specific combination of topography and substrates stiffness that can lead to selective differentiation of NSCs without any exogenous supply of differentiation stimulants. The analysis of the cell processes length revealed extensive neurite outgrowth on material patterns with dimensions resembling those of native tissue. Composite scaffolds supported cell growth, proliferation and differentiation. Immunocytochemistry staining and mass spectrometry coupled with liquid chromatography (LC-MS/MS) proteome analyses confirmed favorable spontaneous NSCs differentiation on groove pattern of specific dimensions compared to all tested topographies. ICC and proteomic studies also allowed for identification of differentiation-stage specific markers of astrocytes, oligodendrocytes and neurons, which will be discussed during the presentation.

Conclusion
Page 1418 of 2028
Our results greatly contribute to the understanding of differentiation process of cells of neuronal origin, which can ultimately lead to promising strategies for neuronal tissue engineering. In particular, underlying cellular processes and mechanism of mechano-transduced differentiation were elucidated and linked to relevant proteins revealed by LC-MS/MS proteome analysis.

Introduction
Hydrogels, a tridimensional (3D) polymeric network, are a promising biomaterial for regenerative medicine. They are attractive due to different properties, such as their biocompatibility, their permeability to oxygen, nutrient growth factors and metabolic waste and their mechanical properties similar to natural tissues. It has been also reported that cells are able to remodel hydrogels to produce a new extracellular matrix (ECM). This behavior is depending on the type of cells and on the appropriate biological cues and mechanical properties of the hydrogel (1).

Among the wide selection of natural polymers, chitosan (CS, a cationic polysaccharide) has been extensively studied as a component of hydrogels applied in tissue engineering. Nevertheless, CS polymer lacks binding sites for cell adhesion. Thus, the addition of a molecule that contains these biological signals is necessary. Fibronectin (Fn) is an ECM dimeric glycoprotein and the principal molecule involve in cell adhesion, migration, and differentiation due to the presence of binding domains (2). It has been shown that the covalent addition of Fn using EDC/NHS ameliorates the cell adhesion and cell proliferation in a CS membrane (2D) (3) and also increases mechanical rigidity in polyelectrolyte-based thin films (4).

In this work, CS/Fn hydrogels were developed using the 1-ethyl-3-[3(dimethylamino)propyl] (EDC) and N-hydroxysulfosuccinimide (sulfo-NHS) as cross-linking agents. This technique would allow at the same time, give a biological cue, and improve the mechanical property of the hydrogel. The aim of this study was to evaluate cell behavior in a 3D biomaterial to better understand the cell-material relation.

Experimental Methods
Different CS:Fn ratios were studied for hydrogel formation. First, a CS stock solution was prepared using an equal molar ratio with acetic acid. Then, a solution of human plasmatic Fn was mixed at corresponding ratio by stirring. Finally, an EDC/NHS solution was added to the mixture and the crosslinking was attended by stirring the solution for 4h at room temperature, then for 20h at 4°C without stirring. A hydrogel without Fn was also prepared.

For cell culture test, samples were prepared in sterile conditions and rinsed with phosphate-buffered saline (PBS, pH 7.4). Hydrogels cytocompatibility was evaluated with pre-osteoblast cells (MC3T3-E1) using AlamarBlue® assay. Cell adhesion and proliferation were evaluated in hydrogels with and without Fn using MC3T3-E1. Hydrogels were incubated in presence of cells for 24h and 72 h at 37°C and 5% CO₂, then samples were staining with DAPI (DNA) and phalloidin-FITC (actin) and imaged using a laser scanning confocal microscope.

Results and Discussion
Stable, homogeneous, and transparent hydrogels were obtained for all CS/Fn ratios. All hydrogels were cytocompatible (with or without Fn) with cell survival greater than 75%. After 24h of incubation, cells adhesion was observed only in CS/Fn hydrogels (Fig. 1a). We can observe a spread morphology with a high quantity of actin fibers in the cell cytoskeleton. However, hydrogels without Fn showed a spherical morphology and lack in actin fibers (Fig. 1c). After 72h of incubation, the proliferation of cells was remarkable in CS/Fn hydrogels (Fig. 1b). While in hydrogels without Fn (and without cell adhesion) there was no proliferation (1d). It has been confirmed that cell adhesion in a 3D biomaterial is also needed to promote cell proliferation and migration.

Conclusion

Page 1420 of 2028
The preliminary results demonstrated the feasibility of forming a hydrogel between CS and FN with a covalent binding and validated the need of biological cues to promote cell adhesion and proliferation. Furthermore, viscoelastic properties should be evaluated to better understand the role of mechanical properties in hydrogels.

Introduction
Over the last decades, most of the strategies to improve the vascularization of biomaterials based on calcium phosphates (CaPs) were based on the incorporation of well-known proangiogenic agents such as growth factors, despite their high cost and the complexity of delivering safe and effective doses [1]. A promising alternative is the use of inorganic elements that naturally occur within the body, namely metallic ions [2]. It has been shown that dissolution products of CaPs are able to induce vascularization [3], although the particular mechanism by which calcium stimulates this process is not very well understood, mainly due to the lack of suitable \textit{in vitro} models.

Experimental Methods
The design of this platform was performed using CAD software and it consists of two cell culture chambers flanked by a total of three media channels. The chambers are delimited by two lines of microposts, which are used to confine the cells. Master molds were obtained in 4" silicon wafers using standard photolithography techniques in a clean room environment. PDMS replicas were obtained from these masters and bonded to 0.17 mm coverslips with deposited aligned nanofibers, which were created by electrospinning a solution of polylactic acid (PLA) in 2,2,2-trifluoroethanol with or without CaP ormoglass nanoparticles at 25 % w/w (PLA vs PLA + NP25). To perform the process, the coverslips were fixed to a grounded rotary collector, which was set to rotate at a speed of 1000 rpm. The applied voltage was 15 kV and the distance between the tip and the collector 20 cm. Most of the deposited nanofibers were carefully removed with acetone to leave only an area corresponding to the section of one of the cell chambers.

Bone-marrow derived rat endothelial progenitor cells (rEPC) and rat mesenchymal stem cells (BM-rMSC) were obtained from the long bones of young Lewis rats (2-4 weeks old) following a previously published protocol [4]. The BM-rMSC were seeded on top of the electrospun fibers (stromal chamber) and rEPC on the wall of a 3D fibrin gel (2.5 mg/ml) loaded in the other cell compartment (migratory chamber). Cells were fixed after 3 days in culture with paraformaldehyde and stained for DAPI/phalloidin. Images were acquired with a confocal microscope (Leica SP-5) and processed using Image J to obtain the number of cells and their mean migrated distance with respect to the end of the microposts. Conditioned media was collected at day 3 and analyzed using ELISA for several pro-angiogenic and pro-inflammatory factors such as the insulin-like growth factor 2 (IGF-2), interleukin 6 (IL-6) and osteopontin (OPN). Student’s \textit{t}-test (unpaired, two-tailed distribution) was used to compare the two samples (a p-value < 0.05 (*) was considered statistically significant).

Results and Discussion
Our results show that the PLA + NP25 is able to significantly increase the recruitment of rEPC respect to the PLA control, both in terms of the mean migrated distance (92.32 ± 5.24 µm vs 69.33 ± 11.24 µm) and mean number of migrated cells (42 vs 12). The protein expression analysis of the conditioned media revealed that the PLA with calcium phosphate nanoparticles caused a significant increase in the release pro-angiogenic and pro-inflammatory factors.
factors (IGF-2, OPN, IL-6). The data obtained with our microphysiological system closely matches the results obtained for in vivo studies using the same material (subcutaneous implantation in rats) [5].

**Conclusion**

In this study, we presented a microphysiological system to evaluate the potential of a biomaterial to recruit endothelial progenitor cells. We show that a material based on PLA fibers with calcium phosphate nanoparticles is able to significantly increase the migrated distance and cell number with respect to the PLA control. This result is in good agreement with in vivo studies previously performed with the material, showing the great potential of microphysiological systems to accelerate the bone-graft substitute research.

Human dental MSC spheroids: development of a pre-clinical imaging model to clarify cellular spheroids behavior in vivo

Jorge Dias¹,², Cristina Barrias³,⁴, Fernando J. Monteiro³,², Christiane Salgado¹,³

¹ INEB - Instituto Nacional de Engenharia Biomédica, Porto, PT; ² FEUP - Faculdade de Engenharia, Universidade do Porto, Porto, PT; ³ i3S - Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Porto, PT; ⁴ ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, PT

Introduction

In the oral cavity, adult tooth tissues contain cells with mesenchymal phenotype and their main advantages are the easy access with limited morbidity, multipotent capacity, rapid attachment and high proliferation rate. Although, in 2D cell cultures, cell metabolism and the cell–cell interactions are reduced. On contrary, 3D cell cultures (spheroids) exhibit increased levels of cell-specific markers, regain tissue functions and gene expression profiles when compared to 2D. One major challenge in tissue engineering is to ensure the functionality of administered cells within the host environment, without premature loss and/or excessive death. In this context, spheroids will be monitored along time with the expression of luminescent/fluorescent signals, for in vivo imaging purposes. Cells transfected with GFP-Luciferase plasmids have an advantage dye-labeling particles, as it is integrated into the genome, retained in the daughter cells, and can follow cell proliferation and tracking in deep tissues. Using this optical imaging approach, the pre-clinical model will monitor the cells engraftment into the bioengineered material and evaluate the tissue regenerative process at a cellular level. In this work, we developed luminescent/fluorescent human dental MSC lines, optimized MSC spheroid formation process and characterized the cells metabolic activity/proliferation/differentiation.

Experimental Methods

Dental follicle was surgically removed from the completely intra-bone impacted third molar. This study was approved by an Ethical Committee of University of Porto (50/CEUP/2018, Portugal). Cells were collected, digested and isolated by adherent culture on plastic tissue culture substrates as described previously (1). Dental MSCs expressing GFP-Luc was developed by efficient lentiviral transduction. The lentiviral vectors was produced by HEK293T cells using a dual-promoter reporter gene (pVSVG – envelop and psPAX2 - Packaging) and pHAGE GFP-IRESG-luc (Transfer plasmid Reporter). hDFSCs was incubated with the GFP-IRESD-luc virus vectors, and were assessed on a ZOE™ Fluorescent Cell Imager and GFP positive cells were sorted by FACS Aria II, after 5 days. Spheroids were produced using commercially available MICROTISSUES® technology. Briefly, agarose (2%) micro-molds were prepared and hDFSC suspension were seeded at a concentration of 5.12 × 10⁵ cells/micro-mold, corresponding to 2000 cells per spheroid. Cells were grown during 10 days, with media being changed every 48 h. Cultures were monitored and the spheroids diameter was measured with Brightfield microscopy at each time-point. Metabolic activity of spheroid cultures was assessed using Alamar blue assay at days 1, 3, 5, 7 and 10, resazurin solution (0.2%) was added to micro-molds and supernatant collected and placed in 96-well black-plates. The obtained fluorescence values were normalized in relation to the number of spheroids placed in each micro-mold.

Results and Discussion

A major obstacle in the assessment of cell-based therapeutic strategies is the ability to track their interaction with local microenvironments and differentiation into various cell phenotypes as they occur in real-time. Transfected human dental follicle mesenchymal stem cells (GFP-Luc_DFSC) were developed and showed into 2D evaluation, adhesion capacity, proliferation rate, and osteogenic differentiation similar to non-transfected cells, as validated ALP enzyme activity and high expressio of osteopontin and BMP-2 by qPCR evaluation after 21 days. GFP-Luc_DFSC spheroids were successfully produced with a narrow size distribution with an average diameter of 150 µm (Fig. 1)
and a uniform spherical shape, and the majority were viable after 10 days, as confirmed by Alamar blue assay (Fig. 2). The osteogenic differentiation of the spheroids was performed and GFP-Luc-DFSC spheroids showed human bone osteopontin and calcium crystals presence (Alizarin red), as observed for the non-transfected cells.

**Conclusion**

In conclusion, human hDFSCs with GFP-Luc (virus vector) showed a luminescence/fluorescence signal that was integrated into the genome and, as a result, retained in the daughter cells, and enable to follow metabolic activity/proliferation rate, for 10 days (3D spheroids) and 3 weeks (2D) in vitro. The GFP-Luc-DFMSC spheroids showed, high ALP activity, a remarkable osteogenic potential and produce mineralized ECM. After these successful results, a spheroid-loaded scaffold will be tested in vivo by a well-established animal model and GFP-Luc-DFSC spheroids engraftment and survival will be followed by real-time imaging, to study their role into the bone regenerative processes.

**Acknowledgement**

This work is a result of the project NORTE-01-0145-FEDER000012, supported by North Portugal Regional Operational Programme (NORTE 2020), under the PORTUGAL 2020 Partnership Agreement, through the European Regional Development Fund (ERDF). In addition, it was supported by Portuguese funds through FCT/MCTES in the framework of the project UID/BIM/04293/2019.
Cell metabolic activity were followed by Alamar blue assay, the potential of hDFSC and GFP-Luc_DFSC spheroids showed similar cellular viability after 1 and 3 days. But, after 5 days, higher metabolic activity was observed in both cell types, showing similar proliferation rate.

Human platelet lysates-based hydrogels to assess osteosarcoma spheroid invasiveness in a tri-culture model for drug screening applications

Cátia F. Monteiro, Catarina A. Custódio, João F. Mano

University of Aveiro, Department of Chemistry - CICECO, Aveiro, PT

Introduction

To date, advances in biomimetic materials have prompted great progresses in biomedical field. However, the synthetic and animal origin of the biomaterials’ majority has opening up some concerns regarding the need for a close recapitulation of the tissues’ biochemical and biomechanical properties to expedite drug discovery and development, namely anticancer therapies. [1,2] Human methacryloyl platelet lysates (PLMA) hydrogels are herein proposed as humanized 3D platforms for tumor invasiveness modelling and explored for drug screening applications through the establishment of a tri-culture osteosarcoma (OS) model. [3,4]

Experimental Methods

To develop the 3D tri-culture OS model, MG-63 OS cells spheroids formed for 3 days in ultra-low adhesion plates were encapsulated into PLMA hydrogels at 15% (w/v), surrounded by human bone-marrow mesenchymal stem cells (hBM-MSCs) and human osteoblasts (hOB) at an established cell-to-cell ratio in which the formation of tumor invasive branches and a network of hBM-MSCs was verified. In order to address effect of the extracellular matrix and tumor-associated stroma in tumor behavior, the tri-culture model was compared with tumor spheroids cultured in a scaffold-free and scaffold-based mono-culture settings. For the three established models, a 3-day doxorubicin treatment was performed after 14 days and the cells were maintained in culture until 24 days. Fluorescent protein-transduced MG-63 and hBM-MSC cells were used to analyze tumor-stromal cells crosstalk and drug response. Cells viability and morphology, tumor spheroid area and invasiveness, and hydrogel protein release were assessed over time, as well as stem cell direction towards spheroid center. The deposition of bone-related matrix in the established OS models was also verified by immunohistochemistry.

Results and Discussion

The architecture and synergistic interaction of an invading OS tumor was recapitulated encapsulating OS spheroids in PLMA hydrogels, alone or co-cultured with human osteoblasts and hBM-MSC. PLMA hydrogels supported tumor growth and the formation of tumor invasive branches from the spheroid in both settings. Stem cell direction revealed their alignment toward OS spheroid, suggesting that tumor cell chemotactically attracted the surrounding stromal cells. Comparing to scaffold-based OS mono-culture model, the presence of stromal cells potentiated tumor invasiveness ability into the ECM-mimicking matrix. The deposition of bone-related proteins and minerals were also observed. The exposure of the established models to doxorubicin revealed a higher IC50-value of PLMA-based models, comparing with scaffold-free spheroids.

Conclusion

The proposed 3D OS models highlighted the potential of PLMA hydrogels to support an invasive tumor behavior and recapitulate tumor-stromal cell crosstalk. This physiologically predictive microenvironment can be used to study early tumor metastatic events, opening up new possibilities for humanized and personalized drug screening and validation of therapeutic agents.

Recombinant scaffolds for the physiological-like expansion of lung mesenchymal stromal cell subpopulations

Arturo Ibáñez Fonseca1, Måns Kadefors1, Linda Elowsson Rendin1, Zackarias Söderlund1, Sara Rolandsson Enes1, José Carlos Rodríguez-Cabello2, Gunilla Westergren-Thorsson1

1 Lund University, Lung Biology Team, Lund, SE; 2 University of Valladolid, BIOFORGE Lab, Valladolid, ES

Introduction
Three-dimensional (3D) cell culture is one of the major promises of biomaterials in the last decades, although it has not become as widespread as it could be expected. One of the reasons is the need of tailored biomaterials that address the different needs of cells living within a scaffold, such as cell adhesion and possibility of matrix remodeling, among others. This can be easily overcome with recombinant biomaterials, like elastin-like recombinamers (ELRs) [1], which can be used to form hydrogels in situ or even more complex and controlled microstructures, as cryogels. These scaffolds can be used to culture therapeutically relevant lung mesenchymal stromal cells (lung-MSCs) [2], given that their expansion in 2D is very far from their physiological niche and this may lead to the potential loss of their regenerative profile. Therefore, we hypothesize that if specific lung-MSC subpopulations are grown and expanded within ELR scaffolds that mimic some of the features of the native tissue, the cells will keep their phenotype to a higher extent.

Experimental Methods
Lung-MSC subpopulations were sorted from healthy human lung biopsies through fluorescence-activated cell sorting (FACS). Specifically, lung-MSCs were identified as CD45−/CD235a−/CD105+/CD90+ [2]. Further sorting allowed to isolate CD13− and CD13+/N-aminopeptidase) subpopulations, which are currently being studied in our laboratory. ELRs were expressed in Escherichia coli and purified by inverse transition cycling, as previously described [1]. ELR cryogels with a controlled pore size of 200-500 µm (similar to human lung alveoli) were formed following a recently established protocol in our group (manuscript in preparation), placed in a 96-well plate and seeded with CD13− sorted lung-MSCs. On the other hand, ELR hydrogels were formed with embedded cells directly in 96-well plates, taking advantage of the thermosensitivity of the biomaterial. The metabolic activity of the cells was measured with PrestoBlue (resazurin; ThermoFisher) up to 3 weeks as a signature of cell growth. Cells were imaged inside the scaffolds by phase contrast and confocal microscopy upon actin (Phalloidin-iFluor 555, Abcam) and nuclei (DAPI, ThermoFisher) staining.

Results and Discussion
The metabolic activity of CD13− sorted lung-MSCs in the 3D scaffolds increased over time, indicating cell growth and expansion, with significant differences (***p < 0.001) in comparison to 2D cell culture (Figure 1). This contrast in cell growth is probably related to phenotypic changes, meaning that the cells cultured in 2D are probably very different from those cultured in 3D. Future studies should dig into these differences and compare them to the phenotype of freshly isolated lung-MSCs. Moreover, cell morphology showed great differences between the groups, with both CD13−low and CD13−high lung-MSCs growing well attached to the plastic surface and with a fibroblast-like spindle and spread shape in 2D, while they associated forming branches in ELR hydrogels (Figure 2). Interestingly, the cells seeded in the hydrogels grew from and through these branches in an anisotropic way, in contrast to the isotropic way found in 2D, with colonies growing in every direction at the same time. These results were also confirmed by confocal microscopy, where lung-MSCs were found to be attached to the cryogels pore walls.

Conclusion
Overall, these results validate the use of two different ELR scaffolds, in the form of hydrogels and cryogels, for the 3D expansion of CD13-sorted lung-MSCs, with the latter being a highly novel microstructure that mimics the lung alveolar space. The differences found in terms of metabolic activity and morphology in comparison with the 2D culture suggest different cell behaviors, probably more physiological-like. Future studies will focus in the phenotypic characterization of both lung-MSC subpopulations through transcriptomics and protein profiling, which might have important implications in lung-MSC culture for regenerative purposes.

Introduction
Bone metastases commonly cause severe morbidities in solid tumors and are considered negative prognostic factors. In neuroblastoma (NB), a malignancy of the developing sympathetic nervous system, bone marrow and bone metastases are particularly alarming (1). However, the molecular mechanism that sustains the growth of NB cells in bone is not yet completely understood.

Experimental Methods
Here, we present a novel 3D in vitro model to reveal the details of NB metastasis. We propose \(\beta\)-tricalcium-phosphate (\(\beta\)-TCP) casted scaffolds with tailored interconnected microchannels for the combined growth of stromal and tumor cells in 3D conditions. The characterization of the composition of the extracellular matrix (ECM) produced by stromal cells was performed using two photon microscopy along with the assessment of its impact on tumor cells growth and structure (2).

Results and Discussion
We confirmed that the organization of stromal cells and ECM component such as fibronectin, are strongly shaped by NB cells. With respect to planar counterparts, cells seeded on 3D \(\beta\)-TCP structures produce more cytokines (eg. IL-6) and define membrane localization of Connexin-43. Inclusion of endothelial cells led to ulterior enhancement of the proposed 3D niche model confirming the 3D growth conditions as a determinant factor for the morphological and functional characteristics of tumor cells. Together, our niche model confirmed that both, the geometry on the cellular scale and the chemistry of the niche material are relevant for translating realistic mechanobiological cues to the metastatic NB. In this model, tumor cells actively interact with all the components of the niche. In turn, stroma assists tumor cells to form spheroid-shaped arrangements facilitating their pro-migratory and pro-invasive patterns.

Conclusion
These results emphasize the use of the model for more systematic biological studies (at cellular and molecular level) and open a window for more sophisticated pharmacological examinations of novel drugs against metastatic NB.

PDAC on-chip for modeling in vitro the pancreatic cancer microenvironment

Viola Sgarminato, Chiara Tonda-Turo, Simone L. Marasso, Matteo Cocuzza, Beatrice Minervini, Giorgio Scordo, Alberto Ballesio, Gianluca Ciardelli

Introduction
Pancreatic ductal adenocarcinoma (PDAC) mainly develops in the head of the pancreas, from the progression of pancreatic intraepithelial neoplasia (PanIN) lesions that occur within the acino-ductal unit, composed by acinar and ductal cells surrounded by pancreatic stellate cells (PSCs) [1]. PSCs strongly influence tumor microenvironment by triggering an intense stromal reaction which consists in an excessive extracellular matrix (ECM) deposition within the tissue surrounding cancer cells. This stroma alteration plays a key role in tumor progression and limits the drugs perfusion representing a barrier against chemotherapy and radiotherapy [2,3]. Furthermore, the lack of prognosis, the genetic complexity and the tumor heterogeneity make the discovery of new therapeutic options extremely difficult. For this reason, the establishment of a scalable in vitro model able to recapitulate the tumoral microenvironment is urgently needed. To this aim, we developed a microfluidic in vitro model of the acino-ductal unit as a powerful tool for a deeper understanding of the early evolution steps of PDAC, identify novel diagnostic, prognostic and predictive biomarkers and, in the end, validate innovative nanomedicine systems.

Experimental Methods
The microfluidic device was fabricated by replica molding (Figure 1). Specifically, an SU-8 patterned master was custom-made using photolithography and then conventional soft lithography was applied on the SU-8 patterned master to produce several polydimethylsiloxane (PDMS) replicas. The microfluidic device was designed to contain an upper layer and a lower layer divided by an electrospun polycaprolactone (PCL) membrane. The bottom layer had three channels: a central compartment (6.38 mm length, 1 mm width and 250 µm height) delimited by micropillars, with 100 µm diameter and 250 µm height, to confine a collagen gel loaded with the PSCs and two lateral channels (20.51 mm length, 500 µm width and 250 µm height) to control the passage of nutrients. The top layer was designed to incorporate PDAC cells which are expected to create an in vivo like crosstalk with PSCs co-cultured inside the bottom layer [4].

Results and Discussion
The reproducibility of the fabrication process was confirmed by optical and scanning electron microscopy (SEM). Diffusivity tests were performed on the bottom layer to evaluate the medium diffusion from the lateral channels to the middle one containing the collagen gel. With this aim, a fluorescence time-lapse imaging was carried out by confocal microscopy and the fluorescence intensity was measured in a specific region of interest (ROI) of the middle channel. The results demonstrated a controlled diffusivity of the dye through the micropillars placed at 75 µm each other. To characterize the microfluidic device from the biological point of view, human foreskin fibroblast cells (HFF-1) were embedded in the collagen solution and seeded in the bottom layer. The cell viability was measured using Live/Dead assay performed after 48h and 72h after seeding. Figure 2 shows the cell viability of HFF-1 at 72h after seeding.
within the collagen gel compared to that of cells grown in the gel-free microchannel. These results confirm the beneficial effects provided by collagen in promoting the proliferation of stromal cells.

**Conclusion**
The here realized microfluidic device reproduces *in vitro* the tumor microenvironment and the interactions that occur between adjacent cell types *in vivo*. Moreover, it provides a model of human pancreatic ductal adenocarcinoma at early stages opening the way to the investigation of the influence of stroma on the tumor’s evolution and perform drug efficacy screening. Advanced technologies which integrate optical components in microfluidic chips could be employed for the real-time monitoring of the tumor’s evolution and for performing *in situ* genomic analysis [5].

Introduction
Cancer is a complex disease mostly with lethal outcome while advances in the field of anticancer drug research are slow and challenging. Conventional methods of anticancer drug testing based on monolayer cell cultures and in vivo animal models often produce misleading results due to inability to adequately mimic the cancer complexity. Consequently, there is an urgent need for new physiologically relevant 3D biomimicking tumor models. One of the approaches includes immobilization of cancer cells in biomaterials as artificial tumor extracellular matrices followed by cultivation in biomimetic bioreactors. In the present study, the aim was to develop a 3D tumor microenvironment based on alginate hydrogel microfibers and perfusion bioreactors. Additionally, chemical engineering methods were applied in order to correlate the observed effects of culture conditions on the cultured cells.

Experimental Methods
Two types of cancer cells (rat glioma cells C6 (ATCC® CCL-107™) and human glioblastoma cells U87 MG (ATCC® HTB-14™)) were immobilized in alginate microfibers by simple extrusion. Briefly, the cell suspensions (1–8×10⁶ cell ml⁻¹) in 1.5–2.8 % Na-alginate solutions (AppliChem, Germany) were manually extruded through a blunt edge stainless steel needle (22–28 G) immersed in the gelling solution containing Ca²⁺ (0.18 M). In the first experimental series, perfusion bioreactors were each filled with microfibers (0.5 g) with immobilized C6 cells and continuously perfused at flowrates in the range 0.12–0.30 cm³ min⁻¹ over 5 days. Static microfiber cultures served as a control. In the second experimental series, microfibers with immobilized U87 cells were cultured under static conditions for 28 days and treated with 100 µM temozolomide (TMZ), while treated monolayer cell cultures served as a control. Cell viability and proliferation were determined by cell counting, MTT test and live/dead staining (CalceinAM (CAM)/propidium-iodide (PI)) using confocal microscopy.

Results and Discussion
Investigations of the effects of needle diameter and initial density of U87 cells on the cell survival have shown that successful cell immobilization in alginate microfibers (~500 µm in diameter, Fig. 1) was achieved by applying a 25G needle and a minimal cell density of 4×10⁶ cells ml⁻¹. Smaller needle sizes induced the immediate cell death probably due to high hydrodynamic shear stresses during extrusion while lower initial densities of these cells resulted in decreased cell viabilities probably due to the reduction in cell-cell interactions.

The effects of flow were investigated in short-term perfusion cultures of C6 cells immobilized at different concentrations in microfibers exposed to continuous superficial medium velocities in the range 40–100 µm s⁻¹. Positive effects of perfusion were found primarily in cultures with lower initial cell concentrations of about 2.5×10⁶ cells ml⁻¹ in which higher cell viability and proliferation were obtained as compared to control static cultures.

In order to elucidate the obtained results, a simple mathematical model of mass transport based on advection, diffusion and reaction was applied for prediction of concentration profiles of bioactive molecules of interest within a microfiber cultured in the perfusion fibrous bed bioreactor. The model indicated that substances with diffusion coefficients in the range of 10⁻⁶–10⁻¹¹ m² s⁻¹ (e.g., oxygen) are sufficiently transported by diffusion only, while for...
substances with significantly lower diffusion coefficients ($\sim 10^{-19} \text{ m}^2 \text{ s}^{-1}$) the convective transport is necessary for efficient supply, thereby stressing the importance of the use of bioreactors in in vitro tumor model systems. Finally, a preliminary study with U87 human glioblastoma cells immobilized in alginate microfibers cultured under static conditions showed an altered cell response to the anticancer drug TMZ as compared to monolayer cultures indicating that 3D systems could be potentially used as more relevant in vitro models for anticancer drug testing. 

**Conclusion**
The overall results have shown potentials of biomimetic 3D in vitro systems as a tool for acquiring more reliable data in cancer cell cultivation and anticancer drug testing. Furthermore, multidisciplinary approach to the analysis of the obtained results could aid in elucidating the underlying mechanisms and pave the way to a simpler and quicker optimization of 3D culture parameters.

Introduction

Osteosarcoma (OS) is a type of bone cancer that often occurs at the sites of bone growth. One of the reasons for slow progress in OS therapies is poor translation of the results from in vitro cultures that are mainly performed in 2 dimensional (2D) environment to in vivo settings. Thus, development of 3D culture models of the tumor microenvironment has been indicated as mandatory\textsuperscript{1}. One of the approaches relies on tissue engineering strategies utilizing scaffolds as cell supports and extracellular matrices (ECM), and biomimetic bioreactors providing efficient supply of biochemical and biophysical signals. In this work we have developed highly macroporous composite alginate scaffolds with embedded particles of hydroxyapatite (HAP) and β-tricalcium-phosphate (β-TCP) doped with Mg\textsuperscript{2+} as a bioactive environment that will possibly stimulate OS cells to express the typical morphology and metabolic functions. First we have studied active transformation of the mineral precursors into HAP in the presence of simulated body fluid followed by biocompatibility studies of the powder and short-term seeding studies of two types of OS cell lines.

Experimental Methods

HAP and β-TCP particles doped with Mg\textsuperscript{2+} with the (Ca+Mg)/P molar ratio of 1.52 were synthesized by a hydrothermal method followed by calcination. The particles were mixed with a Na-alginate solution and the obtained mixture (1 wt% alginate, 1 wt% powder, 0.03 wt% CaCl\textsubscript{2}) was poured into dialysis tubings to provide controlled alginate gelation by diffusion of Ca\textsuperscript{2+} from the surrounding gelling solution (4 wt% CaCl\textsubscript{2}·2 H\textsubscript{2}O). The obtained hydrogel cylinders were submitted to freezing (-70°C, 24 h) followed by freeze-drying (-60°C, 24 h) and rehydration (0.8 wt. % NaCl and 0.3 wt.% CaCl\textsubscript{2}). Finally, the cylinders were cut into discs (15 mm in diameter, 6 mm thick). The precursor transformation into HAP within composite scaffolds was investigated under continuous simulated body fluid (SBF) perfusion of 1.9 cm\textsuperscript{3} min\textsuperscript{-1} over 28 days in perfusion bioreactors (“3D Perfuse”, Innovation Center of the Faculty of Technology and Metallurgy, Belgrade, Serbia), while scaffolds under static conditions served as controls. Murine K7M2-wt (ATCC\textsuperscript{®} CRL-2836\textsuperscript{™}) and human Saos-2 (ATCC\textsuperscript{®} HTB-85\textsuperscript{™}) were used for cell studies. In the biocompatibility study, the powder were added in 12-well plates (15 mg, 0.6 cm\textsuperscript{2} surface area in each well) and then the cells were seeded onto the powder at the seeding density of 4x10\textsuperscript{5} cell cm\textsuperscript{-2}, while in the cell seeding studies, the cells were seeded manually onto scaffolds (~9 mm in diameter, ~4.4 mm thick, 30x10\textsuperscript{6} cells cm\textsuperscript{-3} scaffold volume). Culture medium (3 cm\textsuperscript{3}) was added to each well and incubated for 5 days at 37 °C in 5% CO\textsubscript{2}. The scaffolds were examined regarding porosity, particle composition (by X-ray diffraction, XRD), HAP deposition (by scanning electron microscopy, SEM), mechanical properties by Universal Testing Machine and cell viability and morphology (by Live/Dead staining and SEM).

Results and Discussion

The XRD analysis of the obtained powder has indicated β-TCP as a dominant mineral phase. SEM analysis of the resulting macroporous composite alginate scaffolds has revealed uniform distribution of the filler in the hydrogel.
matrix incorporating open and connected pores. Porosity of rehydrated scaffolds was ~54%. The presence of fillers in the scaffolds induced a significant increase in the Young's modulus (21 ± 8 kPa), as compared to control scaffolds without the fillers (16 ± 3 kPa). Over 28 days under continuous SBF perfusion, β-TCP underwent active transformation to HAP, as confirmed by XRD and SEM. HAP formation was significantly more prominent under perfusion as compared to static conditions indicating the role of mass transport in this process. Both OS cell types started to adhere and spread in the presence of the powder after 24 h of plating retaining their morphology and viability showing excellent biocompatibility of the powder without adverse effects. Similarly, the cells adhered to the scaffolds, both on the surfaces and in the pores exhibiting high metabolic activity. Low cell loss was found in this seeding method, regardless of the cell type. In the next steps, dynamic seeding in the perfusion bioreactor as well as seeding onto dry scaffolds will be investigated followed by perfusion bioreactor cultures.

**Conclusion**
The overall results have shown potentials of the applied approach based on bioactive porous scaffolds for bone tumor engineering.

Introduction
Within the biomaterials field, a prominent application of hydrogels is 3D cell encapsulation. They are used as extracellular matrix mimics for the basic study of cell function, high-throughput drug screening and therapeutic delivery. Several covalent coupling chemistries have been described for simultaneous hydrogel crosslinking, biofunctionalization and cell encapsulation. Ideally, a coupling reaction for hydrogel crosslinking develops efficiently and with adequate rate under physiological conditions, is non-toxic, and presents chemical orthogonality to commonly used biomedically approved polymer backbones. For widespread application, it is derived from accessible and bench-stable precursors, and allows tailoring of materials properties to facilitate adaptability to different biomedical scenarios. Developing a hydrogel that presents all these characteristics remains a challenge. Herein, a hydrogel platform that features all these attributes is presented.

Fireflies produce their bioluminescent reaction from the oxidation of substrates called luciferins, which are formed in vivo through the condensation reaction between 2-cyanobenzothiazole (CB) and aminothiol (AT) groups. Inspired by the biochemistry of fireflies, in this work we apply the CB-AT reaction as a covalent strategy for the crosslinking of hydrogels with tailorable properties (Fig. 1a). We introduce these reactive groups into polyethylene glycol (PEG) precursors and demonstrate CB-AT crosslinking under physiological conditions. The resulting gels present rapid and tunable gelation kinetics; are mechanically stable, homogeneous at the microscale, and cytocompatible. These advantageous properties demonstrate that CB-AT crosslinking chemistry is optimal for gel preparation in the presence of living cells.

Experimental Methods
4-arm, 20 kDa poly(ethyleneglycol) (PEG) macromers carrying CB or AT functional groups were synthesized and used for crosslinking under physiological conditions (25 or 37°C, 20 mM HEPES buffer, pH 7-8) with an enzymatically cleavable dithiol crosslinker, following established protocols.\(^1\)\(^-\)\(^2\) Hydrogel crosslinking, bio-functionalization with cyclo(RGDfK(C)) cell-adhesive peptide, and encapsulation of fibroblast L929 cells took place one-pot. The cell-laden hydrogels were cultured for 1, 3 and 6 days, and cell viability was evaluated by live/dead assay over time. Mechanical properties and gelation kinetics of the resulting hydrogels were characterized in situ by shear rotational rheology.

Results and Discussion
PEG hydrogels crosslinked via the CB-AT condensation reaction were successfully prepared under physiological conditions. Gel formulation was optimized to tune gelation kinetics and mechanical strength within convenient ranges for cell encapsulation applications. Gel formulation was optimized to tune gelation kinetics and mechanical strength within convenient ranges for cell encapsulation applications.

Gels at 5 wt% PEG concentration in HEPES buffer pH 8 showed fast gelation kinetics, with gelation time < 30 s, as revealed by rheology (Fig. 1b). This gelation rate was easily adjusted by external cues, namely pH and redox modulation, to afford gelation times spanning seconds to a few minutes. This time range is adequate for gentle mixing of precursors and cell suspension, thus preventing cell sedimentation in the biomaterial. Importantly, this kinetic tunability was achieved without affecting the final mechanical strength of the gel. In addition, by adjusting molar mass, multivalency and topology of PEG precursors, final mechanical strength after swelling ranged elasticity values of soft natural tissues.
CB-AT hydrogels with cell-adhesive and cell-degradable biochemical features were fabricated and tested for culture of L929 fibroblasts. Successful encapsulation of cells in these gels was demonstrated by the high cell viability found at days 1, 3 and 6 post-encapsulation (Fig. 1c). Cells recognized the adhesive ligand and spread, enzymatically degraded the material and proliferated. These features demonstrate that these hydrogels are non-cytotoxic and support the encapsulation of cells.

**Conclusion**

The presented bioinspired hydrogels demonstrated several advantages for 3D cell encapsulation: fast and tunable gelation rate, adjustable mechanics within physiological range, good cytocompatibility and tunable bioactivity. 3D cell culture gels based on CB-AT coupling chemistry are expected to become valuable as both implantable and injectable culture models for applications in tissue engineering and regenerative medicine.

Introduction
Malignant melanoma is a highly aggressive tumor of melanocytes characterized by early metastasis from small primary tumors. Cell culture models have contributed decisively to our current knowledge of the disease, yet a variety of processes in tumor development and progression remains to be deciphered. In addition to the widely used two-dimensional (2D) cell culture, there is a continuous trend towards culturing cells in three dimensions (3D), as this better represents the physiological environment of the cells. Thus, the use of 3D cell culture models, or more precisely, the cultivation of cells in hydrogel matrices, can help to better understand essential signaling processes in the development and progression of diseases such as malignant melanoma, and to accelerate and simplify target and drug screenings. However, for this to happen, the 3D models need to be very well defined and characterized. Although alginate is widely used as a hydrogel for 3D cultivation and biofabrication due to its advantageous chemical properties, there is only little information on the transcriptome of cells in 3D alginate cultures.

Experimental Methods
In our study, we performed RNA sequencing of melanoma cells cultured on classical 2D culture dishes or in 3D alginate hydrogels. We could demonstrate and analyse changes in the transcriptome induced by this culture switch.

Results and Discussion
Controlled modulation of the tumor cell microenvironment showed an effect on cell cycle, RAS signaling, GTPase signaling, cell spreading, actin cytoskeleton formation, endocytosis, and phospholipid metabolism, among others. This highlights the strong influence of the extracellular matrix on tumor cells. Further, bioinformatic comparison of gene-expression, including previously published datasets, highlight the correlation of the switch from 2D to 3D alginate culture with tumor plasticity in progression and metastasis. Furthermore, by deeper analysis of changes in the transcriptome we found the transcriptional regulator EGR1 to play a role in melanoma plasticity and aggressiveness.

Conclusion
In summary, our study shows that cell cultivation in 3D hydrogels, combined with RNA-Seq analyses, leads to a deeper molecular understanding of cancer cells and contributes to the definition of new therapeutic targets.
Role of silicate ions in bone regeneration: A comparison between 2D and 3D bone formation models

Tim Schaefer, Azadeh Rezaei, Nefeli Vaporidou, Joel Turner, Gavin Jell

University College London (UCL), Division of Surgery and Interventional Science, London, GB

Introduction
The repair of delayed and non-union bone fractures remains a clinical challenge, particularly in elderly and diabetic patients who have a significantly increased risk of fracture and impaired regenerative capability [1]. Silicon (Si) ion releasing biomaterials have been extensively studied for orthopaedic and dental applications [2] and Si has been reported to stimulate angiogenesis, enhance osteoblast proliferation, and promote bone-related gene expression such as ALP [3]. The role of Si in promoting bone regeneration is, however, still unclear and the understanding of the in vitro effect of Si on bone nodule formation is limited. In this study, we use in vitro 2D and 3D bone nodule models, together with multidisciplinary characterisation approaches to further our understanding of the role of Si ions on bone formation.

Experimental Methods
In vitro bone nodule formation was performed as previously described [4]. Briefly, primary osteoblastic cells were isolated from calvaria of 3-day-old Sprague Dawley rats. Osteoblasts were either seeded in 24 well plates (2D) or compressed 3D hydrogels in 24 well plates in MEM-α supplemented with 2 mM β-glycerophosphate, 10 nM dexamethasone and 50 mg/ml ascorbate. Hydrogels were prepared through mixing collagen (type I), 10X MEM, and neutralising agent (HEPES+NaOH) and compressed using the RAFT™ protocol [5]. Cells in both 2D and 3D were treated with Si at concentrations of 0.5, 1, 2 and 3 mM for 21 days. Bone nodules were characterised using Raman, TEM, Interferometry, Nano-CT, VEGF ELISA, Alizarin Red staining, and Total DNA Assays.

Results and Discussion
Si ions dependent decrease in cell number was observed after 24 hours in culture, but not after 7 days (Figure 1a). An Si concentration dependent expression of VEGF (per unit of DNA) was observed (Figure 1b). The results also demonstrated a difference in Si response between 2D and 3D models (Figure 1c). Si (0.5, 1 and 2 mM) appeared to accelerate bone mineralisation, with early evidence of mineralisation observed after 7 days and with no mineralisation evident at 0 mM and 3 mM Si. The 3 mM Si treated osteoblasts had a non-uniform, distressed appearance. It was also observed that bone nodule formation occurred earlier in the 3D cell cultures compared to the 2D cell cultures in all conditions, but particularly in those containing 0.5 and 1 mM of Si (Figure 2).

The results revealed that high resolution characterisation and imaging are valuable in determining the effect of Si on the biochemical (Raman) and ultra-structure (TEM) of the bone nodules.

Conclusion
Furthering our understanding of the role of Si in bone formation, will enable the creation of improved Si-based biomaterials, with optimised release profiles for specific patient groups (e.g., those with delayed healing). The use of 3D in vitro models may offer greater similarity to in vivo responses and thereby increase the translation of bone therapies.
Figure 1
Figure 1a: DNA content determined using DNA Quantification Kit (Sigma-Aldrich). After an initial reduction in cell number, Si containing media can restore cell number to initial levels after 7 days. Figure 1b: VEGF expression normalised to the Total DNA content, shows a concentration dependent increase of VEGF expression in response to Si containing media. Figure 1c: A comparison between VEGF expression in 2D (tissue culture plastic) and 3D (RAFT™) cell cultures. Particularly at day 7 there is a significantly increased VEGF expression in 3D cell cultures containing 2 mM Si media.

Figure 2
Figure 2: Primary rat osteoblasts cultured for 7 days in media containing Si at concentrations of 0, 0.5, 1 and 2 mM in a 2D environment (tissue culture plastic) or a 3D environment (RAFT™ system with rat tail collagen). The images show earlier bone nodule formation in 3D cell cultures compared to 2D cell cultures. (Images taken using EVOS™ XL Core Thermo Fischer Scientific; scale bars = 200µm)

Introduction
Aseptic loosening or bonding failure between implantable devices and bone in the absence of infection remains a significant complication, affecting up to 20% of implants [1]. Such failure leads to revision surgeries with partial or total removal of the implant and increased risk of failure than primary arthroplasty devices [2,3]. The increased costs and recovery times pose a heavy burden on both patient and healthcare system, critically calling for the development of novel implants with enhanced surface-bone interaction. In this regard, surface topology is acutely regarded as a main driver in cell-surface interactions, indicating that careful selection of metallic implant topographies can be used to enhance attachment and differentiation of eukaryotic cells. Consequently, laser ablation offers a versatile approach to texture implant surfaces with minimal effect on the accuracy of the final geometry.

Experimental Methods
A series of surface topologies based on geometrical and nature based textures were applied to enhance the biological response of Ti64 additive manufactured implants. Samples were prepared with textures in the microscale, nanoscale and mixed patterns alongside natural textures and a polished control. The physico chemical properties of all surfaces were analysed through non contact profilometry, SEM imaging and contact angle measurements. The early and late biological response was studied through protein adsorption, proliferation (Protein adsorption, Live/Dead and DNA quantification) and mineralization (Alizarin Red, Alkaline phosphatase and SEM) assays of MG63 cells up to 21 days.

Results and Discussion
Physicochemical analysis showcased the ability of the technique to carve the desired pattern effectively modifying roughness and contact angle. These variations resulted in a modification in the preferential orientation of the deposited MG63 cells after 7d of inoculation. More interestingly, a significant increase in calcium deposition for the grids, dual, triangles and shark skin patterns were shown with a heavy correlation with roughness and wettability.

Conclusion
Thus, this preliminary study demonstrated the ability of laser texturing to enhance the biological response of implantable devices, opening the door to its use in additive manufacturing technologies to tackle aseptic loosening.

Dip- and spin- multilayered coatings onto different substrates based on catechol-functionalized polysaccharides envisaging orthopaedic applications

Ana C. Almeida¹,², Ana C. Vale¹,², Ricardo A. Pires¹,², Rui L. Reis¹,², Natália M. Alves¹,²

¹ 3B's Research Group, I3Bs – Research Institute on Biomaterials, Biodegradables and Biomimetics, Headquarters of the European Institute of Excellence on Tissue Engineering and Regenerative Medicine, University of Minho, Guimarães, PT; ² ICVS/3B's, PT Goverment Associate Laboratory, Braga/Guimarães, PT

Introduction
For effective bone healing, orthopaedic prosthesis and their components should present not only adequate mechanical properties but also important biological functions such as bioadhesiveness, bioactivity, and biocompatibility. Current trends for improving osseointegration for orthopedic implants comprise their surface modification with calcium phosphate-like, bioactive glasses, growth factors, or RGD peptides, however, these approaches still have significant limitations and drawbacks.

Experimental Methods
Addressing these important features, new biocompatible layer-by-layer coatings were constructed onto different substrates, specifically glass, stainless steel, and titanium envisaging their orthopaedic application. New adhesive and bioactive coatings based on chitosan, hyaluronic acid, and bioactive glass nanoparticles were produced by two LbL methods: spin- and dip-coating. In addition, chitosan and hyaluronic acid were catechol-functionalized in order to provide adhesive properties to the constructed coatings. Hence, polymeric (CTR) and multifunctional (MF) coatings were produced and fully characterized, with particular focus on their surface properties, adhesive strength, and cytotoxicity.

The build-up of LbL coatings with CTR and MF configurations was monitored in situ by QCM-D. Their morphology was analyzed by SEM and AFM, and their wettability was evaluated by WCA measurements. Their bioactivity was assessed by SEM. FTIR imaging was used to analyse the layer interdiffusion onto the constructed coatings. Adhesive tests were performed with LbL coatings constructed onto glass plates to test their adhesive strength. Finally, preliminary in vitro cellular assays were performed to evaluate their cytotoxicity.

Results and Discussion
Major differences were found in their structure and surface properties, in particular, the spin-coated constructions onto glass were smoother, with a more homogeneous structure and lower interdiffusion of polyelectrolytes layers, in comparison with the dip-coated ones. As expected, CTR coatings exhibited a significantly higher adhesion strength, and only MF coatings were able to induce the formation of apatite-like structures on their surfaces. In addition, for both configurations, cellular assays exhibited good L929 proliferation and viability after 7 days of culture.

Conclusion
The produced coatings could be used in a variety of applications as biocompatible interfaces between the implant and host tissues. Particularly, MF films could be potentially used as adhesive coatings for orthopaedic implants to promote osteogenesis and hydroxyapatite deposition around the implant. On the other hand, the highly adhesive polymeric coatings could be used to improve the junction between distinct orthopaedic implants and a variety of tissues in a simple and versatile way.

Vitamin E as an anti-adhesive coating for cells and bacteria for temporary bone implants

Francesca Gamna¹, Andrea Cochis², Alessandro Scalia², Sara Ferraris¹, Lia Rimondini², Silvia Spriano¹

¹ Politecnico di Torino, Torino, IT; ² Università del Piemonte Orientale, Novara, IT; ³ Politecnico di Torino, Torino, IT

Introduction
An anti-adhesive coating might be important for any application involving temporary devices that requires poor cell adhesion to prevent tissue integration (e.g. catheters, and voice implants); in this case, the focus is on temporary orthopaedic implants, which could create difficulties once the implant is being removed from the bone. Vitamin E (or more specifically, alpha tocopherol) is a potent lipophilic antioxidant and has been very successful in hip and knee arthroplasty in conferring oxidation resistance to irradiated UHMWPE. In recent years, vitamin E has been widely discussed in the literature and has become known for its potent antioxidant, -inflammatory, -cancer, and -bacterial properties.

The novelty of the present work is to realize a coating on chemically treated titanium alloy, suitable for temporary bone implants and which is anti-adhesive to both cells and bacteria, biocompatible, with anti-inflammatory properties.

Experimental Methods
Titanium Ti6Al4V alloy samples (ASTM B348, Gr5, Titanium Consulting and Trading, 10 mm diameter discs) were ground (up to 400 grit), then washed in acetone and deionized water. The discs were chemically treated to increase nanoscale roughness, to expose OH groups, and to make the surface more suitable for coating adhesion. To reduce carbon contamination and activate the OH groups, the treated samples were irradiated with UV light.

The coating was obtained by soaking the samples for 3 h at 37°C in a solution of vitamin E in ethanol (50 mg/ml), with subsequent rinsing first in ethanol then in water. Therefore, a procedure for a proper characterization of this coating was investigated. Physical and chemical characterization was performed through specific measurement techniques such as FTIR-ATR, Z-potential titration curves, reflectance spectroscopy, contact angle measurements, and tape test. Biological characterization was performed through cellular and antibacterial assays: cell adhesion was evaluated using human mesenchymal stem cells (hMSCs), whereas bacterial adhesion was performed using both Gram-positive (Staphylococcus aureus) and Gram-negative (Escherichia coli) biofilm-producing bacteria.

Results and Discussion
The results from FTIR-ATR and reflectance spectroscopy, z-Potential titration curves, contact angle measurements, and tape test reveal a continuous coating, with hydrophobic behaviour and good mechanical adhesion to the substrate. Cellular and antibacterial tests show anti-adhesive and anti-inflammatory properties.

Conclusion
This work highlights a novel promising application of this biomolecule as a coating for temporary bone implants which reduces the risk of excessive pro-inflammatory response, has antiadhesive properties to prevent unintended osseointegration of temporary devices, and reduces the risk of implant-associated infections.
A universal nanogel-based coating approach for medical implants

Damla Keskin¹, Devlina Ghosh¹, Colin Rosman¹, Clio Siebenmorgen¹, Guangyue Zu¹, Reinier Bron¹, Abigail M. Forson¹, Theo van Kooten¹, Jelmer Sjollema¹, Max Witjes², Patrick van Rijn¹

Introduction
The use of implants has increased the quality of life, for patients. However, secondary complications like infection, inflammation, or immune response in the host body can lead to implant failure. Coatings have been regarded as an excellent possibility to induce desired responses or to prevent complications, as the bulk implant material does not need to be altered. However, to apply a coating, a diverse range of chemical approaches have to be implemented owing to the distinct physicochemical and structural properties of the different classes of implant materials. The aim of the study is to develop a universal nanogel (nGel) coating approach that can be applied to most implant materials, ranging from bioglass, polymers, metals, rubbers, and furthermore, investigate the stability of the coating in vitro and in vivo conditions.

Experimental Methods
N-Isopropylacrylamide–co-N-(3-Aminopropyl)methacrylamide hydrochloride p(NIPAM-co-APMA) core-shell nGel particles were synthesized by free-radical precipitation polymerization reaction.¹ The particles were characterized by Dynamic Light Scattering (DLS) and zeta potential, while the coating was visualized by atomic force microscopy (AFM). The coating was labeled with Fluorescein Isothiocyanate (FITC) for successful detection and imaging by In vivo Imaging System (IVIS). The stability of the coating was determined in vitro by exposing nGel coated teflon surfaces to phosphate-buffered saline (PBS) and fetal bovine serum (FBS), while mimicking physiological conditions in a shaker incubator for 21 days and in vivo by implanting methacryloxyethyl thiocarbonyl Rhodamine B (MRB) labeled nGel coated (polyvinylidene fluoride) PVDF hernia mesh in a mouse model for 13 days.

Results and Discussion
The DLS measurements showed the average hydrodynamic diameter was 540.63 ± 11.2 nm, polydispersity index (PDI) was 0.09 ± 0.08, which indicated a monodisperse colloidal suspension with no particle-aggregations² and positive zeta potential, 15.83 ± 0.11 mV at 24°C was attributed to the presence of V50 along with the protonated primary amine groups,³ introduced by APMA. On plasma oxidation, the surface of the material acquired negative charge. The positively charged nGel particles were deposited onto the surface by spray coating technique and the particles were bound to the activated surface via electrostatic interactions, while the unbound particles were washed away to obtain a homogenous uniform coating.⁴ AFM images showed a closely packed nGel-layer on all the distinct surfaces, irrespective of their varied structural and chemical properties (Figure 1). As a proof of concept, FITC was conjugated to the peripheral NH₂ groups of the coating⁵ and IVIS was used for easy traceability of the nGel coated surfaces. In vitro data analyzed by AFM and IVIS showed that the nGel coatings on teflon were stable after 21 days (data not shown), while the in vivo data demonstrated that the coatings on PVDF mesh were stable enough up to 13 days, after which the fluorescent signal was decreasing (Figure 2a). The short term in vivo test is considered as an initial proof for the stability of the nGel coating, however long term evaluations are still necessary.

Conclusion
The approach successfully formed a homogenous uniform coating on most implant surfaces, belonging to different classes of materials. On fluorescent labeling, the coating was easily traceable and imaged by IVIS. The coating on the implant surface showed high stability in both in vitro and in vivo conditions.

Physical-chemical and biological characterization of a novel Cu and Zn co-doped Plasma Electrolytic Oxidation coating produced on Ti in pulsed conditions

Matteo Pavarini¹, Monica Moscatelli¹, Gabriele Candiani¹, Paolo Tarsini¹, Stefania Cometa², Andrea Cochis³⁴, Ziba Najmi³⁴, Vincenzo Rocchetti³, Elvira De Giglio⁵, Lia Rimondini³⁴, Luigi De Nardo¹, Roberto Chiesa¹

¹ Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering, Milano, IT; ² Jaber Innovation srl, Roma, IT; ³ Università del Piemonte Orientale, Department of Health Sciences, Novara, IT; ⁴ Center for Translational Research on Autoimmune and Allergic Diseases—CAAD, Novara, IT; ⁵ Università di Bari, Department of Chemistry, Bari, IT

Introduction

The Plasma Electrolytic Oxidation (PEO) process is a relatively new, easily scalable and environmentally friendly surface modification technique, based on the same principles of conventional anodizing, which can be exploited for the production of thick microporous coatings, typically showing a high wear and corrosion resistance, on light metals such as titanium, aluminum, magnesium and their alloys [1]. This electrochemical treatment has recently raised particular interest in the biomedical field both for its ability to produce porous biocompatible surfaces and for the possibility to easily embed additive elements, such as antibacterial or osteoinductive elements (like copper and zinc), either as ions or included particles [2].

This work is focused on the physical-chemical and biological characterization of a newly developed copper and zinc co-doped PEO coating produced on titanium to evaluate its potential applicability as a surface treatment for bone-contact devices.

Experimental Methods

Commercially pure grade 2 titanium discs were treated in an alkaline electrolyte composed of 0.1M Na₂B₄O₇, 0.1M NaOH, 0.02M Na₂SiO₃, 0.01M Zn(CH₃COO)₂ and 2mM Cu(CH₃COO)₂. The samples were treated in pulsed conditions, with a 300V final voltage and 50% duty cycle at 100Hz, and characterized both chemically through GDOES and XPS and in terms of wettability by static contact angle. Then, the coatings’ antibacterial activity was assessed by means of metabolic activity and CFU count against S. aureus, S. epidermidis and E. coli after 24h, while their cytocompatibility was tested against MG63 cells for up to 7 days.

Results and Discussion

The produced coating is characterized by a homogeneous and porous surface, with an average pore size of 950 nm and a 9% porosity. The GDOES spectrum of the sample (Fig. 1) shows how all the elements introduced through the electrolytic bath, and in particular silicon, copper and zinc, are mainly present in the outermost layers of the oxide, with an atomic percentage of 4.9%, 1.4% and 0.12%, respectively (as assessed via XPS), while boron is concentrated at the interface between the coating and the substrate, indicating that its embedding happens mostly at the beginning of the sparking process. This early internalization can be linked to the high concentration and steric hindrance of borate ions.

Moreover, the treated samples present an almost superhydrophilic behavior, with a contact angle dropping to around 3° from 89° of untreated Ti, which can be related to both the coatings’ surface porosity and surface charge.

As for the antibacterial properties related to the PEO coating, the results of the direct microbiological studies are summarized in Fig. 2. The coated specimens show a clear bacteriostatic effect even in absence of copper and zinc, feature related to the tuned surface morphology and its superhydrophilicity, which are known to limit bacterial growth.
adhesion and proliferation [3]. However, the metabolic activity and viable colonies reduction given by the doping elements is significant only against the Gram-negative *E. coli*, while on the Gram-positive strains the effect of these low surface concentrations is only marginal, with a slightly higher effect of surfaces only doped with copper, and will require further tuning. Conversely, all the coated surfaces showed a good cytocompatibility, without significant differences in terms of metabolic activity among the treated groups and against the untreated controls.

**Conclusion**

The tuned PEO coatings characterized in this work show promising physical-chemical and antibacterial properties for potential orthopedic applications, without showing in vitro evidence of potential harmful effects on bone cells. However, a deeper tuning of the antibacterial dopants’ concentrations could allow maximizing the antimicrobial features of the coatings while retaining their cytocompatibility.

Differentiation of local inflammatory tissue response following implantation of platelet-derived human growth factor preparations in a rat animal model

Michael Schlosser¹, Andreas Hoene¹, Uwe Walschus¹, Christopher Pohl¹, Olga Hahn², Kirsten Peters², Karin Schuster³, Hans-Georg Neumann³, Cornelia Prinz³

¹ University Medical Center Greifswald, Department of General Surgery, Visceral, Thoracic and Vascular Surgery, Greifswald, DE; ² University Medical Center Rostock, Department of Cell Biology, Rostock, DE; ³ DOT GmbH, Rostock, DE

Introduction
Platelet concentrates from blood donations are used to prevent or treat bleeding in people with either a low platelet count or platelet dysfunction as well as in people receiving cancer chemotherapy. However, they have a limited shelf-life of only five days. Platelet-rich plasma is also potentially valuable in the field of regenerative medicine as platelets contain high amounts of various growth factors. Therefore, expired platelet concentrates could be an important resource to produce cell-free human growth factor (hGF) preparations, potentially useful to coat implants aimed at better implant in-growth or as treatment for chronic wounds. However, an aspect of prime importance for the biocompatibility of biologically derived biomaterials is their potential immunogenicity. Recently, we demonstrated that hGF preparations, differing in the content of particular growth factors, showed a specific IgG antibody response after single application in mice. Thus, this study aimed at examining the time course of local inflammatory tissue response following by simultaneous implantation of different platelet-derived human growth factor preparation containing collagen matrices in a rat animal model.

Experimental Methods
Biodegradable implants (diameter 4 mm, thickness 0.9 mm) were prepared by freeze-drying of 1% porcine collagen solution only (control implants; MBP GmbH, Neustadt-Glewe, Germany) and in combination with three different preparations containing platelet-derived hGF (#190104-1, #190104-2, #190104-3), followed by EtO-sterilization. Twenty-one male Lewis rats (age 100 days) received one implant of each hGF preparation and one control implant via simultaneous implantation into the neck musculature at distance of approximately 2 cm. After 7, 14 and 56 days, implants with the surrounding tissue were retrieved from seven randomly selected animals per respective experimental day. Morphometric analysis was performed on cryostate sections (5 µm) stained with Hematoxyline and Eosine (H&E) staining and primary antibodies against monocytes/macrophages (CD68+, ED1), tissue macrophages (CD163+, ED2), MHC-class II+ cells, T lymphocytes, nestin (rat-401) and the APAAP technique. For morphometric analysis of the sections, pictures were taken with a Olymp 20 camera (Olympus K.K., Tokyo, Japan) and analysed by the ImageJ software. Data were analysed by Mann-Whitney-Test or one-way ANOVA using the GraphPad Prism software.

Results and Discussion
In general, morphometric immunohistological analysis demonstrates a significant increase of all inflammatory cells investigated from the experimental day 7 until day 56 (p=0.012 – p<0.0001), but most pronounced for pro-inflammatory monocytes/macrophages (ED1), MHC-class II+ cells and for T lymphocytes. This was not seen between experimental days 7 and 14. However, no significant differences between the number of inflammatory cells in their peri-implant tissue of the different hGF preparations among one another, as well as in comparison to the control implants was obtained. For the hGF preparations #190104-2 and #190104-3, containing the highest content of TGF-β and/or IGF-1, a tendency of increased number of MHC-class II+ cells and T lymphocytes was observed for
experimental days 7 and 14, possibly indicating a developing B lymphocyte dependent induction of specific antibodies against hGF preparations and/or the porcine collagen matrix.

**Conclusion**

The morphometric immunohistological analysis demonstrates a significant increase of all analyzed inflammatory cell populations in the peri-implant tissue from experimental day 7 to day 56, which, however, did not differ between different hGF preparations investigated and controls on individual experimental days. Thus, the time-dependent increase of local inflammatory reaction might rather be induced by the porcine collagen matrix than by the different hGF preparations. Additional investigations and further studies could clarify possible implications of different amounts of TGF-ß and/or IGF-1 in preparations of hGF, which might influence both, the local inflammatory and the systemic immunological response and are therefore important for future clinical applications.

Time course of MHC-II+ Cells
Percentage of MHC-class II+ cells in the peri-implant tissue of different human Growth Factor (hGF) coated collagen sponges (GF1-3) or a uncoated control implant (Con) on experimental days 7, 14, and 56. A significant increase was observed for all implants from day 7 to day 56 (Kruskal-Wallis Test (ANOVA); p<0.0001), however, no significant difference was seen between the different implants on respective experimental day. Boxes represent median and interquartile range of seven rats per experimental day.
Laser surface modification enhances the antibacterial performance of Ti-6Al-4V without compromising biocompatibility

James Quinn\(^1\), Ryan McFadden\(^2\), Chi Wai Chan\(^2\), Louise Carson\(^1\)

\(^1\) Queen's University Belfast, School of Pharmacy, Belfast, GB; \(^2\) Queen's University Belfast, School of Mechanical & Aerospace Engineering, Belfast, GB

Introduction
As human life expectancy continues to increase, most countries now have an aging population, who unfortunately are more susceptible to chronic musculoskeletal disorders such as osteoarthritis [1]. As osteoarthritis and associated-musculoskeletal disorders are the predominant cause of joint arthroplasty, there has been a consequent, growing requirement for such procedures.

Unfortunately, despite the profound improvements in healthcare throughout the past century, two major problems are still prevalent within arthroplasty, namely aseptic loosening and periprosthetic joint infection [2]. Laser surface modification of titanium alloys offers a promising frontier for combatting the aforementioned problems, with the laser surface treatment of one of the most common alloys, Ti-6Al-4V being discussed herein.

Experimental Methods
Ti-6Al-4V discs were prepared using a fibre laser machine with a near-infrared wavelength of 1064 nm in a nitrogen-containing environment, manufactured by SPI Lasers UK Ltd (Southampton, UK). Three different laser settings of low, medium and high wattage were used with a baseline power setting of 40W, which were tested in relation to the untreated Ti-6Al-4V (base metal).

For microbiological analysis, samples were inoculated with 3mL of either Staphylococcus aureus (ATCC 6538) or Escherichia coli (ATCC 25922) at 37\(^\circ\)C on a 100 rpm gyrotary incubator for 24h to allow biofilm formation. Following which samples were stained with fluorescent Live/Dead® BacLight™ solution for 30 minutes at 37\(^\circ\)C in the dark to capture images via fluorescence microscopy. Image analysis was conducted using ImageJ software to ascertain the ratio of live to dead bacterial cells on each of the surfaces, as well as the total biofilm percentage coverage. Statistical analysis was performed using a one way ANOVA test with Tukey's post hoc test using GraphPad Prism, version 8.3.1.

Biocompatibility was assessed by means of an MTT assay based on ISO 10993-5:2009, which functions to evaluate the in vitro cytotoxicity of materials used in medical devices [3]. Two different cell lines, RAW 264.7 (ATCC TIB-71) macrophages and L929 (NTCC clone 929, ATCC CCL-1) fibroblasts were used throughout this experiment. The culture medium was Dulbecco’s Modified Eagle Medium (DMEM) (Gibco® DMEM) for the RAW 264.7 macrophages and Minimum Essential Media (MEM) (Gibco® MEM) for the L929 fibroblasts, both supplemented with 10% foetal bovine serum (Gibco®) and 1% penicillin/streptomycin (Gibco®). Cells were diluted to a seeding density of 0.05 x 10\(^6\) cells per mL and 1mL was seeded onto 24-well cluster cell culture treated plates (Nunc 6 Well multidish). Following this, samples were aseptically placed upon the cell monolayer and re-incubated for either 24h or 48h.

After exposure, samples were removed and 1mL of MTT (tetrazolium salt 3-[4,5- dimethylthiazol-2-yl]-2,5- diphenyltetrazolium bromide; Sigma-Aldrich) was added to each well and kept in a dark environment for 1.5-2h at 37\(^\circ\)C. The insoluble formazan crystals formed were dissolved using 1mL of dimethyl sulfoxide (VWR chemicals) per well. The intensity of the colour of the formazan solution formed will be proportional to the metabolic activity of the cell. The absorbance at 570nm was then measured using a UV–visible spectrophotometer (PowerWave™ XS Microplate Reader).

Results and Discussion
It is evident in figure 1 for both species investigated that there was a significant reduction in total biofilm coverage (%) for all three wattages investigated. *Staphylococcus aureus* coverage was reduced from ~70% to <30% for all wattages utilised. Similarly, with *Escherichia coli*, there was over a threefold reduction, with coverage falling from ~15% to <5% for all wattages investigated. These results suggest that laser surface treatment has a significant effect on reducing the adherence of both Gram-positive and Gram-negative bacterial upon TiG5.

Regarding live:dead ratio, there again was a significant decrease in the ratio of live/dead bacteria for all three wattages tested. For *Staphylococcus aureus*, the ratio fell from ~4 in the base metal to <1 for all for the laser treated surfaces, similarly for *Escherichia coli*, the ratio fell from ~6 to <1 for all the wattages.

As illustrated in figure 2, laser surface treatment does not compromise cell viability for either of the two cell lines investigated, at any wattage used to modify Ti-6Al-4V, in fact, a modest improvement in cytocompatibility was found in RAW macrophages exposed to Ti-6Al-4V that had undergone laser surface treatment.

**Conclusion**

Laser surface modification of one of the most commonly used alloys in arthroplasty, Ti-6Al-4V was found to improve it's antibacterial capabilities, whilst maintaining bicompatibility, thereby addressing the two most pressing concerns within arthroplasty. It is the authors belief that further work should be conducted to provide additional insight into how this technology can be employed for clinical use.

Plasma surface modification for controlled cell behavior

Jana Markhoff, Stefan T. Oschatz, Michael Teske, Niels Grabow

Rostock University Medical Center, Institute for Biomedical Engineering, Rostock, DE

Introduction
Since most biomaterials cannot fully or sufficiently mimic the structure and function of the tissue to be supported or replaced, modification of these is necessary to control and direct the biological response in dependence of the target area of application. This is crucial in a way as different tissue surroundings may result in different cell responses. As for that, cardiovascular implants often tend to develop tissue fibrosis due to early adhesion and proliferation of fibroblasts and therefore delayed endothelialization of the biomaterial surface by endothelial cells which may result in implant failure. Another example is dermal tissue, whereas fibroblasts are critical in all phases of skin wound healing, but may lead to implant encapsulation and scar tissue formation, inhibiting keratinocyte function. In addition to the mechanical structuring of the material surface or the binding of growth factors, optimization of the implant surface is possible by means of chemical groups or coatings. The aim of our work was therefore to develop a plasma-based surface modification for implants which, depending on the application and target tissue, specifically controls the local cells in order to inhibit or promote their proliferation and function.

Experimental Methods
For this purpose, different plasma polymer coatings from the monomers pyrrole (pPy), allylamine (pAA) and hexamethyldisiloxane (pHMDSO) without and with the addition of different amounts of oxygen and ammonia (5 sccm, 10 sccm) to the plasma reaction chamber, respectively, were applied to conventional polystyrene cell culture plates to generate ultrathin polymer films via plasma-enhanced chemical vapor deposition (PECVD). The yielded plasma polymer coatings were characterized using ATR-FTIR spectroscopy and contact angle measurements were performed to investigate wettability of the polymer layers. Fibroblasts (HT-1080), as well as endothelial cells (E.A. hy 926) and keratinocytes (HaCaT), were used for initial cell tests. Cells were cultivated in defined cell numbers for 48 h on the plasma-modified surfaces. In addition to determining cell viability by Cell Quanti Blue assay and live-dead staining, cell morphology was assessed by phalloidin staining and scanning electron microscopy.

Results and Discussion
A surface- and cell type-dependent expression of cell viability was found, which could be confirmed by fluorescence microscopy images after live-dead staining.

Amounts of 5 sccm oxygen and ammonia, respectively, especially on pPy and pHMDSO, led to reduced fibroblast cell vitality compared to the pure plasma coating. This was also confirmed by live-dead staining showing a greatly reduced cell density and a distinctly altered cell morphology. In contrast, high proportions of ammonia (10 sccm) in pPy and pAA in particular had a stimulating influence on fibroblasts. These tendencies were not quite as pronounced in the endothelial cells. Nearly all plasma coatings showed similar levels of cell activity compared to the pure plasma coatings. Only pHMDSO with 5 sccm oxygen and 10 sccm ammonia lead to greatly reduced levels in comparison, respectively. The results of the Cell Quanti Blue assay were supported by live-dead staining.

HaCaT keratinocytes showed increased cell viability on oxygen and ammonia modified pAA surfaces, whereas pure and oxygen treated pPy as well as pHMDSO mixed with oxygen and ammonia resulted in strikingly decreased
viability. Live-Dead staining of these groups revealed no dense cell layers and further mainly rounded single cells instead of flat and typical cell clusters.

Except in the above-mentioned groups, staining of the actin skeleton, as well as scanning electron microscopy evaluation, showed no clear influence of the different plasma coatings on the cell morphology of fibroblasts, endothelial cells and keratinocytes. Nevertheless, especially endothelial cells did not cover the entire surface in a plasma-dependent manner.

Further investigations, e.g. evaluation of the synthesis of inflammation markers will be done for a more detailed characterization of the several plasma coatings.

Conclusion
Plasma-enhanced chemical vapor deposition is a versatile tool for the modification of implant surfaces while maintaining inherent material properties. The process allows the coating of even complex structures and ultra-thin polymer films with thicknesses in the submicron range. Furthermore, due to the plasma activation of the monomers in gaseous state, unique polymers are accessible which cannot be synthesized by classic polymer chemistry.

Lipid-Nanocoated Hydrophobic Particles As Aspiring Stealthy Bioprotective Carriers

Francisca L. Fernandes Gomes¹, Dorothee Wasserberg², Jasper van Weerd², Pascal Jonkheijm³, Jeroen Leijten¹

¹ University of Twente, Department of Developmental Bioengineering, Faculty of Science and Technology, Technical Medical Centre, Enschede, NL; ² LipoCoat BV, Enschede, NL; ³ University of Twente, Department of Molecules and Materials, Laboratory of Biointerface Chemistry, Faculty of Science and Technology, MESA+ Institute for Nanotechnology, Enschede, NL

Introduction
Biologically sensitive compounds with outstanding therapeutic potential usually require extensive formulation adjustments prior to pre-clinical stages. An estimated >40% of drugs on the market are poorly water-soluble, leading to lower absorption rates and thus reduced bioavailability.¹ Prodrug synthesis or biomolecule conjugation can improve pharmacokinetic behavior, but biological or chemical modifications are not always advantageous. Physical modifications are, therefore, preferred in certain cases, with coating and encapsulation being a popular solution. Bioprotective coatings or carriers are usually made of materials or composites with bifunctional properties that can accommodate sensitive compounds while exhibiting desired biological responses. Hydrophobic cargo, for instance, is frequently incorporated in amphiphilic formulations or composites made of hydrophobic cores and hydrophilic shells. Equally important are the physical properties of the carrier, whose size and surface area should be tuned according to the desired administration route, release kinetics, degradability rates, and other relevant aspects. Polycaprolactone (PCL) is an inexpensive hydrophobic polyester frequently used in biomaterials science due to its physical versatility and biodegradability. With a relatively low melting point (60°C), it has been used in the production of tissue scaffolds via electrospinning or 3D printing², and even micro- and nanoparticles for compound delivery, such as antibacterial product Nanochlorex®³. Despite this, the hydrophobic surface of PCL is prone to protein adsorption, which can trigger severe inflammation, platelet activation, tissue fibrosis, and thrombus formation.⁴ A promising approach to improving the biological response to PCL would be, therefore, to endow PCL with a bioinert surface coating.

In this work, we hypothesize that a cell membrane-mimetic nanocoating will improve the biological response to PCL microparticles by offering anti-fouling and anti-thrombogenic properties. Polymer particles of sizes below 1 µm (0.4-0.8 µm) were produced and nanocoated with a proprietary lipid formulation.⁵ First biological response tests focused on the hemocompatibility of coated vs. uncoated materials to identify possible differences in hemolysis and coagulation induction. Following work will shed light on anti-fouling properties and cytocompatibility by means of protein adsorption and cell viability studies, respectively. To the best of our knowledge, this work constitutes the first hemocompatibility studies of pristine PCL microparticles coated with a synthetic lipid formulation.

Experimental Methods
PCL microparticles of different molecular weights were produced via a double emulsion with solvent evaporation technique using probe sonication for water-in-oil-in-water emulsification. Particularly, particles made of PCL with molecular weight 10,000 (Mₓ10k) and stabilized in a 0.3% Mowiol® 40-88 solution were coated with one of the fluorescent proprietary lipid formulations of LipoCoat.⁵ Coated and uncoated materials were characterized in terms of size, surface charge, and morphology using dynamic light scattering, zeta potential, and optical and electron microscopy. Hemocompatibility testing included hemolysis and coagulation studies wherein particles were incubated at 37°C with isolated human red blood cells and platelet-poor plasma, respectively.

Page 1465 of 2028
Results and Discussion
PCL particles of different molecular weights (MW: $M_n$ 80k, 45k, 10k) exhibited different size distributions, with lower MWs resulting in lower hydrodynamic size distributions. Specifically, particles produced with PCL $M_n$ 10k showed the lowest hydrodynamic particle size range (0.4-0.8 µm) (Fig.1), and thus were selected for further coating experiments. Using LipoCoat’s fluorescent X2TR lipid formulation, the coating efficiency on the microparticles was confirmed using fluorescence microscopy (Fig.2). Zeta potential measurements of coated particles showed rather neutral, buffer-sensitive values, both characteristic of the zwitterionic lipid shell. Hemocompatibility tests show equally low hemolysis on both conditions (Fig.2) and a potential trend in delay in coagulation in coated vs. uncoated particles.

Conclusion
Hydrophobic PCL microparticles were produced and successfully nanocoated with a synthetic cell-membrane mimic. First hemocompatibility testing demonstrated low hemolysis and a potentially delayed coagulation by the nanocoated particles, providing the first results on the biological response to the tested composites. Future studies will elaborate on this response profile and clarify the suitability of these materials as bioprotective carriers in therapeutics.

Effect of plasma treatment on the surface properties of polylactic acid

Veronica Luque-Agudo¹²³, Margarita Hierro-Oliva¹²³, Amparo M. Gallardo-Moreno¹²³, M. Luisa Gonzalez-Martin¹²³

¹ Extremadura University, Badajoz, ES; ² CIBER-BBN, Badajoz, ES; ³ INUBE, Badajoz, ES

Introduction
Polylactic acid (PLA), one of the most widely used biodegradable polymers in the manufacture of medical devices, is a slightly hydrophobic material. As some applications require a hydrophilic surface, there are several methods to achieve this. One of these is plasma treatment, which can generate new functional groups on the surface, increase roughness or simply remove impurities [1]. The aim of this work is to study the surface properties of PLA after plasma treatments.

Experimental Methods
PLA particles (PURASORB®, PDL 04, Corbion) were dissolved in chloroform using a rotator stirrer. Then, the solution was deposited on substrates provided by Ticare (Mozo-Grau S. A., Valladolid, Spain) and they were left to dry at room temperature for one hour. Later, samples were dried in an oven for 48 hours at 70 °C to completely remove any solvent remaining. The hydrophilization of the surface was done by applying low-temperature plasma from different gases. Hydrophobicity was quantified through water contact angle measurements (WCA) by the sessile drop method. The topography, roughness (RMS) and morphology were evaluated by using an AFM and a SEM. FTIR spectra were recorded on a VERTEX 70 spectrophotometer (Bruker®). Secondary ion mass spectrometry was performed using a ToF-SIMS (ION-TOF®) instrument.

Results and Discussion
The contact angle of the PLA before treatment is 83°, while the angle measured immediately after the different plasmas are applied was 59° and 51°, so both treatments hydrophilize the surface. As it has been shown that the plasma initiates a series of radical reactions in the polymer chains of PLA [2], possible changes in the chemical composition of the surface were evaluated. Thus, by means of FTIR it was possible to detect, in one of the treatments, and in a very short time after its application, the presence of CO and CO₂, thus confirming that these reactions have taken place. The bands assigned to these compounds disappeared when the spectra were recorded the next day, probably because the radicals generated recombine to regenerate the polymer chain. The changes in composition were confirmed by the depth profiles performed by ToF-SIMS. In addition to changes in the chemical composition, the plasma also modified the roughness of PLA. Thus, the RMS was determined by AFM before and after the treatment, and it was observed that the RMS increased by an order of magnitude. The AFM and SEM analysis showed that the polymer coating was perfectly homogeneous.

Conclusion
The application of both treatments on PLA hydrophilizes the surface, either by removing any impurities it may have, or because of changes in the chemical composition. This has been proven to be the case by means of FTIR and ToF-SIMS. It also increases the roughness of the samples after exposure to the plasma.

Evaluation of a medical-grade thermoplastic polyurethane in the conception of a 3D-printed custom-made aortic stentgraft

Marie-Stella M'Bengué1,2, Thomas Mesnard1,3, Mickaël Maton1, Valérie Gaucher2, Nicolas Tabary2, Maria-José García-Fernandez1, Jonathan Sobocinski1,3, Feng Hildebrand1, Bernard Martel2, Nicolas Blanchemain1

Lille, CNRS, INRAE, Centrale Lille, UMR 8207 - UMET - Unité Matériaux et Transformations, F-59000 Lille, FR; 3 Institut Coeur Poumon, Regional Hospital Center University of Lille (CHU Lille), 59000 Lille, FR

Introduction
The use of fenestrated stentgrafts in endovascular repair (FEVAR) of abdominal aortic aneurysms (AAA) shows limitations in manufacturing time (8-12 weeks), cost (15-20 k€), and patient customization. Providing a custom-made (CM) medical device made by 3D-printing (3DP) would solve these issues. Thermoplastic polyurethane (TPU) seems to appear as an excellent raw material. Synthesized from a macrodiol (soft segment, SS) and a diisocyanate (hard segment, HS), this polymer is already used as a biomaterial for blood contacting devices [1]. For it to be implantable in the long term, TPU must be biocompatible, sterilizable and maintain its integrity over time. In this context, the aim of this work is to assess the feasibility of using TPU as a raw material in the conception of a 3DP CM aortic stentgraft. The properties of this polymer will be evaluated through the whole manufacturing process from extrusion of raw pellets to sterilization of 3DP samples. Moreover, its susceptibility to degradation by reactive oxygen species (ROS) in a pro-oxidative medium will be investigated. Finally, biocompatibility will also be assessed through cell viability and hemocompatibility assays according to ISO standards.

Experimental Methods
Raw medical-grade TPU pellets were first extruded into a neat filament with a regular diameter of 1.75 mm. Said TPU filament was then used as a raw material for the manufacture of samples using FDM 3D-printing. 3DP samples underwent a sterilization process using gamma (γ) irradiation. Impact of sterilization at a dose of 40 kGy (γ-40 kGy) and stability of TPU have been investigated on 3DP samples. The control group (0 kGy) and the sterilized group (γ-40 kGy) were accelerated ageing test, exposed to a 25% H₂O₂ solution under reflux for 6 hours to provoke oxidation [2], which is known to occur as part of the inflammatory response system of cells to foreign bodies [3]. Surfaces of samples were observed under scanning electron microscope and surface properties were investigated by infrared ATR-FTIR spectroscopy and water contact angle measurements following the Sawsen Sessile Drop method. Molecular weight was determined by gel permeation chromatography coupled to a differential refractometer. Thermal properties were assessed by differential scanning calorimetry and mechanical behaviors were investigated through tensile tests. The response of HPMEC endothelial cells to the extract of the 3DP TPU samples was analyzed via the Alamarblue® test method according to ISO10993-5 standard. Blood compatibility was assayed according to ISO10993-4 standard using whole human blood from a healthy donor. Surface of samples after whole blood contact were observed under scanning electron microscope.

Results and Discussion
Tubular TPU samples (height = 25mm; diameter = 20 mm) were manufactured using FDM 3D printing. Gamma irradiation and H₂O₂ exposure induced macroscopic color changes as 3DP samples yellowed. After γ-sterilization, molecular weight increased as well as HS glass transition temperature that went from 53°C to 59°C. TPU samples were more resistant as stress and elongation at break values augmented. Those changes suggest that reticulation occurred after γ-sterilization leading to the 3DP samples being tougher. After H₂O₂ exposure, peak emergence in...
ATR-FTIR spectra show that oxidation degradation occurred in TPU evidenced by primary amines peaks observed at 1636 cm\(^{-1}\) [4]. Surface oxidation also induces decrease in water contact angle measurements: values that were greater than 90° before are close to 78° after \(\text{H}_2\text{O}_2\) exposure. Concerning cytocompatibility, cell viability of 151% for 0 kGy and of 144% for \(\gamma\)-40 kGy shows non-cytotoxicity of the samples and vitality of cells. Even after exposure to \(\text{H}_2\text{O}_2\), cell viability remains very high: it is of 101% for the 0 kGy-25%\(\text{H}_2\text{O}_2\) sample and 128% for the \(\gamma\)-40 kGy-25% \(\text{H}_2\text{O}_2\) sample. Hemocompatibility rates lower than 2% confirm that 3DP TPU samples do not induce critical red blood cells lysis before and after sterilization and \(\text{H}_2\text{O}_2\) exposure. SEM observation after whole blood contact shows inhibition of platelet activation after \(\gamma\)-sterilization contrary to the 0 kGy-25%\(\text{H}_2\text{O}_2\) and \(\gamma\)-40 kGy-25% \(\text{H}_2\text{O}_2\) samples where adhered pseudopodia and flat activated platelets are visible on the surface of the samples.

**Conclusion**

Our study shows the feasibility of using TPU as a raw material in the conception of a 3DP CM aortic stentgraft. The manufacturing process would seem to have low impact on the properties of TPU regarding our application as it is sterilizable and biocompatible. After \(\text{H}_2\text{O}_2\) exposure, it was shown that TPU is susceptible to oxidation degradation by ROS, however the extent of its impact on the TPU properties does not compromise the application. Further studies should investigate long term mechanical stability and toxicity analysis of degradation products and extractables.

Aligned 3D fibre matrices for the development of chondrocyte-laden anisotropic scaffolds

Angela Semitela¹, Ana Capitão², Susana C. Pinto¹, Alexandrina F. Mendes², Paula A.A.P. Marques¹, António Completo¹

¹ University of Aveiro, Centre for Mechanical Technology and Automation, Aveiro, PT; ² University of Coimbra, Centre for Neuroscience and Cell Biology, Coimbra, PT

Introduction

Current cartilage tissue engineering (TE) strategies have struggled to reproduce the collagen fibrous arrangement, that confers outstanding properties of deformability, resistance to mechanical loading and low-friction gliding to the native articular cartilage [1]. Indeed, tissue-engineered cartilage lacking this native layered structure usually possess inferior biochemical and biomechanical properties, that can compromise a proper regeneration process. In this regard, electrospinning has been widely employed for the development of fibrous scaffolds for cartilage TE, due not only to the topographic resemblance with the native nanoscale extracellular matrix, but also the versatility of the technique to manipulate the properties of the resulting structures [2]. Yet, given their nearly bidimensionality, it remains a challenge to fabricate three-dimensional (3D) electrospun scaffolds. Considerable efforts have been made in an attempt to achieve the tridimensionality of the electrospun structures, with substantial progress made through the use of post-processing strategies, such as rolling and stacking the electrospun meshes [3]. Despite their reported potential, the issue of design reproducibility is still a concern, since these strategies are not automated. Additionally, chondrocyte infiltration within the 3D structures continues to be ineffective. In this regard, in this work, automated 3D electrospinning was performed using a patented electromechanically 3D electrospinning platform [4] in order to fabricate reproducible aligned 3D fibre matrices laden with chondrocytes.

Experimental Methods

All experiments were performed in a recently developed electromechanically 3D electrospinning platform [4], where the fibres were collected and placed in a collector according to programmed alignments. All equipment and material used in these experiments were sterile or thoroughly disinfected. A 10 wt% polymeric blend of polycaprolactone (PCL) and Gelatin (GEL) in 2,2,2-trifluoroethanol mixed in a proportion of 6:4 was employed to produce the 3D scaffolds. Chondrocyte-free scaffolds were fabricated and characterized based on their topography and morphology (via scanning electron microscopy (SEM) and micro-computed tomography (μCT)), on their water absorption ability (swelling assays) and mechanical response (unconfined compression). Afterwards, an immortalized human chondrocyte cell line C28/I2 was incorporated within the fibres of the 3D scaffolds using a micropipette between the layers of polymer. Chondrocyte metabolic activity, via a resazurin reduction assay, and their distribution within the fibres, via SEM and haematoxylin-eosin staining, was later assessed after 1 day of culture.

Results and Discussion

3D scaffolds were successfully fabricated in the electromechanically 3D electrospinning platform, following three different programmed alignments (3D_1, 3D_2 and 3D_3; Figure). μCT 3D reconstruction and SEM images revealed that the resulting fibre alignment remained similar to the programmed input, demonstrating the potential of this platform to fabricate highly reproducible tissue-engineered constructs. Moreover, the versatility of this platform allowed for the development of quite different fibrous architectures. 3D_1 displayed high porosity and pore interconnectivity, while 3D_2 possessed high fibre packing density and low porosity. 3D_3 was a combination of the previous two scaffold architectures. The different fibre arrangements and porosities of the 3D scaffolds also generated distinctive swelling and mechanical behaviour. Indeed, the high porosity of the 3D_1 generated the highest...
swelling ratio, while the low porosity of the 3D_2 triggered the lowest water absorption. Nevertheless, all scaffold architectures exhibited a nearly total deformation recovery after compression up to 20% strain, which can be attributed to the presence of the hydrophilic GEL [2]. The higher amount of fibre deposition of the 3D_2 resulted in the highest compression moduli. 3D_2, on the other hand, displayed a substantially lower compression moduli, but still fell in the range of values reported for native articular cartilage [5]. The in vitro studies revealed that the high fibre density of 3D_2 and 3D_3 possessed an improved retaining capacity of the chondrocytes that were able to survive the layering process. Moreover, these architectures were able to maintain a homogeneous chondrocyte distribution.

Conclusion

3D chondrocyte-laden anisotropic electrospun scaffolds were successfully developed in a versatile electromechanically 3D electrospinning platform with a controlled and reproducible fibre alignment and homogeneous chondrocyte distribution, showing the potential of this technology for cartilage TE.

PLA-Bioglass Composites for Hybrid Bioprinting of Bone Tissue

Eva Schätzlein¹, Shahed Al Zoghool¹, Nicolas Söhling⁴, Dirk Henrich⁴, Johannes Frank⁴, Edgar Dörsam³, Ingo Marzi⁴, Andreas Blaeser¹, ²

¹ Technical University of Darmstadt, Institute for BioMedical Printing Technology, Darmstadt, DE; ² Technical University of Darmstadt, Centre for Synthetic Biology, Darmstadt, DE; ³ Technical University of Darmstadt, Institute of Printing Science and Technology, Darmstadt, DE; ⁴ Goethe University Frankfurt am Main, Department of Trauma, Hand and Reconstructive Surgery, Frankfurt am Main, DE

Introduction

Hybrid bioprinting is a promising technology for biofabrication of tissue implants to be used in regenerative medicine. Two material classes, soft cell-laden hydrogels and rigid polymers are printed in parallel, creating mechanically stable but highly biofunctional composite structures. These composites combine ideal characteristics for surgical handling, high suture retention, and high primary load-bearing capacity with controllable physical as well as bio-chemical cues for cell conditioning. So far, hybrid bioprinting was mostly realized by combining microextrusion methods. In this work, we present a novel approach for combining fused-filament-fabrication and drop-on-demand 3D-bioprinting technology for rapid hybrid bioprinting of cancellous bone mimicking structures. For this purpose, polymer scaffolds made of a custom-made biodegradable PLA-bioglass composite are combined with human mesenchymal stem cells (MSC) which have significant osteogenic regenerative capabilities. We hypothesize, that the incorporation of bioglass can be used to stimulate bone growth due to its bioactive nature.

Experimental Methods

In this study, composite PLA filaments and ultrafine, cancellous bone mimicking 3D-structures with bioglass contents of up to 20 wt. % were processed, fabricated, and characterized. S53P4 bioglass with a grain size of 25 - 42 µm and corresponding weight proportions of transparent PLA granules with a grain size of about 2 - 5 mm were extruded into filaments using a commercial composer (3devo, NEXT 1.0 Advanced). The distribution of bioglass within the filament as well as within 3D-printed samples were investigated using SEM. The mechanical properties of filaments with varying bioglass content were evaluated by uniaxial tensile tests. To assess the composite's cytocompatibility, calcium release and cell viability as well as proliferation studies were conducted. Calcium release of PLA-bioglass composites in PBS was determined photometrically. Viability and proliferation potential of MSCs seeded on printed polymer composite structures supplemented with 5 wt. %, 10 wt. % or 20 wt. % bioglass were determined using an MMT assay.

Finally, macroporous 3D-structures with very fine directed strands were created based on the FFF 3D-printing process. Strand diameter and pore size were determined microscopically. Ultimately, the feasibility of the process for hybrid 3D-bioprinting was demonstrated.

Results and Discussion

Analysis of the produced PLA-bioglass filaments revealed a strong influence of the material composition and extruder settings on its diameter, morphology and mechanical properties. The PLA-bioglass filament obtained from extrusion varied in diameter in relation to the bioglass content, temperature and the extrusion speed. Filaments from 1.65 to 1.85 mm diameter were used. Further morphological investigations using SEM revealed homogeneous distribution of bioglass across both, extruded filaments and 3D-printed samples. Interestingly, the bioglass particles were mostly observed within the bulk material and were found to be only rarely exposed to the outside of the structures.

The elastic modulus of the composite material was shown to increase slightly with rising bioglass content from 44 MPa (0 wt. %) to 47 MPa (20 wt. %), while its tensile strength increased accordingly.
The release study revealed a non-linear relationship between the amount of dissolved calcium and the bioglass concentration. For instance, only minimal calcium release could be detected using composite filaments with 5 wt. % bioglass, while filaments with 20 wt. % bioglass content released a 10-times higher amount of calcium within 24 h.

A porous structure which has similar geometric properties to cancellous bone was printed. Pore sizes between 500 µm and 20 µm and strand sizes between 500 µm and 120 µm could be achieved with a 400 µm nozzle. During printing higher bioglass contents were shown to be more difficult to be process. Compared to native PLA those exhibited lower print bed adhesion and required larger nozzle diameters to avoid clogging. In addition, it was found that the hygroscopic characteristic of the incorporated bioglass affected shape fidelity. However, this effect could be overcome by prior drying the filament at 50 °C for 24 h.

Finally, the material’s suitability for hybrid 3D-bioprinting could be demonstrated successfully. With increasing bioglass content, the cell viability and proliferation potential were in average up to twice as high on 20 wt. % bioglass compared to native PLA samples.

**Conclusion**
In this study, a PLA-bioglass composite was characterized as well as a novel hybrid bioprinting process combining FFF-based 3D-printing and drop-on-demand bioprinting was developed. In future, the proposed composite material combined with the presented printing technology hold great promise for the biofabrication of hybrid scaffolds for the treatment of large bone defects in regenerative medicine.

Engineering an extracellular matrix substitute for the investigation of mesoangioblast extravasation in a 3D in vitro vessel-on-a-chip model

Mattis Wachendörfer¹, Philipp Schräder¹, Florence van Tienen², Bert Smeets², Horst Fischer¹

¹ RWTH Aachen University, Department of Dental Materials and Biomaterials Research, Aachen, DE; ² Maastricht University, Department of Toxicogenomics, Research School MHeNS, Faculty of Health, Medicine and Life Sciences

Introduction
Muscular dystrophies are a group of genetic diseases characterized by progressive skeletal muscle weakness and degeneration. The intra-arterial injection of autologous in vitro cultured, genetically corrected muscle stem cells, called mesoangioblasts, i.e. mesenchymal cells located on the vessel walls, holds potential for an effective stem cell therapy. The mesoangioblasts extravasate from the vessel through the vessel walls into the surrounding muscles, where they form healthy muscle fibers and fuse with existing fibers, thereby supplying the missing proteins and restoring muscle strength and mass. The Interreg-V EMR-project GYM – Generate Your Muscle aims to develop this autologous stem cell therapy as a novel treatment for muscular dystrophies. In our subproject we aim to develop a 3D in vitro vessel-on-a-chip model for the investigation and improvement of mesoangioblasts homing. Biofabricated functional vessel substitutes are used for the investigation of extravasation properties of injected mesoangioblasts under dynamic conditions with higher biomimicry than conventional migration assays under static conditions. The vessel substitutes are embedded in extracellular matrix substitutes (ECMs) composed of hydrogel mixtures. Here, we present the engineering approach for an ECM tailored for the investigation of mesoangioblasts migration.

Experimental Methods
Gelatin-Fibrin-blends with different concentrations of gelatin (2.5, 5, 7.5, 10 %) and varying gelatin synthesis parameters (2h at 90 °C, 12h at 90 °C) and collagen-fibrin-blends (0.16% Collagen; 0.625, 1.25, 1.95% Fibrin) were synthetized. The compressive strength of the hydrogel blends was tested in unconfined compression tests. In a degradation test, the hydrogel blends were immersed in phosphate buffered saline (PBS) and the weight of the samples and the pH of the PBS was measured after 1, 3, 4, 7, 14, 21 and 28 days of incubation. The pore structure and pore size of the ECMS were investigated using scanning electron microscopy. The contact angle of widely used bioinks for 3D Bioprinting (fibrinogen, thrombin, gelatin) to the ECMS was measured. Human Umbilical Vein Endothelial Cells (HUVECs) were seeded onto the ECMS and the proliferation of the HUVECs was investigated every second day up to 1 week. The suitability of the ECMS for mesoangioblasts extravasation was investigated in a modified Boyden chamber setup: The membranes of the upper compartment of the Boyden chamber were covered with a confluent monolayer of HUVECs which was activated with Tumor Necrosis Factor (TNF-α) for 6h. Meanwhile, mesoangioblasts were starved for 24h. The lower compartment of the Boyden chamber was filled with the ECMS (with or without growth factors (TNF-α, stromal cell-derived factor 1 (SDF-1)) and starved mesoangioblasts were seeded in the upper chamber. After 24h or 72h of migration, migrated mesoangioblasts on the lower side on the membrane were fixed and counted.

Results and Discussion
The tested ECMS provided similar compressive strength to native tissue (6-17 kPa) and showed stability during incubation for 28 days, proving their suitability for long-term experiments. The pore sizes of Gelatin-Fibrin-blends were between 0.1-1 µm dependent on gelatin concentration and synthesis, whereas Collagen-Fibrin-blends provided pore sizes from 1-10 µm with decreasing pore size in higher concentrated ECMS. Most ECMS showed suitability for Drop-on-Demand (DoD) Bioprinting as tested bioinks showed hydrophobic contact angles (experiments ongoing),
meaning bioinks could be printed with high accuracy onto the ECMs. The experiments of HUVEC proliferation and mesoangioblasts migration showed promising results in preliminary testing with experiments ongoing.

**Conclusion**

In the end, a tailored ECM which provides high biomimicry to native tissue in terms of compressive strength, stability during long-term incubation and suitability for DoD Bioprinting while supporting fast HUVEC proliferation and mesoangioblasts migration stimulated by the release of growth factors will be shown.
Functionalized 3D-printed silk-hydroxyapatite scaffolds for enhanced bone regeneration with innervation and vascularization

Vincent Fitzpatrick, Zaira Martin Moldes, Anna Deck, Ruben Torres Sanchez, Chunmei Li, David Kaplan

Tufts University, BME department - Kaplan Lab, Medford, US

Introduction
The goal of this study was to generate functionalized 3D-printed scaffolds for bone regeneration using silk-hydroxyapatite bioinks and osteoinductive, proangiogenic and neurotrophic growth factors or morphogens for accelerated bone formation.

3D printing was utilized to generate macroporous scaffolds with controlled geometries and architectures that promote osseointegration. We build on the knowledge that the osteoinductive factor Bone Morphogenetic Protein-2 (BMP2) can also positively impact vascularization, Vascular Endothelial Growth Factor (VEGF) can impact osteoblastic differentiation, and that Neural Growth Factor (NGF)-mediated signaling can influence bone regeneration.

Experimental Methods
We developed and characterized a silk-based bone cement with mechanical properties close to those of bone. We assessed our ability to 3D print this material to generate structures with a controlled geometry, macroporosity, and our ability to adapt the printing process to patient-tailored scaffolds (Fig 1).

We investigated the cytocompatibility and osteoconductivity of these constructs (Fig. 2). We further assessed functions on the 3D printed construct via the osteogenic differentiation of human mesenchymal stem cells. We also examined the migration and proliferation of human umbilical vein endothelial cells, and the proliferation of human induced neural stem cells.

Results and Discussion
The scaffolds provided mechanical properties suitable for bone and the materials were cytocompatible, osteoconductive and maintained the activity of the morphogens and cytokines.

Synergistic outcomes between BMP-2, VEGF and NGF in terms of osteoblastic differentiation in vitro were identified, based on the upregulation of genes associated with osteoblastic differentiation (Runt-related transcription factor-2, Osteopontin, Bone Sialoprotein).

In vivo studies were carried out to assess the biocompatibility and bone regeneration capability of these 3D printed constructs.

Conclusion
The specific cell responses observed here are key steps towards the development of the next generation of functionalized, 3D printed bone scaffolding to promote multicellular responses in the context of bone tissue system regeneration. These results are expected to have a strong impact in bone regeneration in dental, oral and maxillofacial surgery.

Biofabrication using shape-morphing materials

Indra Apsite, Esther Addo, Franco Raviglione, Leonid Ionov

University of Bayreuth, Department of Biofabrication, Bayreuth, DE

Introduction
Recent studies have shown the great potential of polymeric fiber-based self-folding films for various tissue regeneration like – skeletal muscle tissue, nerve, and blood vessels \(^1\)-\(^3\). Extra high porosity not only allows fast actuation rates due to high surface area but as well supports good nutrition and waste product exchange. The use of self-folding bilayers allows controlled deposition and alignment of the cells inside of tubular structures, which is a challenge for existing nerve guide conduits and autografts \(^4\)-\(^5\).

Results and Discussion
We have designed two systems based on electrospun mono and bilayers for skeletal muscle and nerve regeneration. As skeletal muscle tissue structure is highly complex and consists of multiple fibers in one muscle bundle, thus we designed polyelectrolyte bilayers with opposite charges that would lead to the self-assembly of tubular structures into a bundle. Electrospun bilayers consisted of a hydrophobic polycaprolactone (PCL) layer and hydrophilic polyelectrolyte layers like hyaluronic acid (HA, negatively charged) and chitosan (positive charged). The addition of a medium with pH ~6 allows immediate self-folding and assembly of the tubular structures. Cell culture experiments showed good C2C12 mouse skeletal muscle cell viability and proliferation on these scaffolds.

To improve nerve regeneration we designed conductive PCL monolayers that are able to contract and form tubular structure upon temperature increase. To prepare conductive electrospun fibers, we used polypyrrole and carbon nanotube blends. Higher conductivity was achieved for carbon nanotube mats, due to the high aspect ratio of carbon nanotubes in comparison to polypyrrole particles. Cell culture experiments demonstrated that PC12 neuron cells differentiate and form a more uniform monolayer on the conductive material rather than on the nonconductive

Conclusion
Both systems have shown great potential to be used as the next step for the biofabrication of skeletal muscle and nerve tissue.

Optimized parameters to print high concentrated silk fibroin by an innovative 3D freeform method

Enric Casanova-Batlle1, Carla Santiago-Corral1, Antonio J. Guerra2, Joaquim Ciurana1

1 University of Girona, Department of Mechanical Engineering and Civil Construction, Girona, ES; 2 EURECAT, Centre Tecnològic de Catalunya, Girona, ES

Introduction
Silk fibroin has been successfully used for medical devices due to its biodegradability with non-toxic end products, high tensile strength and mechanical robustness, but also because of its high flexibility potential [1]. Even though natural silk fibers have excellent strength and flexibility, regenerated silk materials generally become brittle in the dry state [2]. That is why researchers have studied the effects of its fabrication parameters on its mechanical properties to increase its flexibility, but also others parameters such as gelation time, mechanical properties or biodegradability [3]. Furthermore, post-treatment techniques and fabrications methods have been evaluated to optimise the molecular structure of the silk fibroin to obtain a more ductile material.

Direct Ink Writing (DIW) can be used to manufacture 3D printed silk fibroin applications [4]. However, it requires a silk concentration of 28-30%. Taking into account that most of the research has been carried out with low concentration silk bioinks (5-10%) and with alternative fabrication methods to the DIW process, the aim of this work is to address this lack of knowledge to efficiently 3D print silk fibroin. Therefore, an innovative method based on thermal crosslinking is proposed. The morphology, molecular structure and mechanical properties of the 3D printed silk fibroin, and thus the potential behavior of medical devices printed with this technology have been described. Furthermore, four different post-treatments techniques were evaluated on these features. This work provides the tools to fabricate biomedical applications, such as a cardiovascular stent, as the resulting silk must be flexible and at the same time have high tensile strength.

Experimental Methods
Silk fibroin was prepared at 5-7 wt % and concentrated to 35 -40 wt % as described in the Rockwood et al. protocol [5]. A home-made bioink printer was used to fabricate test-pieces for mechanical trial. The Ultimate tensile strength (UTS), the elastic modulus (E) and the strain at failure ($\varepsilon_{\text{failure}}$) were calculated from stress-strain data for the 4 post-treatment techniques. The effect of the printing parameters, such as the printing speed, the nozzle temperature, the needle gauge and the ink flow were assessed with a DOE model. Fourier transform infrared (FTIR) spectra was obtained using a spectrometer in the spectral region of 4000–350 cm$^{-1}$, to determine the molecular structure of the printed material. The morphological structure was visualized with the stereoscopic microscope. The morphologic characteristics were quantified with image processing tools.

Results and Discussion
The results show trends that interact between the studied parameters and the manufacturing process. The strut width is affected by nozzle speed, temperature and ink flow. As the higher the temperature and deposition speed, the finer the deposited line. Oppositely, the higher the flow, the wider the printed strut. Furthermore, an increase in the $\beta$-sheet molecular structure is observed when the material is printed with a high nozzle temperature. This directly affects the mechanical properties which are also enhanced during high temperature printing trials. In terms of post-treatments, it has been highlighted that methanol increases the elastic modulus. However, the material becomes more brittle. The water annealing treatment has been shown to achieve the most flexible lines, among the tested post-treatments. Nevertheless, the dried at room temperature post-treatment possesses the best compromise between the mechanical properties studied in this report.
Conclusion
This work provides the design parameters to customize silk fibroin applications manufactured through DIW, as it relates the manufacturing parameters to the mechanical, molecular and morphological properties of the resulting printed medical device.

Introduction
Nowadays there is an emerging demand for new wound healings therapeutics, especially with antimicrobial activities since the increasing bacteria’s resistance to antibiotics are responsible for wounds infection persistence and consequently, long-term hospital stays [1]. Electrospun fibers have been contributed for the progress in the wound care field due to their exceptional characteristics such as haemostatic capacity, a porous structure that allows the maintenance of a physiologically moist environment with exudate’s absorption, tissue hydration, and permeation of oxygen, that avoid wound desiccation responsible for scar formation, alongside with extracellular matrix (ECM) similarities [2]. Moreover, this technique’s versatility allows the encapsulation of bioactive molecules (natural compounds, growth factors, drugs, among others) which give electrospun fibers a great potential to be used as drug delivery systems [3]. New sources of natural compounds, like brown seaweeds, are been sought due to their outstanding characteristics (e.g good therapeutic properties for several diseases, lower toxicity and side effects, low-price acquisition, others). Phlorotannins, polyphenols compounds from brown seaweeds, are known to possess several activities of interest to wound healing, including, antimicrobial, anti-inflammatory, and antioxidant activities [4]. Although, their instability due to oxidation and bioavailability might be a concern for pharmacological proposes, concretely in wound healing. To overcome those drawbacks phlorotannins can be incorporating in electrospun meshes enduring their stability and extended-release, joined all requirements to create a potential and innovative drug delivery system [5]. Thus, in this study, an electrospun-based drug delivery system was created integrating the non-toxic and biocompatible properties of gelatin and chitosan, to the potentialities activities of a phlorotannins-enrich extract, obtained from an invasive seaweed from Portugal coast (Undaria pinnatifida), to improve wound healing.

Experimental Methods
Previously to its incorporation, the phlorotannins-enrich extract (1.5 mg·mL⁻¹), was evaluated for antimicrobial activity against principal wounds pathogens, such as Staphylococcus aureus, Pseudomonas aeruginosa, and Escherichia coli. The inhibitory activity stands out, with 43.29 ± 2.85 for S. aureus, 44.79 ± 8.12 for P. aeruginosa, 37.62 ± 4.44 and E.coli, 19.49 ± 5.42. The anti-inflammatory activity was also assessed in vitro against LPS-induced inflammation damage to RAW 264.7 cells, by inhibiting 47% of the Nitric Oxide production at a minimal concentration of 0.01 µg·mL⁻¹. A high antioxidant activity was verified, which is an added value to combat the reactive oxygen species (ROS) generated in the inflammatory stage of the wounds. Afterward, 1 and 2 wt% of the bioactive extract was included by emulsion in gelatin/chitosan electrospun meshes after the solution parameters were optimized for: a 14 wt% gelatin solution mixed with 3.6 wt% of chitosan in 70% (v/v) of glacial Acetic Acid with 2% (v/v) of triethylamine, and 4% (v/v) of 1,4 – Butanonediol diglycidil ether (BDDGE), as crosslinker agent. While the processing parameters obtained were a high tension of 20 kV, 0.2 mL·h⁻¹ of flow rate, and 12 cm from tip-to-collector. The electrospun meshes were physico-chemically characterized by SEM and FTIR, and porosity, density, water contact angle, water absorption, hydrolytic and enzymatic degradation, and mechanical properties were also analyzed. In addition, their
antimicrobial activity against *S. aureus* and *P. aeruginosa* was evaluated by disc diffusion. The biological activity, namely cytotoxicity and neonatal human dermal fibroblast (hDNF) proliferation.

**Results and Discussion**

Results showed that incorporating 1% of the bioactive extract shows to be more advantageous due to its overall activities, such higher porosity (89.22 ± 1.15 %), mimics effectively the ECM fibers diameter (302 ± 83 nm), possess higher water uptake (458.03 ± 41.52%), which facilities the oxygen, nutrient passage and allows hDNF cells proliferation. Correspondingly, it was verified that the decrease in degradation rates both in the hydrolytic and enzymatic environment, as well as the structure’s preservation over time, possibly result from an interaction between phlorotannins hydroxyl group, with gelatin and chitosan, allowing the extract to act as a crosslinking agent. Nonetheless, the extract delivery occurs in two-stages (burst and stationary), reaching a maximum release around 90%, guarantee a potential wound’s protection from external and internal factors, such as bacteria or ROS respectively. Electrospun meshes antimicrobial activity was found to *P. aeruginosa*, the main pathogen found in depth wounds.

**Conclusion**

Thus, combining the physio-chemical and biological characterization results, the drug delivery electrospun system presents a potential therapeutic solution for chronic wounds, which is the wound type with more costs to the health systems.

Bioprinting of Biomimetic Nano-Hydroxyapatite Functionalized Bioinks for Bone Tissue Engineering

Margherita Montanari¹, Elisabetta Campodoni¹, Anna Tampieri¹, Kamal Mustafa², Monica Sandri¹, Ahmad Elsebahy²

¹ National Research Council of Italy, Institute of Science and Technology for Ceramics, Faenza, IT; ² University of Bergen, Department of Clinical Dentistry, Faculty of Medicine, Bergen, NO

Introduction
Recently, the conventional concept of bone tissue engineering has shifted toward biomimetic approaches in which materials, biology and technology are integrated to recapitulate the complexity of bone tissues, allowing fabrication of patient-specific and anatomically shaped constructs. Thus, the whole concept of the scaffold in terms of design, architecture and fabrication technology is moving toward 3D bioprinting of hydrogels functionalized with tissue-mimicking components.

Bioinks components choice must be made based on factors related to biocompatibility, printability, crosslinking mechanisms, and degradation. In this context, gelatin modified by methacryloyl functional groups (GelMA) has recently gained increasing attention. The most common photoinitiator used with GelMA is Irgacure® 2959 which dissociates into free radicals upon ultra-violet (UV) light irradiation. However, the formation of free radicals upon longer UV exposure may lead to DNA damage and impair cellular function. Lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP), instead, absorbs light in the visible region, producing benefits over the commonly used UV photoinitiators.

GelMA as is cannot, however, provide cells with proper cues to form bone-like matrix. Instead, incorporating inorganic calcium-phosphate phases into hydrogels can provide the right stimuli to generate a mineralized matrix. Nonetheless, adding mineral particles to the bioinks may result in increased viscosity, decreased cell viability and printing problems. Therefore, the current study aimed to bioprint human bone marrow-derived mesenchymal stem cells (hBMSC) in GelMA bioink that can be photopolymerized using a LED dental curing lamp (DL), functionalized with two different types of nano-hydroxyapatite (nHA), chemically and morphologically different, to evaluate their effects on the bioprinting process and outcomes.

Experimental Methods
Biomimetic magnesium doped hydroxyapatite (MgHA) and magnesium-carbonate doped hydroxyapatite (MgCO₃·HA) were prepared and characterized utilizing X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR), thermo-gravimetric analysis (TGA), induced coupled plasma (ICP) and scanning electron microscopy (SEM-FEG). For cytotoxicity, 1% nHA (w/v) were suspended in cell culture medium at 37 °C under shaking for 24 h. After centrifugation and filtering, the effect of the nHA leachates on the hMBMSC viability and proliferation was evaluated by live/dead stain and CCK8 proliferation kit.

To prepare the bioinks, GelMA (5% w/v) and Gel (5% w/v) were dissolved in cell culture medium and nHA (1% w/v) added and stirred for one hour. The solutions were stored at 4 °C for 24 h. Before printing, the solutions were heated to 37 °C, and LAP and cells (5×10⁶ cell/ml) were added to the solution. The bioinks were then poured into plastic printing cartridges with a 0.51 mm metal needle and the printing was conducted with 3D-Bioblotter® directly onto sterile 6 well-plates on a cooled platform (4 °C). Square structures (1cm²) of four perpendicular layers and 1.2 mm between the strands were printed. Immediately after printing, the structures were crosslinked by DL using 2 cycles (30 s) of high-power mode of exposure (1200 W/cm²) at 0.5 cm distance. To evaluate the printing quality, non-
crosslinked cell-free structures of one and four layers were imaged with a stereomicroscope. The cell viability and proliferation were evaluated by live/dead stain and CCK8 proliferation kits.

Results and Discussion

The nHAs synthesis were optimized to obtain two morphologically and physicochemical different nHAs, respectively more crystalline and needle-like (MgHA) and more amorphous and round-shaped (MgCO₃HA). XRD and FTIR characterization confirmed the HA identity, while ICP and TGA the successful doping. The indirect cytotoxicity of 1% nHA leachates showed high cell viability and cell proliferation after 1 and 7 days, confirming the safety of these nanoparticles. The stereomicroscope images showed the ability of the GelMA-Gel-nHA to form 3D structures with good fidelity and integrity. The stability of the printed structure in cell culture medium after 7 days confirmed the successful photocrosslinking step and the efficacy of LAP as photointiator. The results of the live/dead stain and CCK8 confirmed the viability of the cells and the ability of the cells to proliferate in the bioinks after 7 days.

Conclusion

All in all, the addition of both nHAs to GelMA-Gel system enhanced the printability and stability of the structures. The use of LAP as photointiator with high energy visible light maintained high cell viability and structural stability and thus holds great promises for 3D bioprinting of mesenchymal stem cells for bone tissue engineering applications.

**Introduction**

Intervertebral disc (IVD) degeneration is a major source of pain and disability for patients worldwide, and a significant burden on healthcare providers. Due to the inadequacy of existing treatments, further study of the IVD pathophysiology is required. It is becoming increasingly clear that conventional models, such as animal IVDs and basic in vitro cultures, fail to adequately represent this complex organ. Its heterogeneous composition and response under challenging mechanical conditions cannot be recapitulated in 2D and simple 3D environments, limiting their usefulness in explaining physiological processes. Animal IVDs on the other hand, while available as mature physiological organs, display wide variability, exhibit biological, compositional, and biomechanical interspecies differences, and present a challenge when translating observations towards human benefit.

Bioprinting, with its precise control over the cell microenvironment, offers a promising avenue for the fabrication of better, tissue engineered models. Mimicking the native tissue more closely in structure and function, they could serve as reproducible and representative specimens for further research. Moreover, they could offer unparalleled control over individual parameters, facilitating exploration of disease causality in a manner not possible with mature tissue. Unfortunately, present capacity for producing such an IVD model is limited due to the lack of suitable bioinks. Despite previous ventures, a bioink representative of native tissue in composition, physical properties, and capable of providing the necessary biochemical and mechanical cues has not been reported yet. Taking the first step towards addressing this issue, we focused our efforts on the gel-like nucleus pulposus (NP) in the centre of the IVD and developed bioinks suitable for the fabrication of NP-like structures.

**Experimental Methods**

We developed a dense extracellular matrix-based bioink, composed of a tyramine derivative of hyaluronic acid (THA) combined with unmodified type I collagen. The THA was synthesized via a one-step amidation of the carboxyl groups and combined with collagen at respective concentrations of 30 and 20 mg/ml. Due to the presence of tyramine functional groups, THA possesses double-crosslinking capabilities. An enzymatic crosslinking mechanism, triggered using a combination of hydrogen peroxide ($H_2O_2$, 4 ppm) and horseradish peroxidase (HRP, 0.1 U/ml), allows the preparation of a soft extrudable gel. Following extrusion, the gel can be further strengthened in the presence of the photoinitiator Eosin Y (0.2 mg/ml) with the application of green light. By varying the concentration of $H_2O_2$, the material can be tuned for optimal extrudability. Similarly, the intensity and duration of light exposure can be adjusted for desired final properties.

The bioink was evaluated rheologically. Its gelation behaviour was studied in a continuous oscillatory time sweep as it was crosslinked half an hour using each mechanism. Its strain-dependent response after enzymatic crosslinking was acquired using a sweep from 0.01% to 1000% strain. In an evaluation of the material's ability for elastic recovery, the high-strain conditions inside the printer nozzle and subsequent low-strain conditions after deposition have been simulated on the rheometer by cyclic exposure to intervals of 300% and 0.1% strain. Finally, a frequency sweep from 0.01 Hz to 100 Hz was conducted.

To demonstrate the bioink's printability, simple lattice-based structures were produced using a 27G needle.

**Results and Discussion**

Page 1493 of 2028
Due to its double-crosslinking mechanism, the THA/collagen bioink is a versatile tool for 3D printing. In addition to good initial extrudability, the application of light can increase the storage modulus of the printed gel more than six times, from ~0.7 to 4.6 kPa (Figure 1a). The bioink has demonstrated elastic recovery behaviour in oscillatory rheology, flowing (G'' > G') when subjected to high strains, and recovering its elastic properties when the strain is decreased (G' > G'', Figure 1b). This is corroborated with the decrease in complex viscosity observed when the oscillation frequency is increased (Figure 1c). In an oscillatory strain sweep, the bioink exhibited a transition to a flowing state at approximately 80% strain (Figure 1d).

Conclusion

Our work demonstrates that using modified matrix components, bioinks suitable for the printing of NP-like structures can be developed. The rheological properties achieved fall within the range of values previously reported for healthy human NP5. To our knowledge, this is also the first bioink simultaneously composed of biochemically suitable components representative of the native NP extracellular matrix, and beginning to approach the high concentrations observed in tissue. The presented work brings us a step closer to better, reproducible, and representative 3D printed IVD models, and the promise of new insights into the treatment of disc degeneration.

Self-folding of fibrous scaffolds for blood vessel regeneration

Mairon Trujillo Miranda, Indra Apsite, Leonid Ionov

University of Bayreuth, Professorship Biofabrication, Bayreuth, DE

Introduction
Fabrication of 3D printed scaffolds has lately demonstrated promising results for tissue regeneration of muscle, bone, and nerve. However, the main drawback lies in the poor resolution and limited nutrition achieved for small tubular structures such as blood vessels (d=8-20 µm) [1]. Hence, 4D biofabrication has allowed the fabrication of multi-layer scroll-like structures, by making use of 2D shape-morphing materials, that react upon external stimuli and recreate 3D structures capable to mimic anisotropic structures [2, 3].

Experimental Methods
In our previous studies, polycaprolactone (PCL) was used as part of electrospun bilayers that underwent extra fast actuation [4, 5], allowing fabrication of highly porous tubular scaffolds, that improved cell seeding, growth, and alignment. Despite being biocompatible, bilayers slowly degraded due to high crystallinity of PCL. Therefore, we are presenting the fabrication of electrospun bilayers, comprising highly aligned hydrophobic poly hydroxybutyrate (PHB) fibers and random hydrophilic methacrylated hyaluronic acid (HA-MA) fibers.

Results and Discussion
High fiber alignment was obtained using a high-speed rotating drum collector. Bilayers underwent ultra-fast shape transformation upon contact with different aqueous media, allowing fabrication of conduits with diameter among 2-3 mm. Dynamic mechanical analysis (DMA) showed that in comparison to widely-used PCL, PHB fiber softness allowed mechanical property drop of the bilayer to 10MPa, which is significantly closer to the native blood arteries (2-6 MPa). Fibrous scaffolds depicted good proliferation and viability of endothelial cells (HUVECs) after a week in the culture. High fiber alignment (60-80%) enhanced HUVECs cell orientation in form of a monolayer, mimicking the intima tunica found within the native vessels.

Conclusion
New designed fully biodegradable bilayer system is highly promising for narrow blood vessel formation.

Carvacrol-loaded 3D printed PLA scaffolds to prevent bone-associated infection

Xián Farto-Vaamonde¹, Andrea Muras², Ana Otero², Angel Concheiro¹, Carmen Alvarez-Lorenzo¹

¹ Universidade Santiago de Compostela (USC), Department of Pharmacology, Pharmacy and Pharmaceutical Technology, Santiago de Compostela, ES; ² Universidade Santiago de Compostela (USC), Department of Microbiology, Center of Biological Investigations (CiBUS), Santiago de Compostela, ES

Introduction
Bone is the second most-transplanted tissue worldwide each year. Autologous grafts are the gold standard, followed by donor grafts. However, their limited number and associated risks, along with an increasingly aging population, requires a search for alternatives (1). 3D printing, particularly Fused Filament Fabrication (FFF), has found many applications in tissue engineering and pharmaceutics (2). Scaffolds produced by FFF offers great advantages compared to conventional ones, such as complexes or personalized designs that match patient’s injury, abundant interconnected pores that allow cell migration and colonization, and high mechanical resistance of the constructs. Moreover, biodegradable polymers can be used as the scaffold materials, thus being reabsorbed by the patient’s own body and avoiding a second surgery to remove the implant. However, implantable materials are prone to contamination with microorganisms, which may result in biofilms that can be hardly managed. Carvacrol is a natural compound found in Oregano spp. with antimicrobial activity against bacteria, fungi and yeast. Along its anti-inflammatory properties, carvacrol is a potential candidate to minimize risk infection and aid the healing process on bone injuries (3). The aim of this work was to prepare poly(lactic acid) (PLA) scaffolds by FFF 3D printing and incorporate carvacrol in them as an antimicrobial agent.

Experimental Methods
PLA scaffolds were made with a 3D printer by FFF. Carvacrol was incorporated into scaffolds following two different approaches: (a) Pre-printing load: where the commercial PLA filament was soaked in carvacrol solution and then fed into the 3D printer. Presumably, the obtained scaffolds would contain carvacrol trapped within the polymer matrix; and (b) Post-printing load: where blank scaffolds are first printed and then soaked in a carvacrol solution. Carvacrol would be mainly located on the scaffold surface.
All scaffolds were characterized in terms of reproducibility, morphology, topography, mechanical properties, drug content, release profiles, crystallinity, anti-bacterial activity (planktonic and biofilm) and anti-inflammatory effects.

Results and Discussion
The scaffolds showed good fidelity with the 3D design. Carvacrol was successfully incorporated into scaffolds following the two mentioned strategies. All scaffolds showed good mechanical properties and compressive modulus values in the same magnitude as those of cancellous bone tissue (4). In a compression assay, carvacrol-loaded scaffolds suffered less plastic deformation compared to blank ones (6% vs 12% height reduction). Pre-printing loaded scaffolds showed a small burst of carvacrol in the first hours followed by a sustained release over more than one month, while post-printing loaded scaffolds showed a burst release of carvacrol in the first 48 h. Scaffolds containing higher doses of carvacrol showed anti-bacterial activity against S. aureus and P. aeruginosa, with greater effect on planktonic population.

Conclusion
Although further research is required, carvacrol is a natural and high available promising candidate to be used as antibacterial and anti-inflammatory agent in tissue engineering and regenerative medicine.

Introduction
Development of inks for extrusion-based 3D printing has been a major challenge in the field of tissue engineering¹. Understanding the relationship between physicochemical properties and composition of shear-thinning hydrogels is key for the design of well-defined large-scale and complex printed scaffolds. One solution to achieve better control over final printed structures is the use of double-network hydrogels. Each hydrogel building block contributes a specific function leading to overall materials with enhanced structures and functions. In this work, we explored the development of double-network hydrogel printable inks consisting of shear-thinning Pluronic F127 and selection of chemically-modified polyethylene glycol-based molecules for printing structures with enhanced shape on deposition, withstanding significant stress during the printing process. The outcomes from this study will contribute to the goal of developing high fidelity hydrogels with a multi-functional and stimuli-sensitive magnetic delivery system with precise control via external stimulus.

Experimental Methods
A range of ink formulations were prepared (as shown in figure 1) using Pluronic F127³ and poly(ethylene glycol) with various chemically modified end-groups. The inks were printed using a commercially-available dual-head 3D printer, Allevi-2. The quality of the prints was assessed by imaging the prints using an Olympus BX51 microscope and rheological measurements were performed on a Physica MCR301 rheometer (Anton Paar) in parallel plate geometry.

Results and Discussion
We successfully demonstrate a double-network ink consisting of poly(ethylene glycol)-based polymers with the shear-thinning agent Pluronic F127. A library of hydrogel-ink formulations with tunable viscosity were made by varying the concentrations of the polymers. To optimize the printing approach, we investigated the dependence of rheological properties of the fabricated inks via applied shear rate measurements. These measurements confirmed shear-thinning and recoverability of the inks (as shown in figure 2), suggesting suitability for 3D printing. Finally, by varying printing parameters such as feed rate and pressure and using a high-resolution printing needle with an inner diameter of ~150 µm, we printed complex structures and demonstrated that our double-network inks can provide defined architectures with good print fidelity.

Conclusion
In summary, we developed double-network hydrogel inks comprising shear-thinning Pluronic F127 and selection of chemically-modified polyethylene glycol-based molecules. We demonstrated that (i) the rheological properties of the double-network inks can be changed by varying the concentration of polymers and (ii) identify the relationship between printing parameters and print quality for the inks investigated.

Introduction
Micro-extrusion-based 3D printing of porous and geometrically complex calcium phosphate (CaP) structures can improve bone defects treatment through the production of personalized bone substitutes. However, obtaining sufficient printing and post-printing shape stabilities for the proficient fabrication and application of fast hardening protocols are still a challenge. In this study, the coaxial printing of a self-hardening CaP cement with water-ethanol solvents aiming to increase the ink yield stress following extrusion and the stability of printed structures was investigated.

Experimental Methods
Helicoidal overhang structures were printed with various solvents and video recorded until structural failing, to test how much the use of water-ethanol solvents would influence structure stability. Cylindrical scaffolds were printed and mechanically tested through a compression test 10 minutes after printing, to assess the influence of solvents on early scaffolds properties. A standard and fast steam sterilization process was used as hardening step on the coaxially printed CaP cement (CPC) ink. Compression tests were used on the cylindrical scaffolds after hardening. Micro-CT imaging was done on cylindrical scaffolds following post-processing, to assess the effect of solvents on their internal structure. X-Ray Diffraction analysis was used to evaluate the influence of solvents on crystalline phase composition after post-processing. Additionally, a human mandibular defect model with a theoretical 72 degrees overhang wall was printed with various solvents, and the deviation from this angle was measured following post-processing.

Results and Discussion
The use of aqueous solvents doubled the printing height before structural failing of the helicoidal overhang structures. When mechanically tested 10 minutes after printing, a 2 log increase of the cylindrical scaffolds stiffness was achieved when using aqueous solvents. Following post-processing, the coaxial-printing resulted in cylindrical scaffolds with 4 to 5 times higher compressive moduli in comparison to the extrusion process not involving aqueous solvents. This mechanical performance improvement is likely due to fast CPC setting, preventing the formation of cracks during the hardening process as observed by the micro-CT imaging. Crystalline phase composition measured by X-Ray diffraction after post-processing were similar for the different groups. In the mandibular model, using solvents significantly reduced the angular deviation from the theoretical wall angle after post-processing.

Conclusion
Thus, coaxial micro-extrusion-based 3D printing of a CPC ink with aqueous solvents increases printability and allows using an easily accessible steam sterilization cycle as a standalone post-processing technique to produce 3D printed personalized CaP bone substitutes.
1st step: Coaxial-printing without support structure

- Solvents (% v/v):
  - 50% Water/50% Ethanol
  - 75% Water/25% Ethanol
  - 100% Water

- Effect of solvent addition:
  - Post-printing stability
  - Mechanical properties

- Successful printing of helical/overhanging structures

2nd step: Post-printing hardening process compatible with clinical setting

- Steam sterilization 134°C autoclave cycle
- Hardening: Crystalline phase transformation
- Effect of solvent addition:
  - Mechanical properties
  - Scaffold cracking

- Successful production of a human mandibular defect model

3D-printing technology towards the development of 3D in vitro model of the pancreatic acino-ductal unit

Chiara Tonda-Turo, Viola Sgarminato, Gianluca Ciardelli

Politecnico di Torino, Department of Mechanical and Aerospace Engineering, POLITEOBIOMED LAB, Torino, IT

Introduction

The duct adenocarcinoma evolves from a pancreatic intraepithelial neoplasia whose mechanisms of evolution are well known and documented, while the alterations that give rise to the early lesions remain still unclear\(^1\). The currently most used pancreatic adenocarcinoma models, 3D organoids, represent imperfect reproductions since they do not mimic the native microenvironment which also includes stroma cells\(^2\). This aspect is particularly relevant because, as recent studies have demonstrated, the tumor-stroma interactions play a fundamental role in the progression of adenocarcinoma\(^3,4\). The overall purpose of this project is to overcome the current in vitro model limitations by reproducing the morphology and the composition of the pancreatic acino-ductal unit, composed of specialized cells surrounded by stroma. More specifically, this work involves the use of additive manufacturing technologies to fabricate a 3D exocrine glandular tissue model that mimics in vitro the physiological structure experienced by cells in vivo.

Experimental Methods

The acino-ductal structure was reproduced through a 3D-printing technology (ROKIT InVivo, Rokit, Seul) by extruding polycaprolactone (PCL) in a layer-by-layer manner. The fabrication process was optimized to achieve high pore interconnectivity, accuracy in geometry and precise control of pore size. Particularly, the control of printing parameters such as temperature, pressure, speed, fill density and infill angle, played a key role in the development of the complex exocrine glandular structure\(^5\). A surface functionalization was performed exploiting atmospheric plasma to enhance cell-PCL substrate interaction. Pancreatic stellate cells (PSCs) were cultured for 21 days inside the 3D structures to create a stomal compartment, then pancreatic duct epithelial cells (HPDE normal and KRAS mutation) were seeded on the glandular structure to recapitulate the physiological crosstalk among stoma and epithelium.

Results and Discussion

3D-printed structures morphology was characterized by optical and scanning electron microscopy (SEM). The images demonstrated the effectiveness of the optimization process which led to the formation of a continuous filament, defect-free structures, accurate acino-ductal geometry and highly interconnected pores. Figure 1 shows the pore interconnectivity significantly improves by varying the infill deposition angle from 90° to 45°. The structures obtained by 3D-printing result in a 15x15x3.5 mm cube and the dimensions of acinus and duct diameters are 5 mm and 2.4 mm, respectively (fig.1A). The adhesion, proliferation and growth of PSCs inside the 3D structure were monitored up to 21 days and confirmed by morphological and immunochemical analysis (fig 1B). The effect of the KRAS-mutated epithelial layer on PSCs was monitored and compared to normal condition to identify the hallmark of the early stage pathology. The cellularized final structure will provide a model of human pancreatic duct adenocarcinoma at early stages which will allow to perform genomic analysis and study the physiologic pathways involved in the tumor evolution.

Conclusion

The overall purpose to reproduce the morphology and composition of the pancreatic acino-ductal unit composed of specialized cells surrounded by stroma was achieved by creating an in vitro cellularized pancreatic acino-ductal unit.
This model will serve as a powerful tool to investigate pathological processes such as pancreatic tumors (e.g. Pancreatic Ductal Adenocarcinoma, PDAC).

![Figure 1](image)

Introduction

3D bioprinting is a powerful additive manufacturing technology for tissue engineering applications that allows manufacture of 3D constructs with extraordinary control over the scaffold design1. Bioinks based on natural hydrogels have attracted much attention because of their unique inherent properties similar to the native extracellular matrix (ECM)2. However, their weak mechanical properties usually lead to poor printing quality and low stability of the printed scaffolds. Some strategies based on extrusion printing have been performed to overcome this limitation, such as increasing polymer content or viscosity, but they can compromise cell viability due to the high shear forces and low nutrients transport. The development of low viscosity bioinks and novel strategies for its suitable biofabrication is still in demand. In this work, we present a novel bioprinting methodology based on a dual-syringe system with a static mixing tool that allows in situ crosslinking of a reactive hydrogel in the presence of living cells. Proposed in situ gelation offers several advantages for 3D extrusion printing: it provides the structural integrity necessary to obtain good printing quality, and it allows using low viscosity solutions to avoid applying high shear stress to the encapsulated cells3. Developed bioink is based on a reactive hydrogel system of two polysaccharides that are covalently crosslinked during the printing process. Finally, as a proof of concept, this novel printing approach is used for coprinting of the hydrogel system with catechol functionalized nanoparticles (NP) developed by the group with proven wound healing promoting activities.

Experimental Methods

The reactive hydrogel system used in this work consists of carboxymethyl chitosan (CMCh) and oxidized hyaluronic acid (HAox). Both hydrogel precursors are loaded in two separate syringes and simultaneously extruded into a static mixer by mechanical force (Figure 1A). During the residence time in the static mixer precursors solutions are homogeneously mixed in a 1:1 ratio, the crosslinking reaction begins via Schiff base formation, and a partially crosslinked hydrogel is finally extruded. Gelation times and viscosities were analyzed by rheology in order to optimize bioink formulation. Swelling and degradation of scaffolds were analyzed in vitro and post-printing treatment with FeCl3 was tested to increase stability. Additionally, bioactive catechol functionalized nanoparticles were coprinted within the hydrogel system and NP distribution and release from the scaffold were analyzed. L929 fibroblasts were used for bioprinting of bioink with and without NP, and cell viability, proliferation and immunostaining of the encapsulated cells were investigated.

Results and Discussion

For adequate mixing and proper printing, crosslinking kinetics of the hydrogel has to match the residence time in the mixing tool. Therefore, bioink composition was optimized by adjusting polymers concentrations, ratios, gelation times and viscosity. The final optimized formulation allowed us to print multi-layers grid square scaffolds with good printing accuracy, low deviance from the needle geometry and stable and uniform filaments (Figure 1B). It was observed that the stabilization step with Fe leads to higher long-term stability of the printed scaffolds and moderated swelling. NP did not impair the printing process and good NP distribution and sustained release were revealed. Bioprinted scaffolds showed homogeneous distribution of encapsulated cells and good biocompatibility with cell viability values
around 90-100% after 7 and 14 days of culture while maintaining their shape integrity during the whole period of cell culture (Figure 1C). Cell proliferation within the scaffolds was continuously increasing over the 14 days. Furthermore, metabolic activity of fibroblasts encapsulated into the bioprinted constructs showed that NP loaded constructs supported a more stable cell growth rate than materials without NP.

**Conclusion**

The presented methodology allows successful bioprinting of cell-laden reactive hydrogels with high cell viability. Applicability of this printing approach with a reactive system loaded with bioactive NP was demonstrated with a great potential for wound healing therapies. Furthermore, since printing conditions and type of precursors can be easily modified, this approach offers high versatility and can be adaptable to a wide range of reactive hydrogels for tissue engineering applications.

Introduction
Additive manufacturing using bioinks, comprising cells and biocompatible polymers, is an emerging biofabrication strategy to produce functional tissue models. Despite advancement in building increasingly sophisticated objects, biological and cellular analyses in printed constructs remain challenging and often imply endpoint analyses. Methods that enable non-invasive monitoring of embedded cells in bioprinted constructs would provide further insights on functionality and viability.

Experimental Methods
We implemented Raman imaging for molecular-sensitive investigations on bioprinted objects. Hyperspectral maps were acquired from bioinks followed by multivariate data analysis (MVA). Different aspects such as culture format (2D, 3D-casted, 3D-printed), cell type (endothelial cells, fibroblasts) and the selection of the biopolymer (alginate/NFC, gelatin, alginate/gelatin) were considered and evaluated.

Results and Discussion
Raman imaging allowed for a marker-independent identification and localization of subcellular components against the surrounding biomaterial background. Furthermore, single-cell analysis of spectral signatures, performed by MVA, demonstrated a discrimination of endothelial cells and fibroblasts and identified cellular features influenced by the bioprinting process.

Conclusion
In summary, Raman imaging was successfully established to evaluate bioinks and access cellular information in 3D culture in situ, representing a promising tool for the quality assessment of bioprinted objects.

Introduction
PLLA (Poly L-type Lactic Acid) of thermoplastic is a well-known biodegradable polymer, and already applied to the absorbable surgical sutures and fracture fixation devices. PLLA is also used as ecofriendly plastic filament for the FDM (fused deposition modeling) 3D printing in various engineering field. The other hand, HA (Hydroxy Apatite) is well-known as calcium phosphate ceramics for bone augmentation material with osteoconduction ability. Naturally, by the combination of PLLA and HA, biodegradable composite material was developed and has been applied for clinical medicine.

In order to develop the 3D printing fabrication of HA-PLLA composite implants, HA-PLLA composite filament was made, and small plate implants were fabricated by the 3D printer. Then in-vivo bone tissue reaction was investigated by animal experiment with 3D-\(\mu\)CT.

Experimental Methods
\textbf{Materials:} Spherical HA powder with the average diameter of 15~20\(\mu\)m (Taihei Chemical Industrial Co., Ltd. Japan), PLLA filament with diameter of 1.75mm (Mutoh Industries Ltd. Japan) were used as raw materials. Uniaxial filament extruder (Filabot EX2, USA) and the single head FDM 3D printer with the nozzle diameter of 0.4mm (MF-800, Mutoh Industries Ltd. Japan) were employed for the fabrication of HA-PLLA composite implants. And the slicer software of Slic3r and the control software of Pronterface were used for the 3D printing.

As experimental animal, Dutch rabbits were used to investigate bone tissue reaction to HA-PLLA composite implants. And the corn beam 3D-\(\mu\)CT (Rm-CT2, Rigaku co. Japan) was applied to periodic investigation of the bone tissue reaction.

\textbf{Methods:} PLLA filament was cut into small pellets with the length of approximately 2mm, and mixed with HA powder with splaying 70% alcohol solution. Then the mixture was dried up at 70°C for 24 hours. By means of weight measurement, the HA composition rate was evaluated. HA-PLLA filaments with two different HA composition rate of 10% and 20% were extruded at 185°C with an additional cooling fan and a filament drawer device.

In order to investigate in-vivo bone tissue reaction, based on Dynamic Compression mini plate system for human fingers, a small plate implant with 3 holes was designed as 16mm in length, 5mm in width and 1mm in thickness using the 3D CAD system (123D design, Autodesk Inc. USA). Then the small plate implants were fabricated by the 3D printer using the HA-PLLA composite filaments and pure PLLA filament. In addition, small screws were made of pure PLLA by heated compression molding at 180°C.

Under 3 mixed anesthesia, HA-PLLA composite plate implants were implanted at the medial aspects of proximal tibiae in Dutch rabbits, and were fixed by the pure PLLA screws. As controls, pure PLLA plate implants were also implanted in the same manner. Then 3D-\(\mu\)CT of the proximal tibiae were taken at just after the implantation (0 w), and at 2, 4, 8 and 12 weeks after the implantation. Surrounding bone tissue reaction was investigated by using a medical image processing system (Expert INTAGE, Cybernet Systems Co., Ltd. Japan).

Results and Discussion
By adjustments of extrusion speed, heating temperature and drawing speed, HA-PLLA composite filament with a diameter of 1.75mm could be made without clogged nozzle due to HA particles. The HA-PLLA composite plate implant...
implants were successfully fabricated with a little rough surface due to HA particles. The filament extrusion and 3D printing are very sensitive to the thermal conditions. It is necessary to take into account that HA particles reduce thermal conduction.

Regarding animal experiment, although PLLA is invisible on 3D-μCT, HA-PLLA composite plate implants were barely visible due to HA particles dispersed in PLLA matrix. And new bone formation was observed along to the side wall of the composite implants, then which enlarged according to the postoperative period (Fig.1, Fig.2). Thus the osteoconduction ability of HA particle dispersed in PLLA matrix was demonstrated in this in-vivo experiment. However, volume reduction of the HA-PLLA plate implant was not yet observed at 12 weeks.

**Conclusion**

Taking advantage of the 3D printing technology, HA-PLLA composite small implants were fabricated. And its osteoconduction ability was confirmed by using 3D-μCT in the animal experiments. In order to evaluate the biodegradation and further bone tissue reaction, long term follow-up is in progress.

Development of a Laponite-collagen bioink

Max von Witzleben, Catherine Cortes Vesga, Tilman Ahlfeld, Anne Bernhardt, Michael Gelinsky

Technische Universität Dresden, Carl Gustav Carus Faculty of Medicine, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE

Introduction

Type I collagen is the most abundant structural protein in the human body and is a crucial component of bone extracellular matrix and therefore considered a suitable biomedical material for tissue regeneration. Therefore, the use of collagen in bioinks is highly desirable. Fibrillation of acidic collagen solutions provides an increase of stability, however, additional cross-linking is necessary to achieve sufficient mechanical stability of the printed strands. Conventional bioinks often contain only small amounts of collagen to circumvent cytotoxic side-effects of crosslinking agents like genipin or tannic acid.

Laponite is a nanosilicate and forms, dissolved in water, a shear-thinning liquid. These thickening and shear thinning properties make it interesting as an additive for bioinks, as lower shear forces allow higher cell survival during extrusion plotting. Furthermore, the different degradation products are non-toxic, on the opposite, they may have a positive effect on bone metabolism and its calcification.[1]

In the present study we therefore combined collagen and laponite to manufacture stable bioprinted constructs without using cytotoxic cross-linking agents.

Experimental Methods

Bovine derived collagen type I (GfN, Germany) was purified and lyophilized before being dissolved in acetic acid at various concentrations at 4°C. Laponite was diluted in ddH2O at various concentrations or directly added to the collagen solutions. The pH and the consistency of the multiple mixes were determined at 4°C to narrow down the possible suitable mixtures for bioplotting. These mixtures were then further evaluated with an initial printing test employing a syringe before plotting with a GeSiM Bioplotter 3.1 (GeSiM, Germany) at room temperature. Printing characteristics were analyzed with established filament fusion and filament collapse tests. Therefore, every mixture was prepared at 4°C and directly transferred to the printer. For cellular investigations, immortalized human-mesenchymal stem cells (hTERT-MSCs) were employed. VybrantTM DiI Cell-labeling (Invitrogen, USA) was used as staining and applied prior to the loading of the respective 4°C cold hydrogel with 5x10⁶ cells/g. Therefore, the cells were suspended in 500µl of media and then placed in a 5ml syringe. The mixing was performed with a custom made mixer. Subsequently, three scaffolds per time point were printed with an applied air-pressure of 55kPa and a speed of 15mm/s, each scaffold comprising of 4 layers with 0°/90° grid. After printing, 3ml of media was added to each scaffold for 10min before replacing it with fresh media (3ml). Fluorescent images of the scaffolds were taken with a fluorescent Microscope (BZ-X810, Keyence, Japan) on the days 1, 5, 7 and 14.

Results and Discussion

Laponite gels of different concentrations showed pH values above 10. The collagen solutions had a pH of 3-6 depending on the concentration of acetic acid and collagen concentration. With a mixing ratio of 50:50 wt% of collagen solution and Laponite hydrogel, different mixtures with varying pH could be prepared. Mixtures with pH below 4 and above 8 were highly inhomogeneous. At the same time, the viscosity of the mixtures liquefied significantly compared to the individual components, making it necessary to increase the concentrations of the components. At least 5 mg/ml collagen and 10 mg/ml Laponite were applied. Comparison of the characteristics of filament collapse and filament fusion tests of the individual components clearly showed the accurate printability of the Laponite hydrogel and the inaccurate and collapsing printability of the collagen solution. The 50:50 mixing ratio
was reflected in the printing behavior of the composites; the addition of Laponite improved the shape fidelity of the collagen solution, but the scaffolds collapsed at lower layer numbers (≤15) compared to the pure Laponite gel. The mixture containing 40mg/ml collagen and 100mg/ml Laponite showed the best shape fidelity. Interestingly, after immersing the Laponite/collagen scaffolds in medium, the gel fibrillated in such a fashion that crosslinking became unnecessary. HTERT-MSCs mixed into pastes survived the plotting process. Further, cells revealed distinct proliferation in bioprinted constructs over a cultivation period of 14 days.

Conclusion
Pasty Laponite-collagen gels with different concentrations could be prepared. Depending on the pH value, only a few mixtures were suitable for the printing process. With their good printability in combination with the observed proliferation of printed hTERT-MSCs the investigated mixtures qualify as bioinks.

**Introduction**

In recent years, biofabrication has evolved as a promising and fast-growing field for applications in general life sciences as well as in regenerative medicine. A special interest in the field focuses on hydrogels which combine cell-supportive properties with accurate 3D printability. To facilitate the generation of 3D printed constructs with an adequate shape fidelity, frequently highly concentrated polymeric hydrogels are used as cell supportive matrices. However, the resulting high network density and material stiffness can distinctly negatively affect cell bioactivity and the homogeneous distribution of extracellular matrix (ECM) newly produced by the incorporated cells. Therefore, the aim of this study was the development of a new versatile dual-stage crosslinking approach of a thiolated hyaluronic acid-based bioink, which should not only provide stand-alone 3D printability, but also facilitate chondrogenic differentiation of mesenchymal stromal cells (MSCs) as a model system and homogeneous distribution of newly produced ECM.

**Experimental Methods**

A range of thiolated HA (HA-SH) with different molecular weights was synthesized and all of them were crosslinked in two stages, utilizing adjustable amounts of polyethylene glycol-diacryl (PEG-diacryl) for pre-crosslinking via Michael addition and PEG-diallyl for thiol-ene mediated post-crosslinking after 3D printing (Figure 1A). Printability of ink formulations was empirically examined by extrusion tests at a 3D bioprinter and a mechanical testing machine. The most promising formulations were also rheologically characterized and diffusion studies were performed with FITC-labeled dextrans. Selected ink compositions were used as MSC cell carrier and long-term cell culture over 21 days was performed in 3D printed constructs. Chondrogenic differentiation of MSCs was examined by gene expression analysis and the quantification of newly produced ECM components like glycosaminoglycans (GAGs) and collagens. Differences in ECM distribution were analyzed via histological and immunohistochemical staining as well as histomorphometric quantification. Mechanical testing further validated the cartilaginous quality of the constructs.

**Results and Discussion**

In general, by adjusting HA-SH and PEG-diacryl concentration and molecular weight (M\(_W\)), a wide range of inks could be generated with regard to printability and diffusion properties. MSCs were demonstrated to differentiate chondrogenically in all bioprinted constructs. Bioinks with low M\(_W\) HA-SH (ca. 50 kDa) required a high polymer content for good printability, but resulted in only pericellular ECM distribution and overall weak mechanical properties of the final constructs after chondrogenic differentiation. In contrast, constructs made from high M\(_W\) HA-SH (> 200 kDa), requiring only a low polymer content for 3D printing, exhibited higher GAG and collagen contents, a homogeneous ECM distribution throughout the constructs (Figure 1B and C) and strongly improved stiffness after chondrogenic differentiation.

**Conclusion**
The here presented dual-stage bioink system using a modified biopolymer and two different crosslinkers can serve as an example to design bioink platforms utilizing two independent crosslinking reactions at one functional group, which allows to adjust printability as well as the material and biological properties of the printed bioinks.

Dissecting the effect of bioink material cues on the biological function of bioprinted 3D skin constructs

Rúben F. Pereira1,2,3, Bianca N. Lourenço2,3, Paulo J. Bártolo4, Pedro L. Granja2,3

1 ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, PT; 2 i3S - Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Porto, PT; 3 INEB - Instituto de Engenharia Biomédica, Universidade do Porto, Porto, PT; 4 School of Mechanical, Aerospace and Civil Engineering, University of Manchester, Manchester, GB

Introduction
Bioprinting has been used to generate grafts for skin tissue repair and in vitro 3D tissue models for drug screening and disease modelling through the deposition of cell-laden biomaterial formulations termed as bioinks [1, 2]. Despite the progress in the design of hydrogel bioinks using a wide range of natural and synthetic materials, the bioprinting of 3D constructs resembling the architecture, composition, and function of human tissues and organs is not widespread. A major limitation in the field relies on the lack of data on the required material cues at biophysical and biochemical level necessary for the bioprinting of 3D tissues with biological function [3]. To address this need, herein, we designed a library of dual-crosslinked hydrogel bioinks which biochemical and biophysical properties can be independently modulated in order to unravel the effect of key material cues on the biological function of bioprinted 3D skin constructs.

Experimental Methods
Norbornene-modified pectin [4] was used to generate single-polymer backbone bioinks, which composition and properties were controlled by the incorporation of a cell-adhesion peptide and a cell-degradable peptide crosslinker. Constructs were extrusion bioprinted into 3D shapes with varying levels of complexity using pre-crosslinked bioinks, which rheology was tuned via either calcium- or barium-mediated ionic gelation. Dermal fibroblasts were embedded within pre-crosslinked bioinks with distinct biochemical and biophysical properties, bioprinted and photopolymerized. Cell response was analyzed at day 14 by Live/Dead imaging, cell morphology and proliferation, as well as deposition of extracellular matrix (ECM) components.

Results and Discussion
Pre-crosslinked bioinks formed homogenous and stable filaments (13-15 mM CaCl2; 15-17.5 mM BaCl2), allowing the bioprinting of 3D constructs that supported cell viability in a crosslinking density dependent-manner. Rheological characterization indicated that the yield stress and viscosity of bioinks were dependent on the cation concentration, while a high percentage of recovery ability (85-86%) was obtained upon subjecting the bioinks to regimes of low and high shear rates. Bioprinted fibroblast-laden constructs fabricated with varying levels of matrix stiffness (G′: 294 to 1098 Pa) via exposure to UV light for different time periods exhibited dramatic changes on cell spreading, proliferation and ECM deposition throughout the culture. At day 14 post-printing, dermal constructs prepared from both low and high stiffness bioinks showed cells with an elongated morphology, indicating that the ability of cells to proteolytically remodel the gel network towards spreading is not dictated by the initial hydrogel stiffness. However, a significant reduction on cell proliferation and deposition of collagen-I and fibronectin were observed in stiffer bioinks, showing that the initial stiffness restricts the ability of the cells to produce new ECM regardless of the degradable nature of the gel network.

Conclusion
The design of bioinks with tunable rheological, mechanical and biochemical properties is essential to perform systematic studies to evaluate the effect of material cues on the biological function of bioprinted constructs. Our
results identified the major role of matrix stiffness on the cell response within protease-degradable bioinks, underscoring the effect of material cues on the deposition of key ECM components in bioprinted dermal tissue analogues.

AVOIDING CELL DEATH IN 3D BIOPRINTING- COMPUTATIONAL FLUID DYNAMICS (CFD) SHEAR STRESSES MODELLING INEXTRUSION

Patricia Santos Beato\(^3\), Deepak Kalaskar\(^1\), Ryo Torii\(^2\)

\(^1\) University College London, Department of Surgery and interventional sciences, London, GB; \(^2\) University College London, Department of Mechanical Engineering, London, GB; \(^3\) University College London, Department of Biochemical Engineering, London, GB

Introduction

In vitro tissue modelling is a growing field which is currently being enhanced with new manufacturing techniques such as 3D bioprinting. This revolutionary technique enables the production of complex hierarchical structures while allowing high cell densities encapsulated in bioinks to be deposited in a controlled manner\(^1\). However, it has been shown that high shear stresses produced during the extrusion process can compromise cells' ability to survive\(^2\) and grow\(^3\). Currently, the printing process is optimised by trial & error, which requires large quantities of cells and materials, and time. A more efficient process of printing optimisation, e.g. towards maximum cell survival post printing, is much needed for the further advancement of 3D bioprinting. Computational fluid dynamics (CFD) modelling used to simulate the extrusion process of bioinks under different extrusion pressures, nozzle and needle diameters, is expected to play an important role in the optimisation of the printing process. The aim of this work is to develop a CFD model to establish a quantitative understanding of the association between the extrusion pressure, choice of bioink material, nozzle or needle size, and shear stress within the nozzle/needle.

Experimental Methods

The CFD model was developed using ANSYS Fluent software. The geometrical model of nozzle/needle and the air bodies combined, were made in a 2D axisymmetric manner and subsequently meshed using quadrilateral elements. After mesh sensitivity test, the simulations were conducted using different bioinks – mixtures of xanthan gum and gelatine, and gelMA 5% – to assess the optimum printing conditions for each material. The materials were characterised rheologically to find their viscosity and fitted into the Herschel-Bulkley model, when non-Newtonian, as inputs for the CFD model. The shear stresses generated were analysed in three different nozzle sizes and three needle sizes (22G–410 µm, 25G–250 µm and 27G–200 µm).

Results and Discussion

The results showed the correlation between smaller nozzle sizes and higher shear stresses generated for the same material and extrusion pressure, which was expected. Additionally, a comparison of the maximum shear stresses showed that the xanthan gum-gelatine mixtures generated lower shear stresses (140 Pa) than gelMA (845 Pa) when extruded with the same nozzle diameter and extrusion pressure. Additionally, the flow rate was assessed and compared to experimental gravitational measurements to validate the model. By examining the flow rate and the experimental results, a further correlation between the maximum pressure and maximum printing velocity that can be used without losing filament continuity was found. Although the simulations and experimental validation tests were conducted under acellular condition, the results provide a quantitative indication which can narrow down the number of possible printing parameter combinations towards a low potential cell damage and high printing output.

Conclusion

Ongoing work will be aimed at establishing the potential association between the predicted shear stress and the cell-specific tolerance of shear stress that causes cell damage in experimental printing, which will make this model a strong tool to design 3D bioprinting processes.

**PCL Micro-Dumbbells – A New Class of Polymeric Particles Reveals Morphological Biofunctionality**

**David Sonnleitner**, Gregor Lang, Patrick Pasberg, Natascha Schäfer, Lena Fischer, Ingo Thievessen

1 University Bayreuth, Biopolymer Processing, Bayreuth, DE; 2 University Hospital Würzburg, Institute for Clinical Neurobiology, Würzburg, DE; 3 Friedrich-Alexander-University of Erlangen-Nuremberg, Biophysics Group, Department of Physics, Erlangen, DE

**Introduction**

The semi-crystalline linear aliphatic polyester Poly-ɛ-caprolactone (PCL) is a highly used material in the field of medical devices, tissue engineering and biofabrication due to its relatively low price, mechanical strength and FDA approval [1]. It can be processed into different morphologies, e.g. films, spheres and foams, but also fibers. Creating PCL fibers in the micro-, submicro-, and nanoscale is possible when electrospinning is used as processing technique [2]. The generated fibers can mimic morphological features of the extracellular matrix and are applied mostly as scaffolds for tissue engineering approaches. By precisely balancing out the electrospinning parameters we were able to apply and control for the first time the in-situ fragmentation of the generated fibers to create dumbbell shaped micro fragments from PCL.

**Experimental Methods**

Fiber fragments were created using electrospinning setup with flow rate 1 ml/h, distance 10 cm, voltage difference 5.5 kV. Morphological analysis was performed with scanning electron microscopy. PCL fragments were immersed consecutively in 1,6-Hexanediamine, 1% Glutaraldehyde and finally 2.5 mg/ml collagen solution to create a bioactive coating. Contact angle measurement was used to assess the surface wettability of the coated and uncoated samples. Dry samples of coated and uncoated fiber fragments were investigated with FTIR using the ATR Ge-crystal setup in direct contact mode. All spectra were measured in absorbance mode with atmospheric compensation enabled with a resolution of 4 cm⁻¹ and a sample scan time of 100 scans in the range from 4000-800 cm⁻¹. TdTomato-farnesyl expressing U87 reporter cells were cultured in Minimal Essential Medium supplemented with 10% FCS, 1% Penicillin 50 U ml⁻¹, Streptomycin 50 µg ml⁻¹, 1% 200 mM GlutaMAX, 1% 100 mM sodium pyruvate. Cells were washed with 1x PBS, fixed with 4% PFA/Sucrose for 15 min, following blocking with 5% normal goat serum and 0.1% Triton-X100 for 30 min. Cells were incubated with ActinGreen™ 488 ReadyProbes™ Reagent for 1 h. After three washing steps cells were mounted with Mowiol.

**Results and Discussion**

Increasing the concentration of the PCL spinning dope in the electrospinning process showed the transition from spheres to continuous fibers with an unstable intermediate state. Precise balancing of the parameters and adjustments to the molecular weight of PCL blends enabled us to control the in-situ formation of dumbbell shaped fiber fragments with diameters between 1.5 – 3 mm and an aspect ratio between 10 and 30. These fragments could be successfully separated and coated with collagen to create a more bioactive surface. The procedure was evaluated by SEM, contact angle and FTIR, verifying the successful coating. Cell culture experiments with U87 glioblastoma reporter cells on fragments and continuous fibers showed clustering of round cells in the fiber samples in SEM analysis [3]. Cells seeded on fragments showed a more homogenous distribution over the sample surface and more pronounced spreading [4]. Additional F-actin experiments showed directed growth of cells in close proximity to fragments with strong integrin activity when cells interacted with the rounded ends [5]. For continuous fibers the observed integrin activity was undirected and less pronounced.
Conclusion
In this work, we could for the first time demonstrate and control the formation of dumbbell-like PCL-structures produced by a simple electrospinning setup with a precisely balanced parameter set. Entropy-elasticity combined with the process-induced anisotropic molecular arrangement is hypothesized to be the driving force behind fiber snapping. Based on these findings, MW of PCL was identified to be crucial for the formation of such morphologies and could be applied to control the aspect ratio of fiber fragments. Considering the fact, that such morphologies might be appealing for cells as they display attractive micro-meter-range dimensions, in-vitro testing with U87 glioblastoma cells was performed. To render the surface biofunctional, collagen coating was applied, moreover leading to hydrophilization and thus improved suspendability of the fragments in water. Strikingly, it was shown that particularly the round-shaped ends of dumbbell-like fragments provide highly efficient structures for integrin-based cell adhesion. Considering, that FDA-approved PCL is one of the most widely used biopolymers in the biomedical field and electrospinning is a popular method to process it into fibers, it is highly astonishing, that this has never been shown before for any polymer. Considering, that dumbbell-like structures combine morphological features of spheres and fibers, this new class of polymeric particles will be further explored as e.g. anisotropic filler material in biofabrication and cosmetics as well as in the field of injectables and drug delivery systems.

Introduction

Breast cancer is the most common type of cancer in women. Depending on tumor subtype, cancer therapy can range from classical treatments based on surgery, chemotherapy and radiotherapy, to hormonotherapies, or monoclonal antibodies directed to ERBB2. Despite great advancements achieved for breast cancer treatment, cancer associated mortality is still a public health problem. There is, therefore, a need for further understanding regarding how breast cancer therapies interact with tumor cells, within the niche, to prevent resistance and improve treatment efficiency. Recently, the study of the tumor microenvironment demonstrated that these effects are in part modulated by the surrounding matrix and cellular elements. The most studied were Cancer Associated Fibroblasts (CAF) and Endothelial cells (EC). The first are essential for matrix remodeling and for secreting supporting factors to the tumor, increasing its proliferation and invasiveness. The second leads to vascularization, providing tumor with oxygen and nutrients. However, EC have also been demonstrated relevant during radio-induced oxydative stress, as their ASMase/ceramide mediated apoptosis can lead to survival signals for cancer cells, thus suggesting that this interaction can mitigate radiotherapy efficiency on cancer cells (1).

Studying these mechanisms in a more complex microenvironment is necessary to confirm this hypothesis. \textit{In vivo} models are limited by their poor versatility for microenvironment modulation, especially when considering human cell interactions. To overcome this breach between \textit{in vitro} models and human pathology, biofabrication has emerged in the last ten years as a powerful tool for cancer modeling. Here, we describe a simplified bioprinted breast cancer model containing both cancer and stromal compartments with CAFs and ECs, thus in part recapitulating the complexity of the cancer microenvironment needed for these investigations.

Experimental Methods

\textit{Cell culture} - MDA-MB-231 cells were maintained in DMEM with 10\% Fetal Bovine Serum (FBS). Breast CAFs were maintained as indicated by supplier in MSC-GRO medium. Human Umbilical Vein Endothelial Cells (HUVEC) were extracted and amplified in IMDM medium complemented with 10\% FBS and ECGS. EGM2-MV medium was used for maturation. Primary Human Skin Fibroblasts (HSF) were cultured in DMEM-F12 with 20\% FBS. GFP and mKate fluorescent MDA231 cells and HUVECs, respectively, were obtained using lentiviral vector transduction.

\textit{Gel formulation} - We based this gel on previous work from our group (2). Briefly, we used rat tail collagen methacrylate at 2mg/mL concentration with Hyaluronic Acid methacrylate at 10mg/mL. The gel was functionalized with IKVAV peptide at 1mg/mL concentration. The LAP photoinitiator was used at 0.1\% (w/v). MDA231 cells were diluted at 5M/mL in this gel for the cancer ink. For the stroma ink, we used 5M/mL of HUVECs associated with 5M/mL of CAF or HSF depending on experiments.

\textit{Bioprinting} - We used the RegenHU 3D discovery bioprinter with two-printing head for the different inks, and 400\mu m nozzle. The model was composed of two circular patterns with a cancer core surrounded by stroma, 3.5mm in total diameter.
Analysis - We used confocal imaging and immunohistochemistry for various markers (Ki67, CD31, VE-Cad) to assess for proliferation of cancer cells, maturation of endothelial cells. Quantification was made with image analysis software (FIJI and Imaris). Statistics were processed on Graphpad.

Results and Discussion
We first demonstrated a 24h post-printing viability of at least 80%, confirming that the printing process enables the creation of a viable 3D model. To improve our ink functionality, and cancer cell proliferation, we tested the impact of a laminin-derived peptide grafting. We observed a significant 2-fold increase in MDA231 metabolic activity with IKVAV peptide, at 1mg/mL, while YIGSR peptide did not show any difference, consistently with literature. We then assessed the effect of CAF/HSF and EC coculture on MDA231 proliferation. We observed a significant increase of proliferation by adding stromal elements. We then exposed our models to 5-15Gy to mimic radiotherapy, and observed a decreased in tumor size over time. Studies are currently underway to further characterize radiotherapy. Future studies will focus on how stromal elements affect the efficiency of radiotherapy.

Conclusion
Here, we describe our model successfully modeling breast cancer and its local microenvironment. Our model demonstrates to be consistent with current literature regarding the effect of microenvironment, and its ability to respond to radiotherapy. We intend to use this model to further characterize ceramide-mediated interactions, during treatment-induced oxidative stress, to further understand these complex mechanisms within the breast cancer microenvironment. We envisage the use of patient derived cancer cells to assess our model's ability to mimic patient's specific response to treatment.

Ion-doped bioactive glass electrospun fibers for wound healing applications

Liliana Liverani, Theresa Reiter, Kai Zheng, Aldo R. Boccaccini

University of Erlangen-Nuremberg, Institute of Biomaterials, Erlangen, DE

Introduction
The successful treatment of chronic wounds has been the aim of several researches in the last years. In particular, the electrospinning technique has been exploited for the fabrication of advanced wound dressing and wound healing constructs, which support and improve the healing process. Bioactive glass particles can be incorporated in polymeric electrospun fibers to enhance the functionalities of those fibers addressing specific applications [1]. Besides the fabrication of those composite fibers, the combined use of the sol-gel and electrospinning methods to obtain bioactive glass fibers has been already reported and allows the fabrication of bioactive glass electrospun 3D cotton-like mats [2]. This approach has been used in the present work to fabricate copper-doped bioactive glass 3D fibrous constructs for wound healing application.

Experimental Methods
Tetraethylorthosilicate (TEOS), calcium nitrate tetrahydrate and copper nitrate hemi(pentahydrate) were used to prepare the sol for the electrospinning. A commercial electrospinning setup (Starter kit, Linari Engineering srl) was used for the fabrication of the 3D mats. The process parameters were optimized and kept in the following range: 10-15 kV, flow rate 0.4-0.6 mL/h, needle-collector distance 10-12 cm. The influence of the relative humidity was investigated since it is the main factor for the obtainment of 2D or 3D mats. The fabricated fibers were characterized from morphological (SEM), chemical (EDX, FT-IR) and biological point of views. Moreover, bioactivity assessment, by immersion in simulated body fluid solution, was performed.

Results and Discussion
The optimization of the parameters allows the identification of the suitable range and related thresholds for the fabrication of 3D mats with all the tested compositions. The average fiber diameter was comprised between 1-1.5 microns for all the compositions. All the compositions showed bioactivity, but the presence of copper delayed the formation of hydroxycarbonate apatite. Biological assays did not show significant differences between the different compositions and demonstrated that all the fibers were not cytotoxic.

Conclusion
The successful fabrication of ion-doped bioactive electrospun fibers was obtained and the presence of copper was not affecting the electrospinnability and the cytocompatibility of the bioactive glass fibers. An optimization of the electrospinning process was required for each composition, to identify the proper parameters which allowed the fabrication of 3D mats. Therefore, it is possible to extend this approach to several complex compositions, but the conditions for the electrospinnability must be considered and optimized.

3D printed Pluronic/PVA/Chitosan/Gelatin dressing for potential healing of chronic wounds

Ioanna Koumentakou¹, Zoe Terzopoulou¹, Anna Michopoulou², Dimitrios Bikiaris¹

¹ Aristotle University of Thessaloniki, Chemistry, Laboratory of Polymer Chemistry and Technology, Department of Chemistry, Thessaloniki, GR; ² Biohellenika Biotechnology Company, Thessaloniki, GR

Introduction
The skin is the largest organ of the body, accounting for about 15% of the total body weight in adults. Surgeries, traumas, abrasions, burns and other factors which cause cutaneous wounds require effective treatment to prevent morbidity or mortality. Wound healing is an intricate process and wound dressings form a significant segment of wound care management.

3D printing technique has shown great potential assisting and promoting the wound healing process. 3D printing facilitates the production of more flexible matrices, possessing well defined architecture and physical orientation. A wide range of biocompatible synthetic and natural polymeric hydrogels have been used for the fabrication of 3D printed dressings.

In this study, a 3D printed hydrogel based on chitosan (CS), gelatin (Gel) and poly (vinyl alcohol) (PVA) was developed for wound dressing application. CS is a naturally derived polymer, non-toxic and biodegradable. It promotes the proliferation of osteoblasts and mesenchymal cells, while it also presents antimicrobial and hemostatic properties. Gelatin was selected to improve the printability of chitosan and the tissue repair capacity of dressing due to its cell adhesion, migration, and proliferation ability. The hydrogel was reinforced with nontoxic, biodegradable, and biocompatible synthetic polymer PVA to improve the mechanical properties of the dressings.

Experimental Methods
Different ratios of CS, Gel and PVA powder were dissolved at 60 °C under magnetic stirring in acetic acid solution until complete homogenization. The mixture was then transferred to 3D printing syringes, which were centrifuged and cooled to room temperature (25 °C) to form the gel structure. The printability of hydrogels was studied, changing the parameters of 3D printer (needle size, pressure and temperature). The material which presented the optimal printability was used to fabricate dressings with different porosity. The 3D printed porous patches were cross-linked using ammonia gas, NaOH/EtOH and KOH solutions for 15 and 60 min to improve the stability of samples. The dressings dried for 24 h in an oven (30 °C) and their physicochemical properties were investigated.

Results and Discussion
Five hydrogels with different ratios of CS, PVA and Gel were synthesized and tested for their printability. The sample with 3 CS % (w/v), 3 PVA% (w/v) and 2 Gel % (w/v) presented the best printing capacity and was thus selected for the crosslinking process (Figure 1).

The successful synthesis of hydrogels was confirmed by FTIR spectroscopy, and their crystallinity was studied by XRD. Moreover, the water swelling, and stability capacity were studied before and after the cross-linking process, proving that the main impact of the cross-linkers was to increase the stability, and at the same time decrease the swelling ability of patches.

Conclusion
The combination of the 3D printed porous structures and the chemical composition of films aid cell attachment and migration which allow better tissue regeneration after injury

Introduction
Using additive manufacturing to create 3D-printed organs could reduce organ transplant shortage saving many lives on waiting lists. In this project, a tissue engineering approach is introduced combining fused filament fabrication (FFF) 3D printing with melt electrospinning [1]. Scaffolds made by this technique integrate nonwoven scaffolds with high porosity made by absorbable polymers with adjusted degradation profiles within more rigid supporting structures to build microenvironments for organoids with additive manufacturing methods. The surface of the electrospun scaffolds can be modified with ECM components to support adhesion and to potentially enable biochemical stimulation via creating niche microenvironments. In 2007, a milestone in regenerative medicine was achieved by creating induced pluripotent stem cells (iPSCs) from human adult somatic cells, fibroblasts [2]. Retroviral vectors were used to express the reprogramming factors Oct4, Sox2, c-Myc, and Klf4 in the cells for the reprogramming of the cells into iPSCs. These cells provide great opportunities to treat many disorders [3]. In contrast to embryonic stem cells (ESCs), the generation of iPSCs from somatic cells, their generation and application avoid ethical concerns. Building macrostructural containments and cell support structures within a single FFF 3D printing session can be one step towards manufacturing organ-like structures that can be populated with different iPSC-derived cells.

Experimental Methods
Filaments of poly-ε-caprolactone PCL (ITV Denkendorf Productservice GmbH) have been produced for FFF printing with 1.75 mm diameter. An FFF 3D printing machine (German RepRap X350pro) was modified with a high voltage electrostatic source (Eltex KNH34) and an electrostatic target as a printing bed. In this approach, PCL filament was extruded through a printing nozzle and the melt jet was established with an acceleration voltage enabling the manufacturing of fibers in the lower micrometer-scale that are deposited as nonwoven scaffold. The same extruder is used for building up complex support architectures. The melt-electrospun PCL scaffolds were characterized by SEM imaging (Hitachi TM1000) and statistically evaluated by directional-diameter-analysis (MAVIfiber2d, ITFM). First seeding experiments were performed with iPSC-derived hepatoblast precursor cells, which were differentiated into hepatoblasts on the vitronectin-coated scaffolds. After finishing hepatoblast differentiation on the scaffolds, the attachment of the cells, spreading, and proliferation were evaluated by fluorescence microscopy using ActinRed staining, which visualized the cytoskeleton. To further characterize the hepatoblasts seeded on the scaffolds, cells were stained with alpha-fetoprotein (AFP) specific antibody.

Results and Discussion
Cell culture plate inserts for 12-well plates have been 3D-printed with PCL filament containing electro-spun nonwoven as porous membranes for cell seeding (Figure 1 a + b). In Figure 1 c, a SEM picture is showing the structure of the nonwoven membrane. A printing nozzle with a diameter of 0.15 mm and an accelerating voltage of 15 kV was used. A mean-fiber-diameter was measured with 10.8 µm (distribution from 1 to 18 µm). The thickness of the membrane scaffold is about 300 µm.

First seeding experiments with iPSC-derived hepatoblast progenitor cells showed an efficient adhesion and proliferation on the scaffolds. The coating of the scaffolds with vitronectin further enhanced the adhesion of the cells. The coated scaffolds were seeded with hepatoblast precursors which were then differentiated into hepatoblasts.
on the scaffolds. Hepatoblasts attached and proliferated very well (Figure 2A). Furthermore, the coating increased the cell-cell contacts. Successful differentiation of the hepatoblast precursors into hepatoblasts could be demonstrated on the scaffolds by the expression of AFP (Figure 2B).

Conclusion
In this study, it was demonstrated that the fabrication of melt electrospun PCL fibers is possible using an FFF 3D printing process that combines additive manufacturing of supporting structures with the production of nonwoven cell culture scaffolds in a highly automated process. Using this technology, we produced new scaffolds within a cell culture insert by melt-electrospinning of PCL filament in a standard FFF 3D printing machine. These scaffolds were successfully seeded with hepatoblast precursor cells that could be differentiated into hepatoblasts. Furthermore, we demonstrated uniformly covered fiber surfaces in this first study. This may be a step towards additive manufacturing of the shelf support structures for organoids, which can be seeded with iPSCs for the cultivation of patient-specific hepatocytes to perform drug testing, cell modifications and analysis for the development of improved therapeutic approaches.

The response of human gingival fibroblasts, keratinocytes and macrophages to Ti surfaces pre-incubated with whole blood

William A. Lackington, Lada Fleyshman, Yvonne Elbs-Glatz, Stefanie Guimond, Katharina Maniura, Markus Rottmar

Swiss Federal Laboratories for Materials Science and Technology (Empa), Biointerfaces Lab, St. Gallen, CH

Introduction
Classical in vitro testing platforms for implantable biomaterials offer limited predictability of clinical performance, which presents a major challenge in implant development. While classical platforms facilitate the study of biomaterial-tissue interfaces using relevant cell types, the importance of the first interaction a biomaterial encounters in vivo, that with whole human blood, is often neglected. In the context of titanium (Ti) implant soft tissue integration, for dental applications, the aim of this study was to assess how the blood-biomaterial interaction influences the tissue healing response.

Experimental Methods
Clinically available Ti implant surfaces (machined, SLA, and SLActive) were used to study the response of relevant soft tissue cells (human gingival fibroblasts, gingival keratinocytes and macrophages), with and without a pre-incubation step in whole human blood. Ti surfaces properties were characterized using contact angle measurements, to determine wettability, and atomic force microscopy, to determine surfaces roughness. Cell attachment was assessed by staining samples with F-actin and counterstaining using DAPI, and imaged using confocal laser scanning microscopy. Scanning electron microscopy was also used to assess cell attachment and morphology on Ti surfaces. Metabolic activity of cells on different surfaces was evaluated using a prestoBlue assay. Enzyme linked immunosorbent assays were performed to determine the levels of TNFα, IL-6 and IL-8 produced in response to the different surfaces, and cytokine levels were normalized to DNA quantity in each sample using a dsDNA picogreen assay.

Results and Discussion
Findings show that, depending on their surface properties, including roughness (Sₐ), contact angle and micro/nanostructures, distinct fibrin networks formed on the Ti surfaces after incubation with blood. Generally, across all cell types, pre-incubation of the Ti surfaces with blood led to enhanced attachment, metabolic activity, proliferation and matrix production. Fig. 1 shows distinct human gingival fibroblast morphologies developing only 24 hours after coming into contact with Ti SLActive surfaces in the presence and absence of a pre-incubation step with whole human blood. Ti surface properties were a key determinant of inflammatory marker (TNFα, IL-6 and IL-8) production by macrophages and pre-incubation of the Ti surfaces with blood led to significant changes in their relative amounts.

Conclusion
Collectively, these findings indicate that while material surface properties play a large role in determining the tissue healing response, the interaction between a biomaterial and whole human blood can significantly alter this response. In conclusion, this study highlights that blood-biomaterial interaction should be taken into account during implant development.

In vitro degradation testing of hydrogels – concept and case study of gellan gum degradation in water

Christine Gering, Jenny Parraga, Minna Kellomäki

Tampere University, Faculty of Medicine and Health Technology, Tampere, FI

Introduction
Over the past two decades, hydrogels have become an indispensable tool for cell culture and regenerative medicine, in part due to their swelling and degradation capabilities. Degradable hydrogels present the advantage of improved biocompatibility and flexibility concerning the diffusion and stability properties. The testing of hydrogel degradation in vitro before its targeted application is required but the evaluation methods are precarious. One of the main obstacles is the manipulation of very soft hydrogels. The samples are often very delicate and measured parameter such as mass may be problematic to determine.

Several strategies to determine mass loss of hydrogels exist, including weighing the wet mass using closed containers, and lyophilization to determine dry mass [1]. Common issues in the experimental setup include errors being introduced by handling and touching the samples, as well as remaining incubation media that is difficult to separate from the gel. Here, we propose a degradation testing setup using a holder for the hydrogel sample and present degradation test results using gellan gum-based hydrogels. As a simple concept study, we incubate hydrogels samples in ultra-pure water and monitor weight change over 24h. Our demands for the method are: 1. the hydrogels are fully surrounded by the incubation medium; 2. it is possible to remove excess liquid; and 3. the sample can be moved without harming.

Gellan gum (GG) is an anionic polysaccharide that easily forms self-supporting hydrogels in the presence of cations, and has been investigated as artificial cell matrix and other tissue engineering applications [2] We have further investigated the modification of GG for extrusion-based applications, and are using an oxidized gellan gum (GGox), prepared using sodium iodate reaction, where a portion of the rhamnose sugars in the structure have been opened and carry aldehyde groups [3].

Experimental Methods
For the testing setup, so-called 'mesh ring holders' were assembled using laser cut polyacrylate rings (ø 18.5 mm, ring width 1.8 mm, height 1.8 mm) with bonded nylon mesh. The cylindrical cast hydrogel [3] was demolded directly on top of the holder (Fig. 1B), so that a sample can then be moved by exclusively manipulating the holder rather than the soft sample. Weights of the holders have to be determined beforehand. The holder with sample is then placed into the incubation chamber on top of the sample stage, which is moved downwards (Fig. 1A). Finally, then media is added carefully and the chamber is closed with a rubber stopper.

In order to weigh the sample at a time point, the steps are reversed: The media is carefully removed with a pipette and the sample stage is moved upward so that the mesh ring can be taken. The excess media is removed by carefully blotting the ring and mesh with a swab (Fig. 1C).

Hydrogel samples of native GG and GGox (both 1% w/v) prepared with spermidine trihydrochloride (SPD, 2 and 10 mM respectively) in volume ratio of 5:1, were cast to a mold and incubated overnight [3] The samples (n=5) were placed on top of the holders as described above and 2.5 mL of ultra-pure water were filled to the chamber. The samples were weighed at 1, 2, 4, 6, 8 and 24h, and fresh water was re-filled after every measurement. The weight of the mesh holder was subtracted from ach measurement and the weight change was calculated according to:

%change = (wet weight – original weight)/(original weight)

Results and Discussion
Using the method outlined above, we observed GG-based hydrogels incubated in ultra-pure water over one day. The weight changes of the immersed hydrogels are shown in Fig. 2 and the respective mass gain and loss can be tracked easily from the continuously monitored samples. Native GG samples disintegrate, and mass loss happens swiftly after a very brief swelling phase. At high polymer concentration (1% w/v) the crosslinking and blending with ionic crosslinker may be hindered by the high viscosity of GG, and thus the integrity of the samples is poorer overall. These hydrogels were especially difficult to handle, as the samples degraded to small pieces very quickly within the observation period. However, due to the pieces remaining on the mesh holder the mass loss could be monitored regardless. In comparison, GGox hydrogels show prolonged swelling period, and mass loss only slowly begins after 24 hours. Likely, the aldehydes present in GGox form a Schiff-base pair with primary amines of SPD [4]. The higher stability and prolonged swelling phase of GGox-SPD gels can thus be understood to stem from these hydrogels having a combination of physical and chemical crosslinking [3].

**Conclusion**

In conclusion, we have presented a successful technical improvement for the tracking of hydrogel degradation by assessing the mass loss. We have shown preliminary results on GG-based hydrogels in water. In the future, this method can be adapted to also track degradation products in the media, as well the visual shrinkage or swelling of each sample.

Phenomenological ex-situ tracking of pitting corrosion and the mechanical integrity of a WE43 magnesium alloy

Kerstin van Gaalen¹, Felix Gremse³, Felix Benn⁴, Peter E. McHugh¹, Alexander Kopp², Ted J. Vaughan¹

¹ National University of Ireland Galway, Biomechanics Research Centre (BMEC), Biomedical Engineering, School of Engineering, Galway, IE; ² Meotec GmbH, Aachen, DE; ³ RWTH Aachen University, Department of Experimental Molecular Imaging, Aachen, DE; ⁴ Queens University Belfast, School of Mechanical and Aerospace Engineering, Belfast, GB

Introduction
Magnesium and its alloys show great potential as biodegradable alternatives to permanent metallic orthopaedic implants. However, they tend to undergo pitting-based corrosion when implanted into the body, which causes significant challenges in predicting the mechanical stability of an implant during fracture healing and degradation [1]. The objective of this study is the development of a three-dimensional automated detection framework that systematically evaluates the severity and phenomenology of pitting corrosion. With these data, first correlations are drawn to the mechanical integrity data

Experimental Methods
Cylindrical tensile test specimens were manufactured from a Magnesium WE43MEO alloy rod containing rare earths (Mg-Y-Nd, Meotec GmbH, Germany). Immersion testing (Figure 1(a)) in simulated body fluid (SBF) was performed for 28 days with weekly time points (Three samples per time step). Hydrogen gas measurement was tracked, which is linked to mass loss [2,3]. Following immersion, micro-computed tomography scanning (Skyscan 1272, Bruker, Belgium) and tensile tests (ZwickRoell GmbH & Co. KG, Germany) were conducted. Only the magnesium core was segmented since it is assumed to be the load-bearing part (Imalytics Preclinical Software, Gremse-IT GmbH, Germany). For the automated pit tracking, an algorithm was developed to track pit formation in every cross-section (Figure 1(c)) and another algorithm reconstructs the complete gauge length of a dog bone with the spatial pit identification (Figure 1(d)). The process chain was developed in python by using OpenCV for the automated image recognition.

This framework outputs measures of pitting corrosion on the specimen surface, including pit density, pit size, pit depth, and pitting factor ASTM G46-94 [4]. Linear and exponential correlations were established between several pit features and the ultimate tensile strength (UTS).

Results and Discussion
For the examined WE43 alloy, a three-fold higher corrosion rate via volume loss tracking through µCT scanning was detected than the determined one over the hydrogen evolution (2 mm/year vs. 6.5 mm/year). Tensile tests show a steady drop of the ultimate tensile strength with an increase in mass loss. In general, the suggested factors in ASTM G46-94 show a poorer correlation to the mechanical integrity than other (Figure 2). Further our results show that over time single pits merge into larger pits together. Our data set show the best correlation between the smallest tracked Magnesium core width and the remaining mechanical strength. The weakest was found for the pitting factor.

Conclusion
The presented tool automatically outputs standardised measures of pit features of circular-shaped specimens. In terms of mechanical strength, there are better pit features than the one described in ASTM G46-94 for a WE43 alloy. All factors related to the reduction of the cross-sectional area show a better correlation to UTS. Further, the pit tracking shows that small pits are formed early within the corrosion process, which eventually merge into one another
over time to form larger and deeper pits that are more harmful to load-bearing capacity. It should be noted that further testing is necessary to underline the determined correlations here.

Fabrication of highly tuned Calcium phosphate/silk sericin composites: exploring new pathways on skin regeneration

Anabela Veiga1,2, Filipa Castro2, Rui Magalhães1, Fernando Rocha2, Ana L. Oliveira1

1 Centro de Biotecnologia e Química Fina, Porto, PT; 2 laboratory for Process Engineering, Environment, Biotechnology and Energy, Porto, PT

Introduction

Calcium phosphates (CaPs) are well established materials for bone tissue engineering. However, new possibilities arise for this “old” bioceramic. Recent studies are focusing on reinventing CaPs for skin tissue engineering [1]. Calcium has demonstrated to play an important role in the barrier function repair and skin homeostasis and serves as a modulator in cell proliferation and differentiation. In this context, the combination of CaPs with biopolymers to promote skin tissue regeneration becomes an attractive strategy, providing appropriate microenvironments for cell interaction. Recently, we have proposed -nano and – micro CaP/sericin (SS) composites as suitable candidates for tissue engineering approaches [2]. Silk SS, until recently considered unfit for biomedical use, it is now accepted as a valuable byproduct from the textile industry, able to stimulate collagen production and to elicit an antioxidant, moisturizing and anti-inflammatory effect [3].

The effectiveness of cell attachment on CaP composite particles highly depends on their physicochemical characteristics which in turn is directly depending on the processing strategy. Continuous flow regimes operated through Oscillatory flow reactors (OFRs), improve particle mixing and mass transfer processes in multiphase systems, generating a product with uniform and controlled characteristics [4],[5]. Moreover, they allow scale-up without compromising the chemical composition. In the present work, we propose, for the first time, fully controlled CaP and CaP/SS particles for skin regeneration, through a continuous coprecipitation process, using a specifically designed modular oscillatory flow plate reactor (MOPR) (WO/2017/175207). For this, the influence of the oscillation amplitude (x0) and frequency (f), residence time (τ) and initial reagents concentration were investigated on the final CaP physicochemical properties and in vitro behavior using human dermal fibroblasts (HDFs).

Experimental Methods

CaPs synthesis was carried out by mixing equal volumes of a solution of CaCl2.2H2O (Merck, 99.5%) and a solution of Na2HPO4 (Sigma-Aldrich, 99.0%) into the MOPR, using a peristaltic pump (Longer Pump, BT100-2J). SS was obtained using extraction in boiling water from cocoons of the Bombyx mori silkworm and added to the calcium precursor solution. Coprecipitation was carried out by a continuous process in a MOPR, at 37ºC. Several experimental conditions were studied with different x0, f, τ and initial reagents concentration were investigated on the final CaP physicochemical properties and in vitro behavior using human dermal fibroblasts (HDFs).

Results and Discussion
FTIR spectra of the synthetized products evidenced a typical apatite structure similar to commercial hydroxyapatite, with the exception of condition 10 where brushite peaks were identified. SEM show aggregated nano/micro particles (1-10^-2 µm) with low crystallinity that adopt a rod and plate-like shape. Uniform and aggregated nanoparticles were only obtained in condition 7. While for the f of 6 and 1.9Hz the increase in $x_0$ seems to be associated with the increase of plate-shaped particles, for the intermediate f this effect is not evident. In fact, at 4Hz there seem to be larger HAp particles surrounded by smaller particles. In condition 11, which corresponds to 5 times increase in the initial concentration of reagents, it is possible to observe large particles, in the form of well-defined and crystalline shapes. Regarding the addition of SS, the particles have a homogeneous appearance, appearing to be surrounded by a structure that could be the protein matrix. Particles with the most distinct characteristics (4,7,10,11) were selected for further analysis in cell culture. Preliminary results using MTT assay showed that all conditions studied promote cell viability.

**Conclusion**

For the first time, a study was carried out on synthesis of CaPs and on the influence of different parameters of OFRs continuous production on the final characteristics of CaPs and CaPs/SS composites. With the tested parameters it was possible to obtain particles with different physicochemical properties. In addition, preliminary *in vitro* tests on these materials show their potential as biomaterials for skin tissue.

Introduction
One of the six most important world problems is health care. As a solution for healthy problems bioactive glasses (BG) are used in several applications, such as bone injuries and healing, cancer metastases, or wound injuries (ex. after burning) \cite{1}.

In the last 40 years, the Bioglass invented by Prof. Larry Hench \cite{2}, was modified for achieving different properties such as porosity, biocompatibility, and stability. Besides the mentioned properties, other specific properties were also achieved such as antibacterial or the cell viability character of BG. By introducing the Ag nanoparticles into the glass matrices, antibacterial behavior resulted \cite{3}, while gold nanoparticles help for achieving the cell viability character \cite{4}.

In our previous work, silver-iodide \cite{5} was used to eliminate the formation of AgCl from the Ag nanoparticles in simulated body fluid. Moreover, in another of our work, differently shaped gold nanoparticle \cite{4} was added into the BG matrix, for achieving the best cell viability.

Therefore, the aim of this work was to combine these two methods in order to achieve both antibacterial and cell viability character in only one bioactive glasses composite.

Experimental Methods
Spherical gold nanocages were synthesized with the galvanic replacement method until AgI was synthesized with the solvothermal method. The BG with Agl and gold content were synthesized by involving two methods: (1) the spherical gold nanocages and Agl microcrystals were introduced in sol one after another (BG-Agl+AuNPs), (2) Agl-Au composites were synthesized via impregnation method and added into the sol (BG-AglAu).

The as-obtained materials were characterized using UV-Vis spectrophotometer (JASCO-V650), X-ray photoelectron spectroscope (SPECS PHOIBOS 150 MCD system), transmission/scanning electron microscope (Philips CM 10 and Hitachi S-4700 microscope), and X-ray diffractometer (Shimadzu XRD 6000). Antibacterial behavior of the composites was analyzed by Pseudomonas aeruginosa and Staphylococcus aureus bacterial and their cell viability was analyzed on Human keratinocytes (HaCaT, Cell Line Service, Germany) cells.

Results and Discussion
The spherical gold nanocages contain a small amount of AgNPs that remain after galvanic replacement reaction \cite{4}. After heat treatment of the glass samples, the gold nanocages become gold nanospheres with a diameter between 11 and 25 nm, and the Agl transforms to calcium iodate and AgNPs. All obtained samples exhibited antibacterial effect against Pseudomonas aeruginosa and Staphylococcus aureus bacteria. The better results were obtained for the BG-Agl+AuNPs. The viability of HaCaT cells indicated a good in vitro tolerance for all investigated samples. The better proliferation rate of HaCaT cells was obtained in presence of BG-Agl+AuNPs.

Conclusion
We have successfully added simultaneously Au nanocages and AgI microcrystals in BG matrix. The obtained composites showed an increase in antibacterial character and in cell viability behavior than the previously obtained composites.

Reaction-diffusion models to predict Hydrogel viscoelastic properties

Nicole Guazzelli, Ludovica Cacopardo, Arti Ahluwalia

University of Pisa, Centro di ricerca E.Piaggio, Pisa, IT

Introduction

Hydrogels’ viscoelastic behaviour is strongly related to liquid molecules’ interaction with the solid network. Despite having been used to simulate chemical and transport phenomena in gels (e.g. reaction, diffusion, and hindered convection), most mathematical models lack correlation with gel viscoelastic properties (e.g., relaxation time, \( \tau \)) or do not provide experimental validations [1, 2]. Therefore, in this study, reaction-diffusion models were implemented to investigate how the presence of different dextran concentrations in the aqueous phase affect liquid molecules diffusion in agarose hydrogels and how these variations can be correlated with experimental relaxation times [3].

Experimental Methods

Agarose-dextran hydrogels were prepared by dissolving 0.5% w/v agarose in different dextran solutions (0, 2, 5% w/v). The viscoelastic parameters (relaxation time \( \tau \), equilibrium modulus \( E_{eq} \), and instantaneous modulus \( E_{inst} \) ) were derived according to the procedure described in [3]. As shown in Fig.1, agarose gels were modelled as a homogenous porous medium and an aqueous phase. Moreover, dextran is considered as a spherical agglomerate that moves in the interstices of the gel together with the free water. A Reaction-Diffusion (RD) Equation (1) was implemented in Matlab R2015 and used to describe the complessive hydrogel behaviour:

\[
\frac{\partial c}{\partial t} - \nabla \cdot (D_i \nabla c) + k_r c = 0
\]  

(1)

The water-dextran binding rate \( k_r \) was estimated using viscosity curves measured as a function of temperature (Brookfield viscometer). The measurements were performed during the process of gelation of the different agarose-dextran solutions.

To consider the hydrodynamic interaction between matrix fibres and diffusing macromolecules, the Brinkman Effective medium equation (2) was implemented to evaluate the diffusion coefficient of the different species in the system [3]:

\[
D_i = \left[1 + (R H_i^2) k_i^4 \right]^{-1/2} + (1/3) \left[(R H_i^2) k_i^4 \right]^{-1} \times \text{D}_0
\]  

(2)

where \( D_0 \) is the diffusion coefficient described by the Stokes-Einstein equation, \( R H_i \) is the hydrodynamic radius of the species, and \( k_i \) is the hydrogel permeability estimated by the Carman-Kozeny equation [2].

A 3D finite element model (FEM) was used to estimate the \( R H_i \) of the dextran molecules, using Comsol 5.3 and including \( E_{eq}, E_{inst} \) and \( \tau \) in the material properties of the domain. The model parameters were optimised on the base of experimental diffusion curves, which were obtained using fluorescein isothiocyanate (FITC)-conjugated dextran (Fig 2c-d).

Results and Discussion

The model showed that, as the dextran concentration increases, the diffusion time of the liquid phase decreases (Fig.2a), reflecting the relaxation time trend shown in Fig.2b.

The results of the Reaction-Diffusion model highlighted the influence of the dextran in weakening the bonds between water and agarose, with a consequent decrease of the steric hindrance and a faster flow through the hydrogel pores. Therefore, although liquid phase viscosity increases with increasing dextran concentration [2], it contributes to reducing the resistance to flow preventing the formation of water-agarose bonds.

Conclusion

Page 1544 of 2028
The proposed Reaction-diffusion model can describe the interaction of the liquid molecules with the solid network; this interaction can be modulated by altering the liquid phase composition and the chemical affinity for the polymeric chains. The RD model can be used to 'predict' the bulk viscoelastic behaviour of the hydrogels, according to their composition. In the future, different materials can be investigated for altering both solid and liquid phase properties, providing a useful tool for the design of engineered viscoelastic hydrogels.

Osteoblastic cell response to an additively manufactured zirconium-based bulk metallic glass

Lisa Larsson1, Jithin James Marattukalam2, Björgvin Hjörvarsson2, Natalia Ferraz3, Cecilia Persson1

1 Uppsala University, Department of Materials Science and Engineering, Applied Materials Science, Uppsala, SE; 2 Uppsala University, Department of Physics, Materials Physics, Uppsala, SE; 3 Uppsala University, Department of Materials Science and Engineering, Nanotechnology and Functional Materials, Uppsala, SE

Introduction
Zr-based bulk metallic glasses (BMGs) with disordered atomic structure have shown high strength, a relatively low Young’s modulus, excellent corrosion resistance and promising biocompatibility [1] [2]. The combination of these unique properties makes the Zr-based BMGs potential candidates for orthopaedic applications, particularly for load-bearing implants. Furthermore, advanced manufacturing techniques of BMGs, such as additive manufacturing (AM) by laser beam powder bed fusion (LB-PBF), provides an effective way to bypass critical casting thickness constraints associated with conventional BMG manufacturing techniques, thereby allowing fabrication of components with almost any desired size and geometry, particularly interesting for the medical industry [3]. A very limited amount of studies has however explored the biocompatibility of newly developed systems of zirconium-based BMGs destined for LB-PBF, and the influence of the process parameters on the biocompatibility of the final built material is seldom reported. The aim of the present study was to investigate the in vitro cell response to a LB-PBF Zr-based BMG, namely Zr59.3Cu28.8Al10.4Nb1.5 (trade name AMLOY-ZR01), and to study the effect of surface roughness, resulting from process parameter variation, on the cell response and ion release of the built material.

Experimental Methods
The as-printed samples were manufactured using an EOS M100 machine with a step size of 20 W laser power within an optimal processing window (55 W, 75 W and 95 W). By changing the laser power during the AM process, the average surface roughness (Sa) of the samples was varied. The as-printed materials were characterized in terms of degree of crystallinity, surface roughness and morphology, followed by a systematic investigation of the response of the MC3T3-E1 pre-osteoblastic cell line to the different surface roughness of the as-printed samples. The ability of the materials to promote cell proliferation was evaluated by culturing the cells on the surface of the material’s discs up to 7 days. The number of adherent cells at the different time points was evaluated by measuring the activity of the intracellular enzyme lactate dehydrogenase (LDH) in the cell lysates. Cell attachment and cell viability at the different time points were assessed qualitatively by live/dead staining of the attached cells, followed by fluorescence microscopy imaging. The cell morphology was evaluated by SEM imaging of the samples after 1, 3 and 7 days of cell proliferation. To evaluate the effect of the materials on cell differentiation, cells were cultured on the material discs under differentiation conditions and the cell response in terms of the activity of the early osteogenic marker alkaline phosphatase (ALP) was evaluated. Ion release experiments of the materials were performed in cell culture medium under physiological (pH 7.5) and inflammatory (with reactive oxygen species and acidic pH) test conditions and the ion release was quantified using inductively coupled plasma - optical emission spectrometry (ICP-OES).

Results and Discussion
Material characterisation confirmed the as-printed BMGs to be X-ray amorphous with a decrease in Sa with increasing laser power during printing (varying from 11 µm to 4 µm). The surface quality was further confirmed through SEM observations, where fewer defects and porosities were observed at higher laser power during printing. The biocompatibility evaluation indicated that the AMLOY-ZR01 substrates supported cell proliferation and differentiation of the pre-osteoblastic cells MC3T3-E1, while no difference in cell response was observed when...
comparing the different surface roughnesses (Fig 1). Moreover, the cell behaviour on the BMG alloy was comparable to the results obtained with the reference material Ti6Al4V, a commonly used and well accepted biomaterial. The promising cell response to AMLOY-ZR01 is in accordance with previous biocompatibility studies on Zr-based BMGs [4], [5], demonstrating that the additively manufactured AMLOY-ZR01 alloy is a good contender among other BMGs. When comparing the ion release rates found for the different AMLOY-ZR01 materials, no clear trend between the degree of surface roughness and ion release rate was found. However, the ion release experiments showed a large increase in ion release under inflammatory conditions as compared to regular physiological conditions, indicating that future studies should investigate the response of the osteoblastic cells when the cell-material interactions take place in an environment where high levels of ions are expected to be released from the alloy.

Conclusion
The findings in this work reveal a promising biological response to the AMLOY-ZR01 alloy, with potential for orthopaedic applications. It also highlights the need of future studies where the cell response is evaluated under conditions of elevated ion release from the alloy surface, i.e. under inflammatory conditions.

Experimental mechanical study of human abdominal aortic tissue with various pathologies

Anna Lipovka¹, Daniil Parshin¹, Andrey Karpenko¹,²

¹ Novosibirsk State University, Novosibirsk, RU; ² Meshalkin National Medical Research Center, Vascular and Hybrid Surgery Center, Novosibirsk, RU

Introduction
The aorta is the largest vessel in the human circulatory system, which plays the most important role in the process of blood supply to all organs and tissues. Any lesions of the aorta lead to serious consequences and even death. When the aorta ruptures due to damage to its wall, the probability of death reaches 90%, even with emergency hospitalization and surgery. The main cause of aortic rupture is an aneurysm, which most often occurs in the abdominal aorta. The risk of rupture in the presence of an aneurysm can be aggravated by concomitant cardiovascular diseases - stenosis, atherosclerosis, which cause pathological changes in the walls of the vessel, leading to a deterioration in the elastic properties of tissues and its gradual degradation.

Experimental Methods
The aim of this work is an experimental study of the mechanical properties of aortic tissues with aneurysms and concomitant pathologies. For this purpose, we used aortic tissue (Fig. 1) excised during cardiac surgery at the Meshalkin National Medical Research Center. Under conditions that ensure the best preservation of the mechanical properties of these vessels, the aortic samples are transported to the laboratory of the Lavrentyev Institute of Hydrodynamics and Science of the Siberian Branch of the Russian Academy of Sciences, where experiments are performed. Before the experiment the obtained tissue is cut into several specimen, paying attention, if possible, to the direction of the bloodflow. After that the parameters of the specimen are measured and it is placed in the uniaxial tensile machine INSTRON 5944 (Fig. 2).

Results and Discussion
The obtained results were processed, the strain-stress diagrams plotted for each experiment. Such data as ultimate stress and strain, as well as Young's modulus were identified for each type of pathology, and statistically analysed.

Conclusion
In the future it is planned to widen the variety of specimens to improve the quality of analysis. Also this work will be combined with the results of aortic wall insicion, revealing the pre-existing stress in the tissue. In prospect, these results can be used for preoperative modeling.

Effects of unconventional setting conditions on the mechanical strength of alpha tricalcium phosphate bone cement

Adelia Kashimbetova¹, Karel Slámečka¹, Mariano Casas-Luna¹, Carolina Oliver-Urrutia¹, Simona Ravaszová², Karel Dvořák², Ladislav Čelko¹, Edgar B. Montufar¹

¹ Brno University of Technology, Central European Institute of Technology, Brno, CZ; ² Brno University of Technology, Faculty of Civil Engineering, Brno, CZ; ³ Brno University of Technology, Central European Institute of Technology, Brno, CZ

Introduction
Calcium phosphate cements (CPCs) are constantly being studied to improve and find new formulations with better properties, as well as to explore new processing routes for pre-set blocks, granules and scaffolds, including additive manufacturing approaches. Traditionally, to mimic the physiological temperature the setting of CPCs is performed at 37 °C, but the processing of pre-set bodies is not restricted to such condition, and other conditions may be used to improve the mechanical strength and reduce the processing time. The aim of this work was to study the effects of the setting temperature and particle size on the mechanical strength of a monocomponent CPC and correlate the results with the microstructure and reaction percentage. Mechanical tests were performed in small and big samples to elucidate the effect of sample size. Moreover, some samples were mixed with gelatine solution to mimic the hybrid composition of natural bone, and the effect of gelatine crosslinking on the mechanical strength was studied in dry and wet state. Gelatine was selected because it has been demonstrated to be a versatile additive in CPCs.

Experimental Methods
The cement consisted of alpha tricalcium phosphate (α-TCP) powder, with 3 different particle sizes (F < 32 µm; M 32-45 µm; C > 45 µm), and aqueous solution of 2.5 % Na₂HPO₄, mixed at a liquid to powder (L/P) ratio of 0.37 ml/g.

The samples were allowed to set in water at 4, 22, 37, 60 and 90 °C for 10 days. Additional samples were mixed with 10 % gelatine solution at L/P ratio of 0.60 ml/g, crosslinked with glutaraldehyde and set in water at 37 °C for 10 days. Compression test was performed in dry state at a constant crosshead speed of 1 mm/min. The small samples were cylinders with diameter of 6 mm and a height of 12 mm, whereas the big samples had a diameter of 20 mm and a height of 20 mm. Some samples prepared with crosslinked gelatine were also tested in wet state. The crystalline phases and reaction percentage were determined by XRD and Rietveld analysis. The microstructure was analysed by SEM, nitrogen adsorption and porosity determination.

Results and Discussion
The set cements consisted mainly of hydroxyapatite and unreacted α-TCP. The reaction percentage increased with increasing the reaction temperature from 4 to 37 °C, then the conversion was nearly constant at temperature up to 60 °C. Above this temperature a second but slight increment of the reaction percentage was observed (Fig. 1a). The fine powder achieved clearly higher reaction percentage than the medium and coarse powders at the same temperature. The microstructure showed the entangled network of hydroxyapatite crystals with different crystal morphology and size depending on the setting temperature and powder size. Plate-like crystals that grew with temperature were observed at setting temperature between 22 and 37 °C, whereas needle-like crystals, the size of which decreased with temperature, were observed at 60 and 90 °C (Fig. 1b). Differences in porosity within a 6 % range were found in spite of cements were mixed at the same L/P ratio. The compressive strength increased with temperature up to a maximum and then decreased (Fig. 1c). The increment of the powder size decreased the compressive strength and shifted the maximum strength towards higher setting temperature. The fine powder and the reaction temperature of 37 °C resulted in the strongest material. Other trends observed are that the compressive
strength decreased with the increase in the size of the samples, increased 4.7 fold when the gelatine was added and crosslinked, and decreased 2.7 fold when the crosslinked sample was tested in wet state.

**Conclusion**

The setting temperature had an important effect on the compressive strength, conversion, microstructure, and porosity of CPCs. The fine powder resulted in higher conversion and the strongest cements set at lower temperature. Further increase in setting temperature led to the decrease in the compressive strength due to the change of crystals morphology.

Data extraction using text mining methods on polydioxanone literature

Carla V. Fuenteslópez¹, Austin McKitrick², Javier Corvi³, Maria-Pau Ginebrà², Osnat Hakimi³,⁴

¹ University of Oxford, Institute of Biomedical Engineering, Oxford, GB; ² Universitat Politècnica de Catalunya, Department of Material Science and Engineering, Barcelona, ES; ³ Barcelona Supercomputing Center (BSC), Barcelona, ES; ⁴ Universitat Internacional de Catalunya, Faculty of Medicine and Health Sciences, Barcelona, ES

Introduction

Information extraction is fundamental to scientific research, however, when done manually, it is extremely time-consuming and often comprises re-work. Alternatively, automated data extraction renders up-to-date, quick, and easy access to information. Nevertheless, there is little precedence of using automated text mining tools to extract information in the biomaterials domain[1].

Here, we compared the ability of contemporary text mining tools to extract useful information from biomaterials abstracts exported from PubMed. As a topic, we selected ‘polydioxanone’ which, despite being a widely-used biomedical material, has a relatively limited available literature, thus enabling manual validation of results.

Experimental Methods

First, we filtered abstracts using a machine learning classifier, training a Support Vector Machine algorithm on a previously-published biomaterials collection[2]. Following corpus definition and classification, we compared various information extraction tools, including the open access annotation tool PubTator[3]; MeSH tagging; an unsupervised topic discovery algorithm (hLDA); text analysis methods using R; and the Biomaterials Annotator, an open-access annotation system of biomaterials, implants and medical devices.

Results and Discussion

Results were analysed in conjunction with a manual review of the literature and existing systematic reviews. Our findings show that automated text mining tools can be useful for mapping the biomaterials literature. In the case of polydioxanone, biodegradation and biocompatibility are predominant terms across all tools. Moreover, our analysis revealed that different tools reveal diverse aspects of the polydioxanone literature. Text analysis makes it easier to follow the evolution and frequency of specific term usage - ‘scaffold’ and ‘repair’ are increasingly used, ‘suture’ and ‘graft’ decrease, and ‘stent’ remains relatively steady (Figure 1). Analysis of MeSH tags permits the identification of major topics and shows unified term usage, making it possible, for example, to identify substances commonly used alongside polydioxanone like polyglactin 910 and collagen. Topic mining allows cluster identification based on similarity of topics between publications and helps cluster dominant areas, this suggests that there are bundles of abstracts related to, possibly, infection following wound site closure (Topic 3) or orbital fracture repair (Topic 15) (Figure 2). PubTator annotates well both species (e.g., humans, rabbits, rats) and diseases, including adverse effects (e.g., infection, fibrosis, cancer). Finally, the Biomaterials Annotator pre-organises identified terms in categories, making it possible to identify, for instance, manufactured objects such as stents or clips.

The information offered by these tools provides a wider albeit less detailed insight of the literature compared with that reported by systematic reviews, which tend to focus on the safety and performance of polydioxanone. Information extraction tools yield more updated information on biomaterials and do so in less time, making them more efficient. This suggests that there is a need for information extraction tools that provide more detailed information.

We also observe a change in term usage trend, possibly associated with topics that become more or less popular over time. The term ‘suture’ exemplifies this change - during the first few years, it dominated the polydioxanone literature, but as polydioxanone became more relevant and therefore had a more widespread use in other
manufactured object’s production, sutures became less predominant. When comparing pre- and post-2010 term usage, we can observe an increased use in terms such as ‘drug’ and ‘safety’, which could suggest the inclusion of a therapeutics as an application for biomaterials, while ‘degradation’ and ‘biocompatibility’ decrease, possibly attributed to the migration of the research focus away from characterisation and compatibility of the material. On the other hand, we noted some specific challenges to indexing polymer-related literature. For example, naming is heterogeneous, and abbreviations are extremely versatile. Only one of the tools (MeSH indexing) displayed unified term usage. The lack of uniformity in term usage makes it more difficult for researchers to identify all the articles published on a specific topic, therefore emphasizing the need for indexing tools and controlled vocabularies, for example for polymer names.

**Conclusion**

Here, we compare different text mining tools, as well as systematic reviews, by using a topic with a relatively limited literature - polydioxanone. While the text mining tools provide a broader overview of the literature and do so in a significantly shorter time, the information they provide is less detailed and some term ambiguity occurs. Also, most of the tools used in this study required some degree of user proficiency, limiting their everyday use by bench side scientists. This highlights the need for field-specific and user-friendly tools.

Introduction
Despite bone’s innate self-renewal capability, some periodontal pathologic and traumatic defects’ size inhibits full spontaneous regeneration. The current research characterizes a 3D porous biodegradable nano-hydroxyapatite/chitosan (nHAp/CS, 70/30) scaffold for bone regeneration, which is prepared through a simple 3 step process: dispersion preparation, freeze-drying and supercritical CO₂ (scCO₂) solvent extraction and sterilization, resulting in a cost-effective and environment-friendly ready-to-use graft biomaterial [1].

Experimental Methods
Full in vitro characterization of the nHAp/CS scaffold was performed comparing with a CS control scaffold. Its microstructure was scanned by micro-CT, the bioactivity in simulated body fluid (SBF) was assessed using scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) elemental analysis. The biodegradation and compressive strength in PBS with and without physiologic levels of lysozyme was evaluated by dynamic mechanical analysis (DMA) for 28 days. The biomaterials innate antimicrobial abilities against Gram positive (S. aureus) and Gram negative (E. coli) bacteria were compared by CFU counts and sessile/planktonic bacteria metabolic activity. The cytotoxicity of the scaffolds leachables after 1 and 24 hours was evaluated using MG63 osteoblastic cell culture through MTT (ISO 10993-5:2009) and live/dead assays. The proliferation of MG63 cells seeded for 21 days within the porous structure of both materials was assessed by their metabolic activity (Alamar blue assay) and DNA quantification. Cells morphology and distribution were observed by SEM and laser scanning confocal microscopy (LSCM).

A pilot in vivo study was performed with CBA nude mice to evaluate the materials’ biodegradation and biocompatibility when subcutaneously implanted in the animals’ dorso. The animals were euthanized at 3 and 5 weeks and histological samples were stained with hematoxylin-eosin (HE) and Masson’s trichrome (MT) stains.

Results and Discussion
The nHAp/CS scaffold microstructure has interconnected pores and a total porosity of 70%, enabling cell migration, growth and diffusion of nutrients, oxygen and metabolites [2]. SEM revealed HAp crystals forming on the surface of the nHAp/CS scaffold after 21 days in SBF, showing its bioactivity in vitro (Fig. 1). The presence of nHAp promoted a significantly lower biodegradation rate when compared to the CS scaffold [3], though the addition of lysozyme to PBS did affect the results. DMA analysis showed that both scaffolds have viscoelastic properties, but the presence of nHAp significantly enhanced the storage modulus (E') under compression after the frequency scan (0.1 to 15 Hz). At 10 Hz (high frequency), the E’ of the nHAp/CS scaffold was 42.34 ± 6.09 MPa after 28 days of incubation in PBS (no significant difference was observed with or without lysozyme), showing that it may support bone ingrowth at low-load bearing bone defects [2]. Both nHAp/CS and CS scaffolds significantly inhibited the growth, attachment and colony formation abilities of S. aureus and E. coli (with a stronger effect on S. aureus), enhancing the relevance of...
chitosan in the grafts' composition for the naturally contaminated oral environment. Leachables from both types of scaffolds did not show cytotoxicity, with the cells' viability ranging from 86 to 124% depending on the leaching conditions. MG63 cells showed normal morphology in SEM and LSCM images, and could adhere and proliferate inside the biomaterials' porous structure [4], especially for the nHAp/CS scaffold, reaching higher proliferative rate at day 14.

The in vivo subcutaneous implantation of both scaffold types did not induce acute inflammatory response. The histological analysis showed an outer thin fibrous capsule with disorganized connective tissue and a few monocytes. Between the 3rd and the 5th week, intensive and progressive ingrowth of new vessels and collagen fibers within the porous structures were observed, especially for the nHAp/CS scaffold (Fig. 2) [5].

**Conclusion**

So far, the nHAp/CS ready-to-use scaffold showed microstructural, chemical and mechanical features making it a suitable bone graft alternative for defect sites in an adverse environment as in periodontal disease. It showed higher biocompatibility in vitro and in an ectopic in vivo model. In the near future we shall evaluate the nHAp/CS potential to support human mesenquimal stem cells proliferation and differentiation, osteoclast and endothelial cells behavior in vitro. Finally, the nHAp/CS bone regenerative properties will be assessed in vivo in rats in calvaria critical defects.

Introduction

Biomaterials based on bioactive glass with gold nanoparticle composites have many applications in tissue engineering due to their tissue regeneration and angiogenesis capacities [1]. This paper outlines a new approach to extending the biomaterials biological properties, composites of biopolymers-bioactive glass with gold nanospheres (AuSP) / spherical gold nanocages (AuIND) in bone tissue engineering. To further obtain data; the composites were tested in vivo, in a bone experimental defect in Sprague Dawley rats. Within the framework of these criteria we also tried to evaluate the biomaterials performance, in vivo, in canine species, a pilot study of TTA procedure.

Experimental Methods

The glasses with gold nanoparticles (gold nanospheres/spherical gold nanocages) content were synthesized by sol-gel method [2]. The alginate-pullulan-bioactive glass with gold nanoparticles (Alg-Pll-BGAuSP, Alg-Pll-BGAuIND) composites were obtained by cross-linking method [2]. The composites were analyzed using FT-IR spectroscopy and transmission electron microscope (TEM).

Experimental bone defects (3 mm wide and 2 mm depth) were performed on 60 rats (2 defects/animal) [3]. The defects were filled with biomaterials (90) or left as control/sham defects (30). Bone tissue samples were harvested at 2, 4 and 8 weeks postsurgical for histopathological and immunohistochemical evaluation.

An 11-months-year-old Kangal was presented with CCL rupture, second degree patellar luxation and moderate stifle osteoarthritis. During TTA Rapid fixation (4), lateralization of the tibial tuberosity was performed in order to correct patellar luxation and a glass-polimer-gold-nanoparticle composite was added in the osteotomy defect in order to accelerate bone healing.

Results and Discussion

The FT-IR spectroscopy measurements were demonstrated the cross-linking between the biopolymers and glasses. The TEM measurements indicate that in the glass samples the diameter of the AuSP was around 25 nm, and the AuIND between 11 and 25 nm.

At 30 days, the histopathological analysis showed osotoblastic proliferation alongside neoangiogenesis concerning both compounds containing gold nanoparticles. The in vivo results, also demonstrated that the Alg-Pll-AuIND had a significant influence on mesenchymal cell proliferation, neoangiogenesis, osteoblast differentiation (BMP2 and osteocalcin immunopositivity) and new bone formation, compared to Alg-Pll-AuSP and hydroxiapatite composite, particularly at 8 weeks.

Clinical and radiological follow-up was performed 30-days after surgery. The dog had excellent clinical outcome (lameness scoring=0) and complete bone healing. The TTA-Rapid gap was filled with bone and no progression of the osteoarthritis was observed.

Conclusion
Overall, these results offer compelling evidence that the newly developed biomaterials have the potential to provide a one-step treatment for further bone regeneration techniques, offering surgical complementary aid, while enhancing bone healing.

Introduction
The purpose of this in vitro study was to determine the metal-ceramic bond strength between dental porcelain and cobalt-chromium (Co-Cr) metal substrates fabricated by different techniques.

Experimental Methods
Forty Co-Cr metal substrates were fabricated according to ISO 9693-1, by casting, milling, soft milling, and direct metal laser sintering. Forty additional substrates were fabricated for each technique to record the modulus of elasticity. A commercially available feldspathic porcelain was placed on the substrates, and then the specimens were also tested for metal-ceramic bond strength with the 3-point bend test, according to ISO 9693-1. The fractured specimens were observed with optical and scanning electron microscopy using electron dispersive spectroscopy to define the mode of failure. X-ray diffraction spectroscopy was conducted to determine changes in crystalline phases after fabrication and the 3-point bend test. Statistical analysis was with 1-way analysis of variance and the Tukey post hoc test ($\alpha=0.05$).

Results and Discussion
No statistically significant differences were found for modulus of elasticity among any of the groups. The metal-ceramic bond strength for casting had no statistically significant differences and the mode of failure in all groups was cohesive. The metallographic analysis of the as-received, the after porcelain firing, and the after 3-point bend test specimens revealed changes in microstructure. The crystallographic microstructure revealed that the patterns had minor changes among the groups.

Conclusion
The study revealed that all of the techniques showed similar results. The modulus of elasticity and metal-ceramic bond strengths presented no statistically significant differences, and the mode of failure was cohesive.

Acknowledgement
Special thanks to Mr A. Chatzipmatzakis for his contribution in the fabrication of the metal ceramic specimens. Also many thanks for the contribution in SEM analysis to Mr P. Tsakiridis and Mrs E. Gomoza.

Introduction
The global acceptance of *Danio rerio*, commonly known as zebrafish, as a modern experimental animal model is increasing gradually. This model is becoming popular in the fields of toxicology and biomedical research during both adult and embryonic stages. The reason for this extensive recognition is due to advantages respect to conventional animal models like a small size, very high reproducibility, quick development, transparency of the embryo and close homology with the human genome, including the immunogenic responses. Furthermore, costs are much lower, reducing space, animal maintenance, tested materials and even experimentation time, making it in a quick, cheap, and facile model to assess toxicity of nanomaterials [1,3].

The robust zebrafish model allows the biocompatibility assessment of a wide array of nanomaterials, facilitating a rapid pre-clinical development of novel biomaterials. Among them, graphene oxide has attracted strong interest for biomedical applications due to its unique 2D structure and exceptional physico-chemical properties. Moreover, it has been shown that graphene oxide exhibits antimicrobial properties [2,5] and even osteogenic regenerative activity, which combined with other materials can become an excellent nanomaterial for the manufacture of different biomedical devices [4].

The purpose of this work is to investigate the biocompatibility of commercial graphene oxide (GO) nanoflakes on larvae zebrafish (*Danio rerio*) as *in vivo* testing model.

Experimental Methods
The percentage survival of 2 days post-fertilization (dpf) zebrafish larvae was evaluated by exposition to different concentrations of GO by bath. Inflammatory response of 3 dpf larvae was performed by microinjection of GO at a concentration of 0.1 mg/mL into the duct of Cuvier. It was performed using a transgenic zebrafish line that specifically marks neutrophils with green fluorescent protein, Tg(mpx:GFP), and the total count of neutrophils and those migrated to the area of the microinjection were counted at different times post-treatment (2 and 24 h) using the ImageJ Software. Also the expression of the pro-inflammatory genes TNFα and IL-1β and tp53 was also assessed by qPCR, 24 hours after the microinjection.

Results and Discussion
The results indicate that the *in vivo* zebrafish model served to confirm the biocompatibility of graphene oxide at 0.1 mg/mL. No significant changes were found in the survival rate compared to the control (Figure 1). Also, there was no amplification of the inflammatory response compared to the control as no increase in the expression of inflammatory genes was recorded. This also prevented an increase in neutrophils (Figure 2) or migration into the micro-injected area.

Conclusion
It can be concluded that commercial graphene oxide (GO) nanoflakes up to 0.1 mg/mL concentration is biocompatible, using *in vivo* testing zebrafish model.

Reactive Accelerated Aging Test, A Time Machine to Evaluate the Durability of Biomaterials for Neural Implants

Blanca Limones-Ahijón, José Miguel García-Martín, María Ujue González, Sahba Mobini

Centro Superior de Investigaciones Científicas, Instituto de Micro y Nanotecnología, Tres Cantos (Madrid), ES

Introduction
Neural implants are increasingly investigated to assist patients with defects or pathologies in nervous system. There is a growing research about developing new biomaterials to improve the effectiveness and biocompatibility of neural implants. For example, inflammatory responses to implantation of these devices, also called foreign body reactions (FBR), are still a challenge for their performance. During FBR, immune cells such as monocytes and macrophages are recruited and activated, leading to several consequences. One of those is the increased amount of reactive oxygen species (ROS) due to differentiation and phagocytosis of macrophages. ROS affects the performance of neural implants in the long-term by increasing corrosion and delamination. Reactive accelerated aging tests (RAAT) are used as a tool to test the durability of bioelectrodes and neural implants, mimicking the presence of ROS in vivo. In RAAT, an H₂O₂ solution with high temperature can mimic several years of implantation during a few weeks due to the increased reaction rate provided by temperature. A RAAT protocol for testing neural implants has been recently approved by FDA.

In this work, we have built a RAAT setup based on this protocol. We have studied different parameters that affect the stability of the system and we have employed RAAT to analyse the durability of different flat and nanostructured metallic layers.

Experimental Methods
The sketch of the RAAT setup is depicted in Fig. 1. The reaction chamber consists of a 750ml solution of H₂O₂ in phosphate-buffered saline (PBS) with a concentration in the range of 10-20 mM. The solution is placed in a double walled jacketed bottle (reaction chamber), kept at constant temperature of 85°C using a water bath. To compensate the H₂O₂ decay, small volumes of highly concentrated (750 mM) hydrogen peroxide are periodically introduced in the chamber using a peristaltic pump controlled by a timer. The excess volume is removed by a second pump programmed by a timer.

To check the concentration of H₂O₂, samples were taken from reaction chamber and tested by means of a classic colorimetric test using titanium (IV) oxyxsulfate sulfuric acid and measuring the absorbance at 410 nm.

To understand the role of the different parameters in RAAT setup, a MATLAB code was developed to calculate the H₂O₂ concentration evolution in the reaction chamber with time.

Results and Discussion
From the different parameters that influence the concentration in the reaction chamber, we found out that the most relevant parameter is the hydrogen peroxide decay time or half-life time (t₁/₂), as it can be seen in the calculation shown in Fig. 2 A and 2B. This t₁/₂ value determines the needed delivery volume of highly concentrated H₂O₂ solution (V_in) to keep the reaction chamber concentration within the desired range. Moreover, for a fixed V_in, the steady state values of concentration reached by the system are determined by t₁/₂. We therefore measured this decay time for H₂O₂ at 85 ºC and obtained a value of 123 min. With this decay time, introducing 1.5 ml of the reservoir each 15 min and collecting the excess volume (V_out) each 4 hours is enough to keep the concentration in the 10-20 mM range (Fig 2B).

Due to the high reaction temperature, there may be small evaporation losses of the solution. We plot in Fig. 2C the influence of a mismatch between delivery and removed excess volumes. According to this, V_in and V_out should be...
equal to reach a stable concentration value: therefore, the losses should be considered and compensated. Moreover, an additional observation was that the initial concentration of the solution has a very small effect on the reached steady state of concentration. This value depends only on the delivery and removed excess volumes (Fig 2D). It is important to remark that the concentration value always fluctuates in a range of at least 2 mM due to delivery and decay time cycles (Fig. 2D, inset).

Finally, we observed that the introduction of implants to be tested could influence the stability of the solution concentration. Once any discrepancies or variations in \(V_{in}\) and \(V_{out}\) were discarded, we attributed this effect to modifications of \(t_{1/2}\) for the degradation of hydrogen peroxide, associated with some catalytic effect of the implant materials (samples introduced in RAAT setup).

**Conclusion**

RAAT is a useful testing method for the durability of materials within a short time, however the different parameters in the setup need to be carefully monitored and adjusted for obtaining stable and reliable results. In general, system destabilizations can be fixed by modification of pump rates and controlling the mismatch between the input and output, as we showed in our MATLAB model. However, we observed unforeseen changes in the decay time of hydrogen peroxide that could be due to the effect of biomaterials on \(H_2O_2\). To solve this problem further in-depth studies are needed.

Design optimization of the mechanical heart valve for a pediatric heart assist pump – RH-PED

Przemysław Kurtyka¹,², Roman Kustosz¹, Artur Kapis¹

¹ Foundation of Cardiac Surgery Development, Artificial Heart Laboratory, Zabrze, PL; ² Silesian University of Technology, Faculty of Biomedical Engineering, Zabrze, PL

Introduction
Mechanical Circulatory Support (MCS) including the Ventricular Assist Devices (VAD) is currently considered to be the most reliable and effective treatment for patients with advanced heart failure (HF). Many new pump constructions have been recently presented. However the clinical experience has provided information that despite many undeniable benefits, VAD constructions still require improvement to minimize the risk of complications. Although the present trend of development of the mechanical circulatory support systems tends towards continuous flow [CF] centrifugal blood pumps, the extracorporeal pulsatile blood pumps are still successfully used. In addition to more physiological flow, the pump due to its placement outside of the body does not require a lot of space in the chest. Therefore, pulsatile blood pumps more often are designed especially for children, due to the increase in the incidence of heart failure in this group. The number of children with heart failure and qualification for transplantation is steadily increasing, the waiting time is usually long and the mortality while waiting for a transplant is high. In Europe, 130-200 operations of this type are carried out annually. In Poland, from 1998 to 2016, a total of 87 heart transplants were performed in group of children. Polish pediatric prostheses are currently at the stage of preclinical research using the sheep model. However the prostheses have undergone laboratory tests and have demonstrated their functionality and safety. Polish pediatric prostheses have treatment options proven in the use of POLVAD heart prostheses still in use for adults.

Experimental Methods
On the basis of the project implemented in 2012-2015, the construction of a family of Polish pediatric heart prostheses (RH-PED) was developed and a preliminary evaluation of the prototype design was performed in laboratory and during experimental tests on animals. Based on the risk analysis of the prototype pediatric system, the design and manufacturing technology of the final sterile clinical product were optimized. In the project four pump constructions were developed and differed in stroke volume: 45ml, 30ml, 20ml, 12ml. Each design required the development of new inflow valves and the optimization of commercially available outflow valves. The optimization of the structure was primarily aimed at suppressing the overloads generated on the drain and valve discs as a result of the flow and minimizing the impact of external forces. The simulations were performed using CFD module in Ansys software as the Fluid-structure interaction (FSI). During calculations a model of a liquid in the form of blood with non-Newtonian properties was used. All simulations were performed for three positions of the mechanical heart valve: open, middle and closed.

Results and Discussion
In the case of the first construction, the obtained results showed that the over-stiffening of the system, which could result in damage to the valve during prolonged work. Two constructions required additional elements made of titanium and polymers of different Shore hardness, allowing for sufficient suppression and load transfer. The final design was selected on the basis on optimization and partner's technological capabilities.

Conclusion
The research confirmed the effectiveness of the presented optimization method. Based on the numerical simulations, it was possible to select appropriate materials for the production of a pediatric prosthesis and estimate the existing stresses.

Introduction
Osteoporosis, a global health hazard characterized by bone fragility, decrease of bone mass and strength, results in increasing danger of fractures. This disease is the most common among bone pathologies occurring in all ages and races with higher frequency in women over 50 years old and more accurately postmenopausal women [1]. In the field of bone regeneration, considerable attention has been addressed towards the use of mesoporous bioactive glasses (MBGs) due their ability to form a strong chemical bond with bone tissue leading to the formation of new tissue. Moreover, according to the final application, MBG composition can be enriched with specific elements acting as cues to impart a specific biological effect. In particular, the incorporation of therapeutic ions, such as strontium (Sr) ions into MBGs is known to stimulate osteogenesis and bone regeneration potential [2]. In this study, we assessed the in vitro osteogenic and osteoclastogenic potential of Sr-containing MBG by investigating the cell viability, proliferation and differentiation of the pre-osteoblastic MC3T3-E1 cells and human peripheral blood mononuclear cells (hPBMCs), respectively.

Experimental Methods
MBGs with binary SiO2-CaO composition were synthesized using two different methods, the first a base-catalyzed sol-gel procedure (SG) for the production of nanoparticles, and the second based on aerosol-assisted spray-drying (SD) approach for micro-sized particles. The binary composition was further enriched with two different percentages of strontium (4% and 10% mol.) using both production methods, the SG and SD, resulting in four different types of MBGs. The obtained materials were suspended to a final concentration of 200 μg/ml and contacted with pre-osteoblastic and peripheral blood mononuclear cells. The Sr-containing MBGs were evaluated for their in vitro cytotoxicity, osteogenic and osteoclastogenic capacity. MC3T3-E1 pre-osteoblastic cells were used for the investigation of cell adhesion, viability, proliferation and osteogenic differentiation potential of MBGs. Cell viability and proliferation was assessed using the PrestoBlue™ assay. An enzymatic activity assay was used to measure the levels of alkaline phosphatase activity, while the alizarin red staining method was used to quantify the calcium deposition. Collagen secretion was measured to assess the formation of the extracellular matrix. Collagen type I is highly expressed by osteoblasts and involved in the formation of extracellular matrix (ECM) in which mineralization can occur. Real time quantitative polymerase chain reaction (qPCR) was performed to quantify changes in the gene expression of the osteogenesis-related markers ALP, Coll1-a1, osteonectin, osteopontin and osteocalcin.

Human Peripheral Blood Mononuclear Cells (hPBMC) have the capacity to differentiate into osteoclasts after treatment with M-CSF and RANKL, and were used for the assessment of the in vitro osteoclastogenic potential of the MBGs. For this, qPCR experiments were performed to evaluate the gene expression levels of the osteoclastogenesis-related markers DC-STAMP, NFATC1, OSCAR and TRAP.

Results and Discussion
Pre-osteoblasts indicated an excellent cell adhesion and spreading in direct contact with all types of Sr-containing MBGs at the concentration of 200 μg/ml. Increased cell viability and proliferation rates revealed the absence of
cytotoxicity with abundant extracellular matrix formation as evidenced from the levels of collagen secretion and calcium deposition. Increased levels of ALP activity were observed after 3 days in culture for all MBGs types. Osteogenesis-related gene expression was upregulated, with the SG-produced and the 4% Sr-containing MBGs indicating a significantly higher ALP gene expression after 14 days in culture. The results from the osteoclastogenesis-related gene expression did not show an induction of osteoclasts formation.

Conclusion
Micro and nanoparticles of MBGs, with and without strontium in their composition, were assessed for their bone regeneration and resorption potential. All types of MBGs indicated an excellent biocompatibility, promoted the osteoblastic cell maturation, and did not induce the osteoclastogenic potential of the hPBMCs.

Miniaturized *In Vitro* Electrical Stimulation Platform

**Sahba Mobini, María Ujué González, Jorge M. García Martínez, José Miguel García-Martín**

*CSIC (CEI UAM+CSIC), Instituto de Micro y Nanotecnología (IMN-CNM), Tres Cantos, ES*

**Introduction**

Bioelectricity facilitates sending and receiving information to/from the body to provide controlling and feedbacking systems to regulate, and monitor biological microenvironment. Also, numerous studies showed electrical stimulation (ES) promotes proliferation, migration and secretion of pro-regenerative factors in the cells and accelerates tissue regeneration, and wound healing. Moreover, ES has a great potential to be adapted as a digital medicine and/or smart therapeutic.

Growing research on the use of ES in biological systems, promotes development of *in vitro* platforms to study the role and applications of ES in contact with cells and tissues. Up to now several *in vitro* ES devices have been established, such as: devices for measuring electrical impedance of cells that is used to evaluate specific biological activities; devices for inducing specific cell responses by means of low voltage ES (e.g., cell migration, differentiation); devices for stimulating and/or recording electrical activity of electroactive cells in CMOS-based multi-electrode arrays (MEAs) and/or multipurpose setups such as lab-on-the-chip. Nevertheless, quality of electrical signals, reproducibility of experiments, increasing of throughput and accuracy of performance of current *in vitro* platforms are yet to be improved. We believe, advances in biomaterials technology, computational modeling, microelectronics, microfabrication, and electrochemistry have opened new doors to meet these needs.

Here we present the evolution of *in vitro* platforms for electrical stimulation and recording for different proposes and introduce our innovative device for low voltage direct electrical stimulation. We discussed design, fabrication and characterization of this platform and its benefits for conducting high throughput and controlled experiments within a standard cell culture vessel.

**Experimental Methods**

We designed and developed a miniaturized *in vitro* device for electrical stimulation (MiDES) of cells and tissues. MiDES is illustrated in Figure 1 A and B. The universal frame and the top lid are fabricated by means of 3D-printed polyether ether ketone (PEEK). The cell culture chamber is fabricated from SYLGARD™ 184 silicone elastomer to be detachable that provides convenient postprocessing for multiple tests. We fabricated platinum electrodes by means of sputter coating and connected them to the printed circuit board (PCB), designed for MiDES, by means of conductive epoxy (EPO-TEK H20E). PCB will be connected to a function generator with automatized or manual operation options. We measured impedance of the system and used this data for defining accurate signal form and intensity in MiDES during stimulation.

**Results and Discussion**

MiDES is designed to be compatible with slid-chamber cell culture systems such as Millicell® EZ SLID manufactured by Millipore. PCB provides 10 channels that are connected to a jumper connector and allows independent electrical delivery in each well. Therefore, each cell culture well can be stimulated separately or simultaneously. Each well supports 200 to 700 µl of culture medium and provides sufficient space for 2D or 3D culture. Live microscopy assessment can be done during electrical stimulation since the surface for cultured cells is made of a high-quality coverslip (0.17mm) attached to the bottom of the universal frame, Figure 1 C. MiDES also designed to be stackable Figure 1 D. Although there are several designs for *in vitro* setups, the majority of these experiments have been conducted without considering the electrochemical characteristics of electrodes and studying the role of electrode material in the quality of delivered electrical signal, and unwanted electrochemical reactions. Therefore, previously...
we run a full study and picked Pt electrodes among other metals (Au and Ti) to be incorporated to MiDES. We acquired electrochemical properties of MiDES system and used them to define amount signal filtration (The study on materials and signal filtration is reported separately).

Conclusion
A miniaturized in vitro device for electrical stimulation of cells is designed and developed. This patented technology will benefit in vitro electrical stimulation research to conduct multiple reproducible controlled experiments within a standard cell platform.

**Introduction**

Stroke affects around 14 million people each year, being one of the major causes of death and long-term disability in the world, with a huge economic and social impact. Stroke survivors remain with major disabilities since there are no therapeutic options to protect neurons and promote regeneration. Therefore, there is an urgent need to develop new therapies to mitigate the extension of stroke damage.

Nanotechnology has shown potential to address these challenges, since nanobiomaterials are promising delivery platforms of therapeutics to the brain, increasing their blood stability and brain bioavailability. Despite this, the complexity of traditional *in vivo* models, often impairs the feasibility and success of pre-clinical studies, contributing to the low number of therapeutic molecules that reach the clinics.

Currently, zebrafish is classified as a complementary animal model to the classic mammalian ones. Its widespread acceptance for drug screening recently increased due to the high genome similarity to human’s, high-fertility, low-cost and easy maintenance. Here we describe the establishment of a global ischemic model by oxygen deprivation of zebrafish larvae, as well as an adaptation of a stroke model in the adult fish.

**Experimental Methods**

Zebrafish larvae (10 days post fertilization) were exposed to oxygen deprived medium. Larvae transparency allows to confirm the compromised blood-brain barrier after dye injection using up-to-date bioimaging techniques. Also, the cerebral damage extension after hypoxia is being assessed *in vivo* by motor patterns monitoring through medium-throughput behavior assays and using different neurodegeneration assays.

Also, a focal ischemic model attained by photo-thrombolysis in adult zebrafish, close to what happens in clinics, is being optimized. Neuronal apoptosis and neurodegeneration after ischemia is under analysis. Neurological outcome analysis is also being evaluated by monitoring behavior.

**Results and Discussion**

Bioimaging techniques of the larval zebrafish model, using light-sheet microscopy, ensued an accurate 3D reconstruction of the larvae brains injected with the dye (Figure 1). Also, scanning confocal light microscopy allowed the determination of the nanocarriers biodistribution. Due to the high fertility rate of zebrafish, low-cost larvae maintenance and fast imaging technologies, a high number of animals can be used, increasing the screened nanobiocarriers and the statistical power of the outcomes.

Pilot experiments performed in the focal ischemic model to determine the infarcted area using X-Ray micro computed tomography (micro-CT), showed the possibility to clearly visualize the brain using several contrast agents (Figure 2). The neurodegeneration in the affected area has been determined by immunofluorescence assays, with apoptotic and neuronal markers, showing neuronal loss close to the occlusion site.

**Conclusion**

Overall, these models are expected to open new avenues towards the assessment of the most promising and recent nanobiocarriers to deliver neuroprotective agents after an ischemic stroke. In the larval model, a medium-throughput screening will additionally permit to analyze safety, biocompatibility, biodistribution of the nanobiomaterials. Furthermore, the pharmacokinetics and neuroprotective effects of the studied nanoformulations will be validated in a focal ischemic model using adult zebrafish.

Tensile model through the finite element to obtain the parameters of the mechanical properties of the porcine earlobe tissue.

Hilda Aguilar-Rodriguez, Javier Ortiz-Ortiz, Miguel Villagomez-Galindo, Marco A. Espinosa-Medina, Georgina Carbajal-de-La-Torre

UNIVERSIDAD MICHOACAN DE SAN NICOLAS DE HIDALGO, Facultad de Ingeniería Mecánica, Morelia, Michoacán, MX

Introduction
The skin is a highly complex biological tissue, due to its specific physical characteristics and mechanical properties. For this investigation, because of its similarity to the human, the porcine skin samples were taken from the earlobe since it is a soft area. And they were taken to a tensile test, to obtain the mechanical parameters of the tissue. Due to its mechanical behavior seen, it was chosen by hyperelastic models that help explain its mechanical behavior.

Experimental Methods
With Comsol® Multiphysics, the skin was characterized, which the constitutive behavior was adjusted to the curve and the parameters of the Ogden model for engineering stress. Based on the ASTM D638 standard, a mold was designed for a tensile model for finite element analysis.

Results and Discussion
With these results, it can be discerned that the Ogden model can determine the nonlinear behavior of the skin concerning a traditional mechanic model, likewise, using the parameters of said model a stress analysis is performed in Comsol® Multiphysics replacing traditional models of material behavior in finite element.

Conclusion
The Ogden model is a hyperelastic model that allows determining the non-linear behavior of the skin in a more punctual manner. These results will help the development of biomechanical models of the finite element that explain the behavior of the skin and reduce the analysis in-vivo models of biological tissue.

PLA 3D scaffold to improve bone reconstruction

Aurora F. Pérez Jiménez¹, Ana Monteiro¹,², Erwan Plougonven², Jérôme Hurlet¹, Christian Grandfils¹

¹ Interfaculty Research Center of Biomaterials (CEIB), University of Liège, Liège (Sart-Tilman), BE; ² Department of Chemical Engineering, University of Liège, Liège (Sart-Tilman), BE

Introduction

Three-dimensional (3D) printing, also known as additive manufacturing, is a digital fabrication process used to produce 3D objects, printing layer by layer with different materials. 3D printing has become very popular in tissue engineering due to the ability to mimic complex tissue architectures and seed them with different cell types. Considering the increasing need for new bone grafts in clinical orthopedics, a 3D scaffold mimicking natural structure features can help to improve bone reconstruction.

For the development of successful biomimetic scaffolds, the microstructure and porosity are very important to promote cell colonization and guarantee their viability. For this reason, three different scaffolds with different architectures and designs have been printed to evaluate how the pore size could affect bone reconstruction.

Experimental Methods

The scaffolds have been manufactured layer by layer using a Prusa I3 MK3 printer with a nozzle diameter of 0.2 mm. The scaffolds have been printed using an aliphatic biodegradable and biocompatible polymer called poly (lactic acid) (PLA). Micro-computed tomography (CT) was used to analyze the resulting 3D prints, its porosity and the pore sizes. Their mechanical features were assessed under static mechanical compression (Lloyd equipment).

Results and Discussion

Scaffolds have been designed to comprise an interconnected network, one of them with a uniform pore size and the two others with variable size and anisotropic characteristics. After 3D reconstruction of the CT scans, the three scaffolds showed similar porosity around 66% and the volume of each scaffold around 3200 mm³. The uniform pore scaffold exhibited a pore size between 1.007-0.975 mm³, the anisotropic pore scaffold presented pore size between 0.840-0.728 mm³ and the gradual pore scaffold showed pore size between 0.642-0.569 mm³.

Conclusion

This exploratory study has highlighted the potentialities of additive manufacturing using thermal deposition to adjust the pore size network within 3D scaffold tailored for bone reconstruction. Playing on the pattern of filament distribution for each layer has given rise to 3D objects with controlled pore size range and spatial distribution, while keeping constant the total porosity and maintaining their connectedness. Future efforts will start with in vitro evaluation before considering any preclinical trials.

Bioengineering cytocompatible 3D printed capillary-like multilayered structures embedded in hydrogels for vascular tissue engineering

João Borges, Catarina A. Saraiva, Cristina F. Sousa, Tamagno Pesqueira, Tiago R. Correia, Maria I. Rial-Hermida, Sónia G. Patrício, João F. Mano

University of Aveiro, Department of Chemistry, CICECO - Aveiro Institute of Materials, Aveiro, PT

Introduction

Bioengineering highly organized prevascularized networks to support the growth of vascularized functional tissues is a critical unmet clinical challenge that has been gathering tremendous attention by the medical, materials science and engineering communities aiming to better emulate and repair damaged tissues [1]. In particular, the emergence of the bottom-up approaches has opened new and exciting routes to rationally design and develop robust, complex, highly organized and biofunctional 3D vascular tissue-like constructs for pursuing advanced regenerative therapies [2]. Among them, the Layer-by-Layer (LbL) assembly has proved to be highly versatile technology to functionalize any type of surface and precisely engineer highly hydrated and hierarchical extracellular matrix (ECM)-mimetic biomaterials, with fine-tuned structures, properties and functions at the nanoscale, by resorting to a myriad of biological components exhibiting complementary interactions [3]. However, the lack of a carrier platform that could encapsulate, protect, and endow the developed biomaterial structures with superior biomechanical stability to be administered in the human body via minimally invasive procedures extensively limits the use of LbL technology standalone. In this regard, hydrogels are the most promising and customizable 3D biomaterial platforms for cell encapsulation, controlled therapeutics delivery, and construction of 3D tissue-like constructs embedded with 3D printed perfusable tubular structures recreating vascular tissues owing to their numerous appealing features [4,5].

Herein, we report the bioengineering of advanced bioactive and hybrid 3D cell-biomaterial constructs encompassing (i) cytocompatible 3D printed capillary-like multilayered structures embedded in (ii) photopolymerizable natural-origin hydrogels to promote the formation of tissue-mimetic vascularized networks in vitro and be potentially used as injectable systems in tissue engineering strategies.

Experimental Methods

The build-up of electrostatic-driven bioactive multilayered thin films encompassing alternate layers of biocompatible oppositely charged chitosan (CHT) and arginine (R)-glycine (G)-aspartic acid (D)-grafted alginate (ALG-RGD) biopolymers was firstly monitored in situ by quartz crystal microbalance with dissipation monitoring (QCM-D). Following the optimal assembling conditions gathered in the QCM-D experiments, similar (CHT/ALG-RGD)n multilayers were assembled on top of 3D printed ALG microfibers. Then, either uncoated or LbL coated ALG fibers were embedded in a methacrylated xanthan gum (XGMA) pre-hydrogel solution to develop mechanically robust 3D constructs after crosslinking with UV light, as confirmed by rheological measurements. The constructs were further immersed in a EDTA aqueous solution to obtain hollow microtubular structures in which human umbilical vein endothelial cells (HUVECs) were cultured for 3 days aiming to control cell functions (Live/Dead assay).

Results and Discussion

ALG microfibers were successfully produced by 3D printing and further LbL coated with six CHT/ALG-RGD bilayers, as revealed by fluorescence microscopy by labelling CHT with rhodamine B isothiocyanate. The encapsulation of the bioactive LbL functionalized ALG microfibers within biocompatible photocrosslinkable XGMA hydrogels of the desired size and geometry, and formation of liquified multilayered microtubes that replicate vascular tissues was accomplished by EDTA-induced chelation of the ALG fiber template. The formation and perfusion extension of the hollow microchannels was unveiled by the naked-eye visible flow of a fluorescent dye aqueous solution injected.
through the microchannel across the hydrogel. With the aim of replicating the vasculature of native tissues, HUVECs were seeded in either (CHT/ALG-RGD)₆ LbL functionalized microchannels or LbL-free microchannels, both embedded into XGMA hydrogels, and the in vitro cell viability assessed after 3 days by fluorescence microscopy, revealing a higher number of viable cells in the LbL coated microchannels.

**Conclusion**

Robust, bioactive and hybrid 3D constructs were successfully bioengineered by embedding cytocompatible LbL functionalized 3D printed ALG microfibers into photocrosslinkable XGMA hydrogels, which provided biomechanical stability and support to the whole construct. The ALG sacrificial core was further liquefied into hollow microtubular structures having the capacity to withstand flow and retain the original size and geometry of the fibers, aiming to recreate native vascular tissues. HUVECs viability within the hollow multilayered microtubes was assessed by a Live/Dead assay after 3 days, revealing a higher number of live cells in comparison with LbL-free hollow microtubes. This work holds great promise to surpass the major limitation associated with the absence of the formation of a prevascularized functional network on the developed 3D biomaterials to repair damaged tissues.

Bioorthogonally Cross-Linked Laminin-Functionalized Hyaluronan Hydrogels for 3D Neuronal Cell Culture

Michael Jury1, Isabelle Matthiesen2, Robert Selegård1, Anna Herland2,3, Daniel Aili1

1 Linköping University, Laboratory of Molecular Materials, Division of Biophysics and Bioengineering, Department of Physics, Chemistry and Biology, Linköping, SE; 2 KTH Royal Institute of Technology, Division of Micro and Nanosystems, Stockholm, SE; 3 Karolinska Institute, AIMES, Center for Integrated Medical and Engineering Science, Department of Neuroscience, Stockholm, SE

Introduction
Laminins are central for neuronal function and is closely associated with neuronal development, affecting e.g. the direction of neurite growth and stabilization of neuronal synapses in vivo. Laminin coated substrates are thus widely used for in vitro culture of neurons to promote neuronal attachment, viability and network formation. The use of laminin-rich biologically derived extracellular matrix (ECM) based hydrogels can provide more native-like three dimensional (3D) cellular microenvironments but suffer from poor reproducibility and difficulties in tailoring the properties of the hydrogels. Engineered hydrogels for 3D cell culture can offer better reproducibility and possibilities to control composition and stiffness and can enable development of sophisticated tissue models. Presentation of laminins in 3D hydrogels for providing optimal conditions for neuronal cell culture can, however, be challenging. Most engineered hydrogel systems thus resort to laminin-derived peptides, which can be incorporated and conjugated to various polymers. Here, we show a new means of producing very tunable and stable ECM mimicking hydrogels for 3D neuronal cell culture by using full sized and covalently conjugated laminin-521 using bioorthogonal copper-free click chemistry.

Experimental Methods
Two different variants of azide were conjugated to human recombinant laminin 521 (Biolamina, Sweden) by carbodiimide coupling to lysine residues in the laminin. Bicyclo[6.1.0]nonyne (BCN) was grafted to hyaluronic acid (HA) via the glucuronic acid carboxyl-moieties. The final HA-BCN product had a derivatization degree of about 19%. Hydrogels were formed by strain-promoted alkyne-azide 1, 3-dipolar cycloaddition (SPAAC) by first combining the HA-BCN product in cell media with the azide-functionalized laminin and then incubated at 37°C for one hour to create laminin-functionalized HA-BCN. Then SH-SY5Y neuroblastoma cells or human induced pluripotent derived neuroepithelial cells (NES) were suspended in cell media containing 8-arm poly(ethylene glycol) (PEG) with terminating N3-moieties (p(N3)8). The components were then combined and incubated at 37°C and 5% CO2 for one hour prior to adding cell media.

Results and Discussion
HA-based hydrogels were formed by cross-linking with multi-arm-PEG using SPAAC. An excess of BCN groups were included in HA for conjugation of azide modified laminin-521 prior to addition of cells and p(N3)8. The storage modulus of the hydrogels was about 0.3 and 0.7 kPa at 1% (w/v) to 2% (w/v), respectively, and did not change significantly when including laminin (100 µg/ml). Functionalization of laminin with azide moieties (Figure 1a) promoted retention of laminin within the hydrogel. The release was negligible for the higher hydrogel concentration when using a short PEG linker between the laminin and the azide. Softer hydrogels and a shorter linker led to higher laminin release (Figure 1c). Scanning electron microscopy (SEM) showed that increasing the concentration of the hydrogel components from 1% (w/v) to 2% (w/v) produced a marked difference in the hydrogel structure with thicker pore walls in the latter (Figure 2a). The hydrogels supported proliferation of both undifferentiated and differentiated SH-SY5Y cells and NES, but no significant effect of laminin was seen in any of the conditions. Confocal microscopy of SH-
SY5Y in hydrogels with Cy5-labeled laminin indicate that the cells remodel the hydrogels and accumulate the laminin in their immediate vicinity after 24 hours of cell culture.

**Conclusion**

Here we show a flexible hydrogel system that enables integration and retention of recombinant laminin for neuronal 3D cell culture. Bioorthogonal copper-free click-chemistry was used for both cross-linking of the hydrogels and for conjugation of laminin. This approach enables fabrication of well-defined ECM mimicking materials that both ensures efficient cell encapsulation and supports neuronal proliferation.

How sintering temperature influences the physicochemical properties of tricalcium phosphate (TCP) scaffolds?

**Szymon Skibiński, Ewelina Cichoń, Joanna Czechowska, Anna Ślósarczyk, Aneta Zima**

**AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Kraków, PL**

**Introduction**

Biomaterials designed for bone regenerative medicine include three-dimensional porous scaffolds, which provide support for bone cells and thus enable the reconstruction of damaged tissues. Such materials should meet a number of requirements, for instance in terms of their phase composition, adjustment of mechanical properties to replaced tissues, porosity and appropriate pore architecture as well as biocompatibility. Among the materials used as bone substitutes, tricalcium phosphates (α-TCP, β-TCP) have unique properties that distinguish them from other compounds [1,2]. Therefore, the aim of this work was to prepare TCP-based scaffolds by a polyurethane sponge replica method with appropriated porosity, interconnectivity and mechanical strength for application in as scaffolds tissue engineering.

**Experimental Methods**

In this study, ceramic TCP-based scaffolds were prepared by a polyurethane sponge replica method. Initial β-TCP powder used for preparation of ceramic slurries was synthesized via a wet chemical method. Materials were sintered in conventional furnace at four temperatures: 1100°C, 1150°C, 1200°C and 1250°C. Influence of sintering conditions on physicochemical properties of the scaffolds was determined (phase composition, microstructure, porosity and mechanical strength). Additionally, chemical stability was evaluated in vitro.

**Results and Discussion**

XRD analysis revealed that the materials sintered at 1100°C and 1150°C consist of only one crystalline phase i.e. β-TCP meanwhile in scaffolds sintered at 1200°C and 1250°C the second phase i.e. α-TCP was noticed. Additionally, changes in the microstructure were observed in terms of shape and size of grains. In the samples sintered at temperatures above 1150°C the microcracks were observed (Figure 1). All materials possessed high total porosity (~60 vol%). Interestingly, sintering temperature did not affect significantly the compressive strength of the obtained scaffolds (from 3.2 ± 0.8 MPa to 3.9 ± 1.1 MPa). The investigated materials were chemically stable, pH of the simulated body fluid solutions were close to the physiological conditions.

**Conclusion**

It was found that the sintering temperature in the range from 1100 to 1250 °C influences on the phase composition, microstructure, porosity and the average grain size of the obtained materials. Scaffolds sintered above 1150 °C consisted of two crystalline phases, i.e. β-TCP and small amounts of α-TCP. All materials possessed similar total porosity. The best compressive strength (3.9 ± 1.1 MPa) was achieved by the materials sintered at 1150 °C. In the case of scaffolds sintered in 1200 and 1250 °C, besides of the β-TCP → α-TCP polymorphic transformation, there was no significant loss on mechanical properties. Moreover, all studied materials are chemically stable and do not show any significant pH fluctuations during 28 days of incubation in simulated body fluid. Due to favourable physicochemical properties and expected biocompatibility developed materials seem to be prosperous candidates for cancellous bone tissue engineering.

Composite electrospun fibers for tissue engineering and wound healing applications

Elisa Piatti¹, Marta Miola¹, Liliana Liverani², Aldo R. Boccaccini², Enrica Verné¹

¹ Politecnico di Torino, Department of Applied Science and Technology (DISAT), Torino, IT; ² University of Erlangen-Nuremberg, Department of Materials Science and Engineering, Erlangen, DE

Introduction
Tissue engineering (TE) and regenerative medicine are alternative therapeutic approach to organ and tissue transplants towards the repair and regeneration of diseased or damaged living human tissues. Various strategies are available for the development of scaffolds as temporary templates for tissue regeneration, providing a supporting structure for cell proliferation and differentiation. In this context, the synthesis of composite materials merging the properties of flexibility of polymers and bioactivity and rigidity of ceramic materials such as bioactive glass (BG) particles is of interest.

Among others, the electrospinning is widely used for the fabrication of micro- and nanofibrous mats, because of the versatility of this technique and the advantageous properties of the electrospun fibers, such as fibrous structure, tuneable size (in the range of sub-micrometers down to nanometers), high aspect ratio, high surface area and high porosity with interconnected pores, easy incorporation of functional components (like drugs, genes, enzymes, living cells, etc.), that allow to physically mimic the ECM of many human tissues.

Experimental Methods
Novel B- and Cu-doped bioactive glass nanoparticles (62 wt% SiO₂ - 15 wt% B₂O₃ - 9 wt% CaO - 9 wt% P₂O₅ - 5 wt% CuO) were synthetized using sol-gel methods. Composite electrospun fibers were obtained by the incorporation of these particles inside poly-ε-caprolactone (PCL) mats, electrospinning a solution of PCL, acetic acid and BG particles after a careful process optimization. EM-EDS, DLS, BET, FTIR, XRD and bioactivity test were performed on the synthetized bioactive glasses, whereas SEM-EDS, FTIR, contact-angle measurements, degradation test, mechanical test and bioactivity test were carried out on the composites.

Results and Discussion
Bioactive nanosized round-shaped particles were obtained and successfully incorporated in PCL electrospun mats. The synthetized composite fibers were indeed very rich of glass as desired, although the presence of some glass particles clusters, resulting in uneven distribution within the polymeric matrix, in agreement with previous results. The in vitro acellular bioactivity test showed a good bioactivity of both bioactive glasses (since the first days of immersion in SBF) and the fabricated composites, as revealed by the increased amounts of phosphorus and calcium during immersion in the simulated fluid solution (SBF) and the deposition of HA-like crystals on the composite surface.

All other tested properties (mechanical properties, wettability and degradation) were satisfying, but sometimes affected by the presence of glass powder clusters. The proliferation of bone murine stromal cells (ST-2 cell line) was not inhibited, confirming that the synthetized composites were nontoxic and promising for potential TE applications.

Conclusion
Because of the angiogenic and antibacterial properties of the doping ions (boron and copper), these glasses are considered novel promising angiogenic and antibacterial agents.
The synthetized composites electrospun fibers showed good biocompatibility and bioactivity and, considering their potential angiogenic and antibacterial properties (to be examined in future work), they are considered adequate for soft TE applications.

Chemically-modified Gellan-Gum as composite and bioactive bioink for the design of 3D printed scaffolds for bone tissue engineering

Ugo D’Amora¹, Alfredo Ronca¹, Stefania Scialla¹, Alessandra Soriente¹, Maria Grazia Raucci¹, Paola Manini², Alessandro Pezzella³, Luigi Ambrosio¹

¹ National Research Council, Institute of Polymers, Composites and Biomaterials, Naples, IT; ² University of Naples Federico II, Department of Chemical Sciences, Naples, IT; ³ University of Naples Federico II, Department of Physics “E. Pancini”, Naples, IT

Introduction
Over the past years, the linear anionic hetero-polysaccharide gellan-gum (GG) is emerging as a promising noncytotoxic biopolymer for bone tissue engineering (BTE)¹. Among its advantages, it is worth noting that GG is a natural, biodegradable, and hydrophilic polymer, which exists in abundance. Furthermore, the water-based process does not require the use of harsh chemicals. The primary structure of GG is composed by repeating units of glucose, rhamnose, and glucuronic acid. The secondary structure changes upon the temperature from a random coiled form, at high temperature, to a double-helix form, at room temperature. This peculiar transition allow producing hydrogels from GG by simply decreasing the temperature. However, the mechanical performances as well as the stability are still the limiting issue, especially considering its application as bioink for 3D printing. In particular, bioinks should be able to: i) be extruded through a thin needle, ii) retain a 3D structure and iii) create a cytocompatible environment, suitable for embedding living cells².

To this aim, GG was chemically modified in order to add functional moieties and making possible a further cross-linking of the hydrogel by UV light using a photo-initiator. Furthermore, the material was enriched by incorporation of hydroxyapatite nanoparticles (HAp) obtained by sol-gel method and eumelanin (EU) extracted from natural fonts. On one hand, HAp has widely demonstrated to be a bioactive signal towards osteogenic induction, owing to the synergic contribution of its inherent biomimicry and improved mechanical properties. On the other hand, a few studies have recently suggested that EU could promote osteoblast differentiation, inhibit osteoclast differentiation, strengthen the bone, and increase alkaline phosphatase activity and bone mineralization³.

Experimental Methods
GG (Gelzan™, Sigma Aldrich) was chemically modified by the reaction with methacrylic anhydride (Sigma Aldrich) to produce a photocrosslinkable derivative (GGMA) with a shear thinning behavior and tunable mechanical properties. The materials were fully investigated in terms of physico-chemical properties to validate the success of the functionalization. The bioprinting was performed using a 3D printer “In vivo Rokit” (Rokit Healthcare Inc.). Different formulations of biocomposites based on GGMA (2 and 4 %wt/v) and bioactive components, as HAp and EU, were developed. HAp were added at a concentration of 10 and 30 %wt referred to GGMA amount while, based on the cytocompatibility data, EU was added at a concentration of 0.3 %wt/v. The morphology of the 3D structures was investigated by scanning electron microscopy (SEM). The mechanical properties of the scaffolds were tested by dynamic mechanical analysis. The cytocompatibility was assessed by using murine fibroblast cell line according to ISO guidelines, meanwhile human mesenchymal stem cells were used to evaluate the differentiation in osteogenic lineage. The cell proliferation was assessed by confocal microscopy and Alamar blue assay. To evaluate the osteoinductive properties of 3D materials, the expression of some osteoblast-related markers, including alkaline phosphatase, type I collagen, osteocalcin and osteonectin were analyzed.

Results and Discussion
The methacrylation of GG was confirmed by the presence of carbon double bond peak at 1640 cm\(^{-1}\), known to be present in methacrylate groups but not in GG chains, as shown by Attenuated total reflect Fourier transform infrared spectra. The three different structures (GGMA, GGMA/HAp and GGMA/EU) were successfully 3D printed with a good shape fidelity, proving to be able to maintain their structure without collapse in the Z-direction. A homogenous porosity with lateral pores clearly visible was confirmed by SEM. Mechanical properties of GGMA/HAp scaffolds showed values of the storage modulus generally higher than GGMA scaffolds. Furthermore, the nanoparticles improved the nanoroughness and bioactivity. Biological analyses demonstrated a difference of cell attachment and proliferation among the different groups. In particular, the presence of bioactive signals (HAp and EU) seemed to stimulate bone tissue formation.

**Conclusion**

Here, 3D well-organized structures were produced by 3D bioprinting. The obtained results proved the potential use of these materials as bioinks for BTE. The scaffolds showed enhanced mechanical, morphological as well as good biological properties.

Influence of pore size, morphology and fibroin molecular weight on 3D silk fibroin scaffolds

Melisa Kafali¹, Yiğithan Tufan¹, Batur Ercan¹,²,³

¹ Middle East Technical University, Metallurgical and Materials Engineering, Ankara, TR; ² Middle East Technical University, Biomedical Engineering, Ankara, TR; ³ METU Center of Excellence in Biomaterials and Tissue Engineering, BIOMATEN, Ankara, TR

Introduction

Controlling pore size, pore morphology and molecular weight distribution of silk fibroin (SF) are important for the production of 3-D scaffolds which is the crucial framework for the cell cultures.[1] For changing pore size and morphology of the scaffold, SF concentration, cooling temperature and cooling rate can be changed, and also a secondary phase can be added into the scaffold to obtain various pore sizes [2]. For instance, SF scaffolds having 1wt. % SF concentration are synthesized with 250-300µm pore size while using 5 wt.% SF concentration reduces pore size to 80-150µm [2]. Furthermore, the molecular weight distribution of SF can be altered by alkaline hydrolysis or lithium bromide salt – SF interaction [3]. In the study of Kim et al, the molecular weight distribution (MW) is altered between 263.1 – 82.7 kDa by regulating the hydrolysis time(10 - 180 min). Here, SF scaffolds are synthesized by changing distribution of MW and tuning the pore architecture to optimize mechanical, rheological, morphological, and biological properties. Three different processing parameters used in this study are dissolving time, cooling rate, and cooling temperature.

Experimental Methods

Bombyx mori cocoon shells were cut into small pieces to extract fibroin protein inside boiled 0.02M sodium carbonate solution. SF was primarily dissolved in 11M lithium bromide solution for 4h and 48h, then dialyzed against distilled water for 3 days. Afterward, dialyzed SF solution was frozen at -20°C and -80°C and lyophilized to obtain a porous scaffold and to examine further characterization. The metabolic activities of the osteoblast (ATCC – CRL 11372) at a cell density of 20.000 cells/cm² were analyzed using MTT assay. The cross-sectional morphologies of the SF scaffolds were investigated using FEI Nova Nano SEM 430 microscope. The secondary crystalline structures of the SF scaffolds were analyzed using FTIR and confirmed with XRD analysis. Mechanical properties of the scaffolds were measured based on ASTM 683D standard with Instron 5565A, Norwood, MA.

Results and Discussion

The altered parameters for SF scaffold production could divided into two groups: those that affect the MW and those that control pore morphology. Firstly, the parameter that affects MW distribution of SF was dissolution time. To generate SF solution, strong hydrogen bonds of SF were destroyed in high ionic strength salt solution (11M lithium bromide) for 4h and 48h. During this step, the MW distribution of SF was altered, and thus, the viscosity of SF solution was affected. For instance, dissolution in lithium bromide for 48h at 60°C resulted in higher MW distribution and viscosity than dissolution in lithium bromide for 48h at 60°C. In FTIR and XRD tests, the methanol-treated SF scaffolds had stronger intermolecular beta-sheet crystalline structure than the extracted and not methanol treated ones. Secondly, the parameters that affected the distinct pore morphology of SF scaffolds were cooling rate and cooling temperature. Freezing the dialyzed SF solution in isopropanol at -20°C resulted in a circular pore morphology (99.39 ± 6.66 µm). When the same process is repeated at -80°C, a lamellar-like pore morphology (266.33 ± 89.19 µm) is obtained as shown in Figure 1a-b. Pore characteristic was important in the design of SF scaffolds to provide enough space for cell migration and transportation of waste and nutrition with the surrounding environment. The osteoblast cell culture that have been prepared by using circular pore scaffolds (at -20°C in isopropanol) showed
better cell proliferation and cell migration compared to the one that have been prepared by using lamellar-like pore scaffolds (at -80°C in isopropanol) (Figure 1c). In the swelling test, since smaller pore size limits infiltration, swelling is slower in scaffolds that have been synthesized at -20°C with isopropanol. Thus, with one being 4 h⁻¹ and the other being 7.830 h⁻¹, the swelling rate is almost 2 times for the larger pore size specimen, complying with Schotts second order diffusion kinetic model. In the uniaxial tensile test, circular pore shape scaffold was resulted in 242± 39.2 kPa tensile strength while lamellar-like pore shape scaffold was reached to 167± 22.87 kPa tensile strength as shown in Figure 1d.

Conclusion
In the field of tissue engineering, SF is an important natural, proteinaceous material due to its biocompatibility, tunable degradation characteristic and excellent mechanical properties. These features of SF scaffolds are related to scaffold fabrication parameters. By altering SF is dissolving time in LiBr, it was possible to control molecular weight and secondary structure of SF and altering freezing temperature and cooling rate it was possible to control size and distribution of pores. Our preliminary results showed enhanced cellular viability and mechanical properties on scaffolds having globular-shaped pores. Thus, scaffolds SF having globular pore morphology should be further studies for tissue engineering applications.

Fabrication of Methacrylate Hyaluronic Acid scaffolds with axially oriented pores

Paola Nitti, Marta Madaghiele, Christian Demitri

University of Salento, Department of Engineering for Innovation, Lecce, IT

Introduction
The aim of this work was the development and characterization of biomimetic scaffolds based on hyaluronic acid with axially oriented pore channels for nerve regeneration. Matrices with elongated microstructure, suitably oriented porosity and controlled degradation rate have the potential to improve the regeneration of peripheral nerves and spinal cord by physically supporting and guiding the growth of neural structures across the site of injury [1]. Highly porous and functionalized tubular scaffolds were successfully produced using methacrylate and photo-crosslinked hyaluronic acid. In addition, to create axially oriented pore channels, scaffold manufacturing technique based on unidirectional freezing and subsequent freeze-drying was optimized.

Experimental Methods
Hyaluronic acid (HA) was methacrylated by means of a glycidyl methacrylate (GDM) grafting reaction, with an excess of GDM equal to 10 with respect to the disaccharide unit [2]. Next, a few photocrosslinked hydrogels were synthesized by exposing 26 mg/ml methacrylate HA (HAm) to UV light in the presence of increasing concentrations of the photoinitiator Irgacure 2959 (1%, 2% and 3% wt), in order to obtain different photo-crosslinked HAm hydrogels. To create axially oriented pore channels, the optimized HAm solution resulting by rheological tests (HAm 26mg/ml + 3 % wt PhI) was freeze-dried using three different strategies. They distinguish for the methods of preparation of support plates, before inserting the gel into the tube, in: Full ice (the cavities between guide tubes were completely filled with water and frozen), ice bottom (cavities filled only for 1/3 of their height) and no ice (water added after filling of tubes with gel). In addition, three HAm concentrations (26, 35, 50 mg/ml) and three different sequences of photo-crosslinking and freeze phase were studied: (i) photo-crosslinked of HAm, filled tube, cavities filled with water, frozen and freeze-drying; (ii) filled tube, cavities filled with water, frozen and freeze-drying, UV exposure of scaffold; (iii) filled tube, cavities filled with water, frozen, UV exposure and freeze-drying. All scaffolds produced were observed by SEM and the evaluation of the weight loss % in PBS at 37°C up to 28 days of soaking was carried out.

Results and Discussion
The metacrylated and photo-crosslinked hyaluronic acid hydrogel was optimized and characterized. By assessing the variation of photo initiator concentration, the best rheological properties were achieved by hydrogel produced with PhI at 3% by weight. Starting from these results, the optimized solution based on HAm 26 mg/ml + PhI 3% was used for the production of tubular nerve scaffold by freeze-drying technique. From different strategies of freeze-drying tested, scaffolds with elongated and suitable porosity have been obtained using strategy called NO ICE, in which water at room temperature is placed around the material. The use of material in which photo-crosslinking was interposed between two successive stages of freezing and the control of temperature gradients during freezing, allows the columnar growth of crystals thus obtaining a structure totally oriented and aligned according to the longitudinal axis of the scaffold (Figure 1 and 2 ). The scaffolds produced using method described above and with three different HAme concentrations were tested up to 28 days of soaking in PBS. The scaffolds HAme 26 mg/ml and HAme 35 mg/ml showed loss of structure and swelling after 1 day compared to scaffold HAme 50 mg/ml, which presented good stability.

Conclusion
Highly porous and functionalized scaffolds were successfully produced using methacrylate and photo-crosslinked hyaluronic acid, using tubular guides and water at room temperature as a means of controlling the columnar growth of ice crystals within the hydrogels, which subjected to the freeze-drying process left room for an engineered scaffold. In order to mediate between the high concentration of methacrylate hyaluronic acid, necessary for stabilizing the support in a physiological environment, and the growth of columnar crystals, an alternative method of production has been developed and optimized.

Heatable PLA/CaP scaffolds for bone therapy through electromagnetic induced hyperthermia of iron oxide nanoparticles

Laura González-Rodríguez\textsuperscript{1,2}, Sara Pérez-Davila\textsuperscript{1,2}, Stefano Chiussi\textsuperscript{1,2}, Julia Serra\textsuperscript{1,2}, Pío González\textsuperscript{1,2}

\textsuperscript{1} CINTECX, Universidade de Vigo, New Materials Group, Vigo, ES; \textsuperscript{2} Galicia Sur Health Research Institute (IIS Galicia Sur). SERGAS-UVIGO, Vigo, ES

**Introduction**

Calcium phosphate (CaP) based scaffolds are very demanded in bone tissue engineering for repairing, replacing or regenerating defects in human bones or teeth due to their similar composition to the mineral part of the human bone. In fact, CaP content improves the attachment, differentiation, and proliferation of significant cells, in particular fibroblast-like and osteoblast cells. Moreover, it has been shown that CaP granulates embedded in a biodegradable polymer matrix, like polylactic acid (PLA), enhance the mechanical properties of organic scaffolds, mimicking as close as possible the bone mechanical strength [1].

An innovative strategy in the scaffold development for bone therapy is the possibility of incorporating an adjuvant effect through a hyperthermia process. The induced heating can enhance the bone regeneration [2], stimulate the vascular irrigation [3] and even can play an important role in the elimination of tumour [4] and microbial cells [5]. Local hyperthermia can be generated using different methods, among them, the use of iron oxide nanoparticles (Fe\textsubscript{3}O\textsubscript{4}NPs) activated by electromagnetic fields in the radiofrequency range (Figure 1).

The purpose of this work is to develop CaP/PLA heatable scaffolds through electromagnetic induced hyperthermia by using embedded iron oxide nanoparticles.

**Experimental Methods**

Scaffolds were produced by 3D-FDM printing based on a mixture of commercial PLA pellets and marine origin CaP granulates in different concentrations, with a CaP weight percentage up to 30%. After that, Fe\textsubscript{3}O\textsubscript{4} nanoparticles (5 mg/mL) were deposited on the scaffolds in several volumes. Biocompatibility of different concentrations of Fe\textsubscript{3}O\textsubscript{4} nanoparticles, from 0.1 mg/mL to 0.05 µg/mL, was assessed by \textit{in vitro} tests using MG63 osteosarcoma cell line. Cytotoxicity was evaluated using MTS assay after 24 h. Hyperthermia was induced by an electromagnetic inductor working at 340 kHz and operating with different current intensities, ranging from 60 to 99 A. The temperature rise on the scaffolds was recorded by an optical pyrometer.

**Results and Discussion**

\textit{In vitro} biocompatibility tests demonstrate a threshold of non-toxicity for Fe\textsubscript{3}O\textsubscript{4} NPs concentrations below 0.05mg/mL. PLA/CaP scaffolds embedded with Fe\textsubscript{3}O\textsubscript{4} nanoparticles were submitted to different electromagnetic radiation intensities. Hyperthermia induced on the scaffolds can be tuned by selecting the appropriate current of the inductor. As shown in Figure 2, for PLA/CaP30% scaffolds, a temperature rise up to 23°C is reached for 99 A current intensity. The PLA/Fe\textsubscript{3}O\textsubscript{4}NPs scaffolds were used as a control.

**Conclusion**

The biocompatible concentration threshold of Fe\textsubscript{3}O\textsubscript{4} nanoparticles has been determined. The generation of local hyperthermia in PLA/CaP/Fe\textsubscript{3}O\textsubscript{4}NPs scaffolds by electromagnetic induction has been demonstrated.

\textsuperscript{1} New Therapeutic Targets Laboratory (TargetsLab) - Universitat de Girona, Department of Medical Sciences, Girona, ES; \textsuperscript{2} Product, Process and Production Engineering Research Group (GREP) - Universitat de Girona, Department of Mechanical Engineering and Industrial Construction, Girona, ES

Introduction

Two–dimensional culture mediums have traditionally been used in the vast majority of studies involving cell culture. This methodology, however, is not representative of the true conditions in which cells proliferate in the organism. Cells rely on the extracellular matrix (ECM) not only for architectural support, but for biochemical and biomechanical signals for morphogenesis, differentiation and homeostasis.\textsuperscript{1} Three–dimensional (3D) scaffolds allow for the assimilation of physiological cellular conditions in cell culture, leading to closer replication of in vivo environment,\textsuperscript{2,3} this includes cellular morphology, differentiation, proliferation rate, protein synthesis and gene expression, as well as drug metabolism.\textsuperscript{4,5}

This study aims to compare the proliferation of MCF7 breast cancer cells in the different materials available for 3D cell cultures, polylactic acid (PLA) and polycaprolactone (PCL), as well as the different techniques for scaffold synthesis by comparing fused filament fabrication (FFF) and electrospinning methods.

Experimental Methods

Fused filament fabrication (FFF) and electrospinning were compared using two different aliphatic polyesters, PLA and PCL; resulting in four 3D scaffold models for cell culture: FFF–PLA, FFF–PCL, electrospun PLA and electrospun PCL.

FFF printing technique was used to manufacture 3D scaffolds in order to compare PLA and PCL materials. Three scaffolds were printed for both PLA and PCL with deposition angles of 90\(^\circ\). The resulting scaffolds were cultivated with MCF7 breast cancer cells; at 3 and 6 days the adhesion and proliferation were measured using colorimetric assay (MTT).

Electrospinning printing technique was also used to manufacture 3D scaffolds to compare PLA and PCL materials. Again, three scaffolds were printed for both PLA and PCL, both with a material concentration of 15\% w/v. The resulting scaffolds were also cultivated with MCF7 cells at 3 and 6 days, the adhesion and proliferation were measured using colorimetric assay (MTT).

These same MCF7 cells were also cultured on a traditional 2D culture medium as a control for both FFF and electrospinning techniques.

Results and Discussion

Cell adhesion and proliferation of MCF7 breast cancer cells were observed at 3 and 6 days after seeding on the 3D scaffolds.

At 3 days, cell adhesion and proliferation on all 3D scaffold cell cultures was observed to be significantly less than in the traditional 2D culture, which presented increased cell proliferation. When comparing the 3D scaffold models amongst themselves, scaffolds manufactured with PCL through electrospinning presented increased proliferation when compared to both FFF–PLA, FFF–PCL and PLA electrospun scaffolds (Figure 1). Six days after initial seeding, adhesion and proliferation were measured again, where no significant differences were observed when comparing traditional 2D culture and all four scaffold groups. When comparing 3D culture mediums, an increased adhesion and proliferation was observed when using electrospun PCL scaffolds (Figure 2).
Conclusion

In summary, cellular culture of MCF7 breast cancer cells (as determined by cell adhesion and proliferation) on 3D scaffolds, using both FFF and electrospinning with either PCL or PLA, does not differ from traditional flat 2D cell culture. When comparing the four groups of 3D scaffolds, the one that yielded the highest cellular proliferation was the electrospun PCL scaffold.

Introduction
The treatment of bone defects, arising from infections, is a big challenge for the orthopedic field. 3D printing is a promising technology to produce scaffolds with customized architecture able to stimulate and support bone growth [1]. Bioceramics, such as β-TCP and S53P4 bioactive glass, used for scaffold manufacturing, have shown a great biological response [1]. However, a multifunctional scaffold, able to inhibit microbial proliferation on the defect site, is of increasing interest not only to avoid infection recurrence but also to decrease the dosage of antibiotics, preventing complications due to resistant bacteria [2]. Tea tree oil (TTO) has aroused interest as antimicrobial agent to minimize the use of antibiotics [3]. Therefore, combining the regenerative potential of a bioceramic scaffold with the antimicrobial properties of TTO could result in an innovative biomaterial capable of stimulating tissue growth and treating infections. In this context, this study aims to produce and characterize 3D printed β-TCP/ S53P4 scaffolds coated with TTO.

Experimental Methods
The scaffolds were produced by the “Direct Ink Writting” (DIW) method and the morphological and chemical characterizations by means of XDR, SEM, FT-IR were carried out.

The scaffolds were coated by immersion in an ethanol/TTO solution with a TTO concentration of 5, 10 and 15% (v/v) until the ethanol evaporated. The release of TTO was evaluated with a UV-vis spectrophotometer. Samples in triplicate were incubated in PBS under constant agitation at 90 rpm and 37°C for up to 14 days. After the TTO release evaluation, antibacterial and in vitro bioactivity assays are performed. The antibacterial activity of the coated scaffolds was evaluated against S. aureus.

Results and Discussion
Figure 1 shows the XRD pattern of β-TCP/S53P4 scaffolds. It is possible to notice the formation of different crystalline phases due to the sintering temperature. SEM images of the scaffold show the fracture surface of the filaments and the pore geometry pattern (Figure 2), the obtained porosity of sintered scaffolds was 48%.

Preliminary turbidity assays showed the potential antibacterial properties of the coated scaffolds with higher TTO concentration during the first 7 hours in contact with bacteria.

Conclusion
It was possible to produce β-TCP/S53P4 scaffolds using Direct Ink Writting method and coat them with Tea Tree Oil. The XRD pattern shows the β-TCP phase and others due to the sintering temperature.

SEM images show the pattern in the filaments and pore geometry.

The other assays are in progress and we will hand in the results as soon as possible.

Continuous peptide gradients in 3DP scaffolds to control osteochondral differentiation

Ivo Beeren, Sandra Camarero-Espinosa, Piet Dijkstra, Ravi Sinha, Carlos Mota, Matt Baker, Lorenzo Moroni

Maastricht University, Biofabrication group, MERLN institute, Maastricht, NL

Introduction
Articular cartilage has little capacity for repair and damage can easily progress to osteoarthritis. The current clinical treatment is microfracture or autologous tissue transplantation; however, this often results in fibrocartilage formation. Hence, tissue engineers are designing a new supportive base at the site of defect – an osteochondral (OC) construct – capable of enhancing OC regeneration. The OC region is described by gradual transitions between cartilage and bone via multiple zones each with its specific cell type and matrix composition. Continuous gradients are required to create biomimetic tissue engineering constructs. We hypothesized that a construct with gradual control over human mesenchymal stromal cells (hMSC) differentiation is needed to improve gradual tissue formation for osteochondral applications. To this end, we designed a 3D printed (3DP) construct with gradients of differentiation-inducing peptides on the surface. We employed the gradient printing of polymers with orthogonal functional groups for post-fabrication functionalization with different peptides. Here, we will show our work from polymer synthesis, to preliminary in vivo experiments.

Experimental Methods
Polycaprolactone (PCL$_{45k}$) polymers were modified with an azide via end-group modification or with a maleimide via ring-opening polymerization (figure 1A). The countercurrent polymer gradients were created by a custom-made print head$^1$. The print head has two reservoirs with individual control over pressure and temperature, which is used to mix materials in a certain ratio (figure 1B). The material gradient in a single construct was confirmed by $^1$H nuclear magnetic resonance (NMR) and colored dyes. To confirm surface availability of the functional group, we attached complementary fluorescent dyes to single material scaffolds. An alkyn-TGF-$\beta$1 binding peptide$^2$ and a thiolated BMP-2$^3$ derived peptide were attached onto the surface to direct hMSC differentiation osteogenically and chondrogenically, respectively. hMSC differentiation on single and dual-material scaffolds was investigated by evaluating gene and protein expression such as RUNX2, Sox9 and extracellular matrix molecules. Furthermore, biochemical assays and histological analysis were performed. Finally, the scaffolds were implanted in a rat subcutaneous model to assess biocompatibility and cellular infiltration.

Results and Discussion
Synthesis and characterization of PCL-derived polymers with a terminal azide or maleimide was accomplished on a multi-gram scale (figure 1A). We were able to mass-produce constructs (figure 1C) in a high throughput fashion with our custom-made print head (18 scaffolds per run). Our material gradient was visualized by blending a dye into one of the polymer melts (figure 1D). $^1$H NMR analysis confirmed having functional groups and polymers on opposing sides of the scaffolds by the appearance of the methylenes of the maleimide (c and d) and depletion of the azide (b, figure 1E). Spectrofluorometric measurements confirmed surface attachment of fluorescent dyes in the nmol/cm$^2$ range. We assumed similar reactivity for our peptides as they based on the same click chemistry. Currently, we are looking into TOF-SIMS measurements to also confirm peptide binding, but encouraged by the spectrometry results we proceeded with cell experiments. We now aim to measure the up/downregulation of characteristic differentiation markers, such as gene expression or protein expression that are influenced by the peptide signals attached to the surface. In our rat model, we observed high cellular infiltration with or without attached peptides.
Conclusion
In this project, we have successfully printed 3D constructs with a continuous material and functional group gradient without creating discrete interfaces. Fluorescent dyes validated availability of the functional groups on the surface. Moreover, due to the nature of click chemistry, we made a chemical versatile system in which numerous modified peptides or bioactives could be attached onto the surface. The surface gradients can be exploited to improve biomimicry for OC constructs by gradually directing cell differentiation.

Co-axial 3D printed composite biopolymer scaffolds based on AlgMA/GelMA for bone tissue engineering

Amanzhol Turlybekuly, Aruzhan Naren, Dana Akilbekova

Nazarbayev University, Department of chemical and materials engineering, Nur-Sultan, KZ

Introduction
Trabecular bone is a dynamic, multifunctional tissue that goes through continuous remodeling process by osteoclasts and osteoblasts paired action [1], [2]. Polymeric scaffolds that mimic essential extracellular complexity and cellular processes of trabecular bone cavities can be used to mimic the natural bone regeneration process and create three-dimensional (3D) in vitro models to study bone osteogenesis and pathology. For that purpose, 3D bioprinting (3DP) provides the ability to manufacture reproducible 3D structures with well-defined spatial cell location [2]. Here, we describe a coaxial 3DP capable of printing simultaneously two bioinks that can contain separately various cell types [3], [4]. High fidelity 3DP of cell-laden scaffolds depends on the bioink that possesses favorable physical characteristics such as shear thinning to be printable and at the same time the ability to retain its shape after printing. In present study we used alginate (Alg) and gelatin (Gel) based bioinks with phototunable mechanical properties for creating 3D engineered bone tissues.

Experimental Methods
Co-axial nozzle was developed according our design and produced by SLA FormLabs 3B printer. The advantage of this co-axial nozzle is the ability to use of standard conical nozzles (18G-27G) as inner (core). Moreover the design of co-axial nozzle allows to control the core filament diameter by regulation of pressure (as an issue the current velocity). Methacrylated Gel and Alg were printed using co-axial nozzle adapted for the Cellink, Inkredible bioprinter. GelMA was used for creating core filament diameter, because it has higher mechanical properties and works as scaffold support. During printing, a lattice-rod model was extruded at the pressure of 30kPa for core nozzle and 34 kPa for shell nozzle. The scaffolds were photo-crosslinked with UV for 5 min and 0,25 M CaCl2 solution for 10 min. Rheological properties, printability, mechanical properties and scaffold morphology were systematically investigated.

Results and Discussion
Rheology studies showed the shear-thinning behavior for all AlgMA and GelMA based bioinks. Higher GelMA content decreased the degradation rate after 14 days in culture medium.

Conclusion
In summary, the co-axial nozzle for Cellink Inkredible bioprinter was developed. The composite AlgMA/GelMA scaffolds were produced by use co-axial nozzle. The composite scaffolds are beneficial by tunable mechanical properties that provide control over biodegradation. The disadvantage of that method is a lower degree of core element dual crosslinking by calcium due to gradient diffusion from a shell. Future studies will investigate the mechanical properties enhancement of core element by increasing photoinitiator concentration. The construction of a co-axial nozzle allows controlling core filament diameter by increasing the pressure in the printhead and bioink consumption.

Optimization of novel 3D composite scaffolds for bone reconstruction

Ana Monteiro1,2, Aurora Perez Jimenez1, Erwan Plougonven2, Stéphanie Lambert2, Christian Grandfils1

1 University of Liège, CEIB-CEntre Interfacultaire des Biomatériaux, Liège, BE; 2 University of Liège, Chemical Engineering Department, Liège, BE

Introduction

Custom-made scaffold-mediated regeneration is an emergent field in bone reconstruction. However, the optimization of 3D degradable implants with suitable biological response and mechanical features still remains challenging today. The focus of this study was to tailor a 3D scaffold made from a polymeric macroporous matrix filled with hydroxyapatite (HA) and amphiphilic hydrogel. Accordingly, three different implant designs composed of PLA have been developed by 3D printing with various interconnected porous in an optimal range of 300 to 600 µm. In a second step, the scaffolds have been filled with an amphiphilic gel containing HA in order to optimize the dissolution rate of the gel and its ability to enhance cell colonisation and proliferation.

Experimental Methods

3D matrix manufacturing was performed by Prusa I3MK3 printer using degradable PLA filament. The resulting scaffolds were characterized by Micro-computed tomography (CT) in order to analyse their porosity (total area, volume and size distribution of the pores). Hydrogel dissolution studies were assessed in PBS buffer at 37 °C and cell permeability were evaluated via diffusion of different polystyrene beads (2 to 10 µm).

Results and Discussion

The scaffold design was satisfactory optimized with pore size around 600 µm. The scaffold porosity plays an important role in the vascularization and cell proliferation, hence, in the integration of these implants in the body. On the other hand, the amphiphilic gels were quickly dissolved in PBS buffer at 37 °C, indicating that future efforts should be devoted to increase the cohesiveness of the physical reticulated polymeric network.

Conclusion

In conclusion, this work represents an attractive strategy for bone reconstruction by proposing composites made of a polymeric scaffold filled with an inorganic HA dispersed in a soft biocompatible hydrogel. The opened porosity of this biocomposite should promote cell colonization. However, further efforts should be required to adjust the stability of the amphiphilic gel to promote cell colonization and tissue rebuilding.

Introduction
Bone replacement for critical-sized defects like after infection or cancer debridement is still a major issue in bone surgery. Autografts are still the materials of choice but have disadvantages like low availability and donor site morbidity. Therefore, the aim of the presented work is the development of a biodegradable implant material for non-load-bearing implantation sites which supports the formation of new bone and in the end is replaced by it.

Experimental Methods
In a first step nano- and macroporous bioactive glass scaffolds are produced via a foam templating procedure. Polyurethane foam is repeatedly soaked with a bioactive glass precursor solution. After coating and drying the initial foam is removed by calcination at 600 °C [1]. To overcome the inherent brittleness of the bioactive glass, the replicas are coated with the biodegradable polymer polyglycerol sebacate (PGS) [2]. Additionally, we developed a new phosphate derivative of the latter and tested it in comparison to PGS.

Results and Discussion
The bioactive glass replicas exhibited nanopores with a diameter of 5 nm and a high inner surface area for further functionalization. For example, the nanoporous system could be equipped with strontium ions to support bone formation. The three-dimensional interconnected macroporous structure of the initial foam template is well reproduced. The polymer coatings (PGS and the phosphate derivative) on the bioactive glass replicas led to an elastic composite material, which was proven via compression tests. This improvement enables typical press-fit implantation in the defect without collapse of the macroporous structure, which is a crucial factor for good biointegration. Release experiments show long-term delivery of relevant ions like calcium, phosphate, and silicon, which will support osteogenesis while degradation of the scaffold. Good biocompatibility was proven via cytotoxicity and cell adhesion tests with dental pulp stem cells. In vivo experiments in an observation chamber model confirmed a fast vascularization of the scaffolds in contrast to the control group.

Conclusion
The combination of nano- and macroporous bioactive glass replicas coated with the elastic PGS and its phosphate derivative proved to be promising candidates for effective bone replacement. Especially, the newly developed phosphate derivative of PGS showed promising results in all investigations and will now be tested in terms of its osteogenic differentiation capability.

Electrospun composite scaffolds with PHBV and HA particles for bone tissue regeneration

Joanna E. Karbowniczek, Lukasz Kaniuk, Krzysztof Berniak, Adam Gruszczyński, Urszula Stachewicz

AGH University of Science and Technology, Faculty of Metals Engineering and Industrial Computer Science, Krakow, PL

Introduction

Biomimetic approaches in designing scaffolds for tissue engineering are gaining more and more attention. To address the requirements of each tissue the right composition, structure and properties of supportive materials are needed. Bone is a natural composite build of collagen fibers and hydroxyapatite (HA) crystals. Therefore, in this study scaffolds combining poly(3-hydroxybutyric acid-co-3-hydrovaleric acid) (PHBV) and HA nanoparticles were prepared by blend electrospinning [1].

Experimental Methods

Two solutions: 8% PHBV and 8% PHBV+1% HA in solvents mixture: chloroform and dimethylformamide (DMF) (9:1, v/v) were prepared by stirring for 4 hours. Both solutions were electrospun using an EC-DIG device (IME Technologies) by applying 17kV to the needle distanced at 20 cm to the collector. Fibers morphology was studied by scanning electron microscopy (SEM, Merlin, Zeiss) followed by focused ion beam (FIB) sectioning to expose fibers interior. Additionally, energy dispersive X-ray spectroscopy (EDS, Brucker) was used to confirm HA particles incorporation into PHBV fibers. In vitro studies with MG-63 cells were performed up to 7 days of incubation. Cell proliferation was evaluated using Cell Titer-Blue® Assay and cell morphology was studied by confocal and SEM imaging.

Results and Discussion

Randomly oriented smooth fibers with an average diameter of 2.92 ± 0.28 μm were obtained from electrospinning of PHBV solution. Addition of HA particles caused formation of porous fibers (Fig. 1 A, B), with increased diameter of 3.76 ± 0.37 μm. Ceramic particles were present both inside fibers as well as exposed on their surface. Based on proliferation test and confocal imaging results, the higher cell number was observed on composite PHBV+HA scaffolds compared with solely PHBV fibers. Especially significant boost in cell proliferation was observed between 4th and 7th day of incubation. Microscopy imaging enabled to visualize cells elongation, filopodia formation and penetration in depth on both type of scaffolds. Importantly, PHBV+HA fibers due to particles on their surface provided more anchoring points for cells spreading, therefore, higher cell number with longer filopodia were observed for composite scaffolds (Fig. 1 C and D).

Conclusion

In this study we showed that by simple approach of blend electrospinning combining PHBV and HA we could obtain scaffolds improving bone cells proliferation and growth. Therefore, we proved that such composite scaffolds are a very promising material for bone tissue regeneration.

Influence of pectins and other polymer additives on the properties of biomicroconcrete type bone substitute materials

Aneta Zima, Piotr Pańtak, Joanna Czechowska, Ewelina Cichoń, Anna Ślósarczyk

AGH University of Science and Technology, Faculty of Materials Science and Ceramics, Krakow, PL

Introduction
The continuous efforts of scientists to create new and improved implants for the regeneration of bone tissue and the increased demand for bone replacement biomaterials lead to many innovative materials solutions. An interesting concept is the development of biomicroconcretes [1]. This type of materials consists of granules that are embedded in the biocompatible bone cement matrix. Surgically handy biomicroconcretes could be a new solution for tissue engineering allowing for easy adjustment of the material to the complex shape of bone defect. They can act as an alternative to commonly used sintered ceramic implants of predefined shape and size.

In this study, new hybrid biomicroconcretes with high surgical handiness were developed. Solid phase of the investigated materials composed of highly reactive α-tricalcium phosphate powder (α-TCP) and hybrid hydroxyapatite-chitosan (HAp/CTS) materials (in the form of granules of 300–400 μm and powders). The new idea of using the citrus pectin solution (5 wt%) as the cement liquid phase was applied. Moreover, the obtained biomicroconcretes were modified by adding into the solid phase polymer additives such as sodium alginate (SA) or hydroxypropyl methylcellulose (HPMC).

Experimental Methods
The initial highly reactive α-tricalcium phosphate (α-TCP) powder was synthesized by the wet chemical method according to the procedure described by Zima et al. [2]. The hybrid hydroxyapatite-chitosan granules were prepared after 48h freezing of hybrid hydroxyapatite-chitosan precipitate according to the previously developed method by Zima et al. [1]. To prepare granules, the obtained precipitate was sieved and dried at 40 °C to receive granules of 300-400μm. Biomicroconcretes were prepared by mixing α-TCP powder with hybrid hydroxyapatite-chitosan material (with 15, 20 and 25% wt.% of chitosan) in the forms of a precipitate, powder and granules. To the powder phase of biomicroconcretes also polymeric additives i.e. sodium alginate and hydroxypropyl methylcellulose were added in the amount of 2 or 4 wt.%. In order to prepare cement pastes, the citrus pectin solution was added into the well-mixed compounds of the solid phase and hybrid precipitate (L/P= 0.8). Then, the physicochemical and biological properties of the obtained biomicroconcretes were determined.

Results and Discussion
The new generation of fully injectable biomicroconcrete-type biomaterials combining α-TCP powder, hybrid hydroxyapatite-chitosan materials in the form of powder and granules and polymeric additives in the form of gel (pectin) and powder (sodium alginate or HPMC) were successfully obtained and investigated. After 7 days of setting and hardening in air, materials possessed two crystalline phases which were HAp and α-TCP. FTIR analysis of the studied materials confirmed the presence of functional groups characteristic for hydroxyapatite and polysaccharides such as chitosan or pectin (figure 1). The compressive strength (5.38 up to 17.2 MPa after 7-days after setting and hardening, and 1.56 up to 13.23 MPa after 7-days of incubation in SBF) was similar to that of human cancellous bone and allowed for low-load bearing applications [3]. The SEM observations revealed that obtained biomicroconcretes are characterised by the presence of numerous polymeric bridges between granules and the matrix which can suggest the occurrence of the system of various bonds in their structure (figure 2). Results showed that developed materials were chemically stable in SBF.

Page 1610 of 2028
Conclusion
Studies have shown that obtained biomicroconcretes have unique physicochemical properties due to the dual setting system originated from hydrolysis of α-TCP and gelation of pectin. Polymeric additives have shown the promising potential of using them as modifiers of developed hybrid materials. The properties of the manufactured biomicroconcretes result directly from the characteristics of the starting components as well as the presence of various bonds due to interactions between the biopolymers. Developed innovative biomicroconcretes based on hybrid HAp/CTS granules, highly reactive α-TCP powder and the citrus pectin can be prospective injectable materials for regenerative medicine.

The efficiency of bone and cartilage decellularization by means of High Hydrostatic Pressure

Christopher D. Pohl1, Charlotte Koppe1, Nico Brandt1, Janine Waletzko-Hellwig2, Friederike Poosch3, Daniel Strüder3, Michael Dau2, Rainer Bader4, Michael Schlosser1

Introduction
The tissue replacement by allogenic materials is of increasing importance in clinical practice. To ensure optimal transplantation outcome, it is of utmost importance to reduce immunogenicity to minimize adverse inflammatory effects in recipients. The established decellularization methods are chemical treatment and/or β- and γ radiation. However, these methods also affect matrix integrity. Therefore, High Hydrostatic Pressure (HHP) is currently under investigation for the decellularization/devitalization of allotransplantation tissue. It utilizes pressure levels up to 500 MPa to induce apoptosis in cells, while preserving matrix integrity and biomechanical features. Especially for supportive tissue such as bone and cartilage, structural integrity is important for transplant functionality and host integration. Yet important aspects of this promising method remain unknown including proof for a full inactivation of tissue specific cells prior to implantation. Though cell devitalization is well documented, matrix compartments and cell debris could still pose an immunological/inflammatory risk, which might also effects the matrix integrity. Therefore, this in vitro study investigated different HHP treatment protocols with and without additional washing steps on bone- and cartilage tissue regarding decellularization by means of quantitative histological imaging.

Experimental Methods
Tissue samples were extracted post mortem from organ donors in the Institute of Anatomy of the University Medical Center Rostock with the apprroval of the local ethical committee (case number A 2016-0083). Following extraction, tissue samples were kept in PBS and HHP treated with either 250 mPa (Bone) or 450 mPa (cartilage) for 10 minutes. Additionally, selected samples received treatment with ultrasound in a washing chamber, to wash out debris created by the HHP. After treatment, all samples were fixated for 24 h with buffered 4% formaldehyde-solution at room temperature followed by a washing step of 2 hours in tap water. Bone tissue was further decalcified via aqueous EDTA-ammonia solution up to 14 days. Pre-treated tissue samples were placed in an embedding medium consisting of TissueTek®/PBS solution and shock frozen in liquid nitrogen, followed by preparation of cryosections of 10 µm thickness with a Leica CM 3050 S Cryotome. Hematoxylin and Eosin (H&E) staining was performed according to standard protocols. For morphometric analysis of the sections, pictures were taken with a Olympus 20 camera (Olympus K.K., Tokyo, Japan) and analysed by the ImageJ software. To compare different treatments of tissues, quantitative data were analysed by Mann-Whitney-Test (Cartilage) or a one way ANOVA (Bone) using the GraphPad Prism software.

Results and Discussion
Bone and cartilage revealed no macroscopic differences in structure and general appearance after HHP treatment (Figure 1). Both showed a significant reduction in cell number after treatment with HHP (Figure 2). For bone tissue HHP treatment resulted in an up to 10-fold reduction of median cell number per mm² (33.97, interquartile range IQR 25.66-49.82) in comparison to the untreated control (312.2, IQR 245.0-397; p<0.0001). The additional ultrasound treatment had no effect (257.7, IQR 183.8-351.9). The combined treatment by HHP and ultrasound, however,
resulted in a significant decrease up to 43.51 cells per mm² (IQR 34.55-112.7). For cartilage, HHD treatment also resulted in a significant (p<0.0001) up to three-fold reduction of cells per mm² in comparison to untreated controls (25.11 (IQR 14.8-32.38) vs. 76.47 (IQR 63.93-91.25), respectively).

Conclusion
Morphometric histological analysis demonstrates a significant, up to 10-fold reduction of cell number in bone and a three-fold reduction in cartilage caused by HHP treatment and in combination with ultrasound also for bone tissue. Since the ultrasound treatment alone showed no significant reduction in cell numbers, the main decellularization is most likely caused by HHD. No effect on the matrix structure as well as the general tissue appearance could be seen. Thus, the results indicate that HHD treatment is suitable method for a specific decellularization, however further efforts on the protocols, especially for the combination with more intense ultrasound procedures is needed.

Apatitic bone cements with effective antibacterial and antibiofilm ability

Massimiliano Dapporto1, Francesca Carella1, Marta Tavoni1, Elisa Restivo2, Livia Visai2, Laura Mercatali3, Toni Ibrahim3, Anna Tampieri1, Michele Iafisco1, Simone Sprio1, This work was supported by the Italian Ministry of Health (Bando Ricerca Finalizzata 2016, no. GR-2016-02364704

1 National Research Council of Italy, Institute of Science and Technology for Ceramics, Faenza, IT; 2 University of Pavia, Molecular Medicine Department, UdR INSTM, Pavia, IT; 3 IRCCS Istituto Romagnolo per lo Studio dei Tumori (IRST), Osteoncology and Rare Tumors Center, Meldola, IT

Introduction
Self-hardening pastes and cements based on calcium phosphates are widely used biomaterials for several clinical applications, including spinal fusion, vertebroplasty and periodontal surgery. Their preparation involves the mixing of solid powder and liquid components, which then self-harden in vivo and transform into nanostructured, nanocrystalline apatitic phases. However, the occurrence of bone infections, i.e. osteomyelitis or bone tuberculosis, still represents a major responsible of therapy failure in orthopaedics. If bone infections occur, the clinical protocols usually include the long-term oral administration of antibiotics, which however is characterized by limited bioavailability of the drug at the healing site and, often, provoking the occurrence of systemic adverse side effects. A further drawback is represented by the bacterial resistance to antibiotics, which is widely considered as a major threat in medicine and particularly in orthopaedics in the incoming years. In this scenario, the development of biomaterials with regenerative ability and effective antibacterial and antibiofilm properties is a goal of ever-increasing relevance. Key aspects are the ability of biomaterials to prevent bacterial adhesion and proliferation, thanks to bioactive composition and surface texture, as well as the ability to act as carrier able to release drugs in situ in a sustained and therapeutically effective manner. The present work describes a novel approach to prepare osteointegrative Sr-doped apatitic bone cements featuring nanostructured architecture and capable of controlled release of tetracycline (TC), intended as broad-spectrum antibiotic, but also chemically close to anthracyclines, another wide group of drugs commonly used as first-line chemotherapeutic treatment of osteosarcoma and other solid tumors as breast cancer.

Experimental Methods
Firstly, the synthesis of nanocrystalline biomimetic apatites was performed by wet chemistry, followed by surface adsorption of TC. Then, drug-loaded bone cements were obtained by mixing proper amounts of TC-loaded nanoparticles (TC-NPs) to Sr-doped α-tricalcium phosphate powders and aqueous solutions enriched with sodium alginate. The antibacterial and antibiofilm effectiveness of native and TC-loaded cements was evaluated by microbiological tests assessing the viability of Staphylococcus aureus and Escherichia coli, among the most diffuse bacterial strains in nosocomial infections, proving substantial bacteriostatic and bactericidal properties in the native cement and complete eradication of bacterial cultures in the TC-loaded device.

Results and Discussion
The injectability, setting times and drug release profile of these final pastes were optimized according to the clinical need. A possible application is the treatment of cancer patients with implantation of self-hardening pastes and cements during surgery or radiological interventions. In order to achieve an antitumoral effect, specific concentrations of anthracyclins should be delivered. Clinical pharmacokinetic profiles of the drug administered systemically and locally are used to identify the correct concentration to be delivered in order to optimise the therapeutic effect and avoid toxicity. Chemotherapeutics concentration were setted at 0.6-1.2 ug/ml with a delivery duration within three four days. An extensive physico-chemical characterization of the cements was performed. The presence of TC-loaded apatites allowed to modulate the drug release profile in physiological conditions, if compared with the formulation...
without NPs. This work proved the ability of apatitic cements to contrast bacterial infections only by virtue of their composition and nanostructure and, furthermore, to act as a drug carrier capable of effective and controlled release, thanks to the possibility to modulate the release profiles by implementing the cement with apatite nanoparticles able to chemically link the drugs.

**Conclusion**

These results are relevant in the view of design and development of new devices for bone regeneration, more effective to improve the patient safety and clinical outcomes, and potentially able to limit or even prevent the use of drugs, thus aiding to contrast the steady increase of bacterial resistance to antibiotics.

Dental implants surface roughness can influence bacterial site infection? A clinical in vivo prospective clinical study on 109 patients, preliminary results on radiologic evaluation

Nicola De Angelis, Luca Solimei, Alberto Lagazzo, Fabrizio Barberis

University of Genova, Genova, IT

Introduction
Dental implants are intended to provide long-term reliable dental restorations. Limited data exist on the comparison between different implant surfaces. This study aims to investigate if the surface topography and roughness might increase the bacterial adhesion and intensify the possibility of implant failure in patients with and without a previous history of periodontal disease.

Surface topography and roughness are some of the aspects that can be easily manipulated by resorting to post-production surface treatments and that play an important role in the determination of cellular response, influencing adhesion, adsorption and differentiation. Bacterial activity and colonization is faster where the surface shows deep irregularities, thus in patients with high risk of periodontal disease and Gram negative anaerobic presence, different surface treatments might generate early failures and onset/recurrence of inflammatory periimplant diseases.

Some of the frequently used treatment techniques include sandblasting, acid etching and electropolishing; each one imprinting unique topographic features on the treated surfaces. By projecting pressurized particles, the sandblasting treatment delivers titanium surfaces with roughness values highly superior relative to the ones in a controlled polishing technique, and is responsible for the introduction of contaminants into the surface. Regarding the acid etching, the treatment with strong acids cleans the metal substrate and delivers homogeneous roughness attributes throughout the entire surface. In turn, electropolishing is a electrochemical process that delivers titanium surfaces with a bright, clean and smooth appearance, through the removal of a thin top layer of the material.

Experimental Methods
109 patients were included in the study. After comprehensive evaluation, including non-surgical and surgical therapy for the treatment of periodontal disease, 59 implants with sand-blasted surface (Straumann Basel Switzerland – SLA surface) and 50 implants double etched surface (Biomet 3i Palm Beach FL USA - Osseotite®) were placed according to the guidelines, provided by the two different manufacturers. Implants were received directly from the companies and surface treatments were declared as mentioned above. Before implant installation a profilometric analysis was done randomly on both groups. Each treatment site was subject to X-Ray examination at 3 to 6 months after the final coronal restorations were placed. Patients were enrolled in the follow up maintenance program and radiological evaluation was carried out at 5 and 10 years.

Results and Discussion
A total of 109 SLA and Osseotite® were placed at the beginning of the study. Data recorded from 91 patients who completed the final T2 follow-up were included in the analysis (SLA, n=50 and Osseotite®, n=41). At the 10-year interval, in periodontally compromised patients the DIB (Distance Implant-Bone) between SLA and Osseotite® was significantly different (p = 0.001, 95% CI of mean difference: 0.55, 1.89 mm). Mean (SD) DIB for SLA implants was 2.1 mm (1.1 mm) compared to 0.9 mm (2.1 mm) for Osseotite® Implants. The overall survival rate of SLA and Osseotite® implant surfaces is high over the period of observation.

Conclusion
In conclusion, only non statistical differences were found in terms of bone loss around the two different surfaces in healthy patients. In periodontally compromised population failures were noticed in both groups and bone loss was evident and higher than the acceptable values but not probably attributable to the different roughness. Thus the history of previous periodontal disease plays an important role in the incidence of complications, regardless of the type of surface. This investigation will be continued with the profilometric analysis of the explanted and failed implants, in order to assess whether the surface shows signs of wear over the period of permanence in the oral cavity.

Bioresorbable and Biomimetic Adhesives for Bone Repair and Regeneration

Antzela Tzagiollari1,2, Gerard Insley2, David Kelly2, Philip Procter3, Helen O. McCarthy4, Tanya J. Levingstone5, Nicholas Dunne1

1 Dublin City University, School of Mechanical and Manufacturing Engineering, Dublin, IE; 2 PBC Biomed, Shannon, IE; 3 GP Bio Ltd, Rathkeale, IE; 4 Queen’s University Belfast, Belfast, GB

Introduction
Complex bone fractures present significant challenges for orthopaedic surgeons [1]. Current surgical procedures involve the reconstruction and mechanical stabilisation of complex fractures using invasive techniques that often lead to poor clinical outcomes. An injectable, biocompatible, biodegradable bone adhesive that could glue bone fragments back together and at the same time meet clinical requirements presents a highly attractive solution [2]. This study aims to develop a new bioresorbable and biomimetic bone adhesive, comprised of alpha-tricalcium phosphate (alpha-TCP), phosphoserine and deionised (DI) water, with bone regenerative properties. Specifically, a phosphoserine-modified calcium phosphate cement (PM-CPC) will be developed and through analysis of chemical and biomechanical properties using Design of Experiment (DoE), the formulations that provide suitable setting and adhesive properties for application in bone repair will be identified.

Experimental Methods
The alpha-TCP powder was prepared by mixing calcium phosphate (CaHPO4) and calcium carbonate (CaCO3) at a 2:1 molar ratio (both from Sigma Aldrich) [3]. The powders were turbo-blended and heat-treated in a furnace (Elite BRF1600®, Elite Thermal Systems Ltd., UK) for 6 h at 1400 °C. Following rapid quenching using compressed air, the powder was subjected to particle attrition using a planetary mill (Pulverisette 6, Frisch, Germany) at a rotating speed of 600 ± 5 RPM for 5 min periods over 2, 6, 10, 11, 13 and 15 cycles. The physicochemical properties of the alpha-TCP powder were characterised in terms of particle size (laser diffraction particle analysis), morphology (SEM), phase purity (XRD) and chemical composition (FTIR spectroscopy). Alpha-TCP and phosphoserine (Flamma, S.p.A. Italy) at different percentages (10, 25, 40 wt.%) were combined with deionised water at liquid:powder ratio (LPR) ranging from 0.2, 0.35, 0.5 mL/g. the setting characteristics and biomechanical (compression and shear) properties were measured, analysed and optimised through DoE analysis.

Results and Discussion
XRD refinement technique confirmed the alpha-TCP demonstrated a phase purity of 99.9% (Figure 1a), which was corroborated by FTIR analysis. The particle size of the alpha-TCP powder reduced as a function of the number of attrition cycles (Figure 1b) with a D50 of 5.4±1.25 μm following 15 cycles. SEM analysis (Figure 1c) demonstrated the TCP-powder was non-spherical in morphology and also demonstrated a negative correlation (R² = 0.90) between the particle size and number of attrition cycle. The zeta potential of the alpha-TCP had an unstable range of -22.3 ± 0.36 mV. This difference was a function of the D50 value for the powder and agreed with findings of Valentim et al. [3]. The initial (t1) and final (t4) setting time of the PM-CPC increased as a function of particle size (Figure 2a), which agrees with previous studies [4]. Compression and shear properties were significantly increased as a function of phosphoserine, enhancing the adhesive/cohesive strength (Figure 2b, c).

Conclusion
Various compositions of PM-CPC have been successfully prepared. Initial results indicate the important role that particle size of the alpha-TCP powder plays in the setting properties. Measured biomechanical and adhesion properties were within the required clinical range [5]. These findings offer the potential to tailor the requirements of
the proposed bone adhesive for the treatment of bone fractures. Future work will optimise the rheological and biodegradation properties and also the *in vitro* and *in vivo* biocompatibility of the PM-CPC based bone adhesive.

Chondroprotective effects of ibuprofen-loaded PLGA nanoparticles in a pro-inflammatory condition

Cecília J. Alves, Alexandra Freitas, Marina Couto, Catarina L. Pereira, Daniela P. Vasconcelos, Beatriz Sousa, Bruno Sarmento, Raquel Gonçalves, Meriem Lamghari

Instituto de Investigação e Inovação em Saúde, NeuroSkeletal Circuits group, Porto, PT

Introduction
The inflammatory response initiated as a consequence of traumatic chondral lesion imposes a major challenge in cartilage repair. The released pro-inflammatory factors induce a shift in chondrocytes activity towards a catabolic metabolism and promote further cartilage degradation [1-2]. Several anti-inflammatory drugs have been proved to mitigate the deleterious effects of inflammation on the cartilage [2], and we propose the use of Poly(lactic-co-glycolic acid) (PLGA) nanoparticles loaded with ibuprofen as a strategy to deliver locally an anti-inflammatory treatment.

Experimental Methods
In this work, we aimed to evaluate the chondroprotective and chondrogenic effects of the ibuprofen-loaded PLGA nanoparticles. To achieve this, human chondrocytes cultured as 3D pellets under an inflammatory condition (stimulation with 100ng/mL of IL-1b), were treated with PLGA nanoparticles loaded with 15 or 30 mg/mL of ibuprofen. Effects on the chondrocyte activity were assessed on day 3 of exposure.

Results and Discussion
The results showed that the PLGA nanoparticles loaded with 30 mg/mL of ibuprofen induced, under inflammatory conditions, a decrease in the mRNA expression levels of metalloproteases, such as MMP-1 and MMP-9 and MMP13. Moreover, data from the immunohistochemical analysis showed that the treatment with PLGA-Ibuprofen 30μg/mL NPs induced the recovery of collagen II expression, and the expression of aggrecan also recovered after treatment with PLGA-Ibuprofen 15μg/mL.

Conclusion
Altogether, the obtained data suggests that treatment with ibuprofen-loaded PLGA nanoparticles mitigates the chondrocytes’ extracellular matrix degradation activity induced in an inflammation scenario.

Acrylate plasma polymerised 3D scaffolds for bone regeneration

Vineetha Jayawarna\textsuperscript{1}, Jane McLaren\textsuperscript{2}, Felicity Rose\textsuperscript{2}, Matthew Dalby\textsuperscript{1}, Manuel Salmeron-Sanchez\textsuperscript{1}

\textsuperscript{1} University of Glasgow, School of Engineering, 1Centre for the Cellular Microenvironment, Glasgow, GB; \textsuperscript{2} University of Nottingham, School of Pharmacy, Faculty of Science, Nottingham, GB

Introduction

Worldwide, more than 2.5 million bone grafts are carried out annually at a cost of approximately $3.4 billion, being the second most commonly transplanted tissue after blood\textsuperscript{1}. Bone grafts are used to provide stability, to replace missing bone from trauma, congenital defects, cancer etc., or to stimulate osteogenesis. However, current bone grafts, which mainly include autograft and allograft, are associated with several drawbacks such as limited availability, donor-site morbidity and pain, inflammation, risk of infectious disease transmission and immune rejection. Tissue engineered bone grafts have emerged as an effective solution to regenerate bone defects while addressing these shortcomings\textsuperscript{1}. In particular, three dimensional (3D) porous synthetic scaffolds made from bio-degradable materials with favourable osteogenic ability and mechanical properties produced using additive manufacturing offers promising conditions for bone repair and regeneration. Efficient presentation of proteins and growth factors (GFs) is however a major challenge when using synthetic materials for tissue engineering. Fibronectin (FN), an extracellular matrix protein that regulates cell adhesion, binds GFs via specific structural domains, offering synergistic signalling effects on mammalian cells. Here we used an inductively coupled plasma system to modify 3D printed polycaprolactone (PCL) scaffolds with a nanometer-thick coating of poly (ethyl acrylate) (PEA), a polymer known to induce FN organisation into a nanonetwork exposing its integrin and GF binding domains\textsuperscript{2,3}. Bone morphogenetic protein-2 (BMP-2) was used to promote osteogenic differentiation, osteointegration and bone regeneration. Human mesenchymal stem cell (hMSC) adhesion and differentiation were assessed in different scaffold geometries at the protein-GF interface to determine the overall efficiency of the system. The chick chorioallantoic membrane (CAM) assay was used to explore the angiogenic potential of the scaffolds. In addition, the coated scaffolds were subcutaneously implanted into rats to assess early-stage osteogenesis and vascularization.

Experimental Methods

Five different scaffold geometries (0/30°, 0/45°, 0/60°, 0/90°, 0/45/90/135°), utilizing various stack angles were designed using an extrusion-based fused filament deposition 3D bioprinter. A custom-built inductively coupled plasma chamber was used to deposit PEA onto printed scaffolds via plasma polymerisation. The efficiency of plasma polymerization, as well as FN adsorption and interaction with BMP-2, on PEA coated PCL scaffolds was evaluated. We then studied the \textit{in vitro} ability of PEA/protein coated PCL scaffolds to facilitate cell proliferation and osteoblast differentiation. The two optimal modified PCL scaffolds were then implanted into rat subcutaneous pouches, for a duration of 12 weeks, with micro computed tomography and histology used to evaluate ectopic bone formation and early-stage vasculature.

Results and Discussion

Porous PCL scaffolds with different angles were printed successfully. X-ray photoelectron spectroscopy (XPS) results confirmed the deposition of PEA coating throughout the entire 3D structure of scaffolds. ELISA results confirmed significantly higher availability of integrin and GF binding domains on PEA-coated scaffolds. Scaffolds coated with PEA/FN/BMP-2 showed improved cell growth, matrix deposition and osteogenic differentiation compared to uncoated scaffolds. Scaffolds with 0/60° interlayer rotation angles significantly enhanced the cell growth and differentiation compared to the other scaffold geometries. \textit{In vivo}, both coated and non-coated implanted scaffolds
were fully infiltrated with highly vascularised soft tissue and low levels of calcium deposits were detected using von Kossa staining.

**Conclusion**

We propose that our functionalised 3D scaffolds which significantly enhance MSC osteogenesis hold great promise for bone tissue regeneration and this new GF delivery mechanism should maximise the clinical effectiveness and reduce the side effects of BMP-2. Further work will include the testing of the optimised scaffold within a larger animal bone defect model.

Introduction
Nanomedicine is an emerging field of biomedical research and is defined as the applications of nanomaterials for diagnosis, monitoring, control, prevention and treatment of diseases. One of the most promising field in nanomedicine is the development of nanosized drug carriers to deliver anticancer drugs. Nanoparticles are characterized by very high surface/volume ratio, thus promising to control the drug adsorption and release. Moreover, nanoparticles may be capable to protect the drug from premature degradation. The possibility to use calcium phosphate nanoparticles as carriers for local and controlled delivery of drugs is attractive. Traditionally, apatite-based materials are used for bone regeneration applications due to their properties such as osteoinductivity and bioactivity. Furthermore, they are provided with low-cost production, low toxicity, high biocompatibility, biodegradability, tuneable chemical-physical properties and pH-dependent dissolution profile. This latter property comes to be very useful in case of tumor tissue, generally associated with lower pH.

Experimental Methods
In this work, hydroxyapatite nanoparticles (NPs) were developed by wet chemistry at low temperature and characterized, followed by the surface adsorption of doxorubicin (DOX), a drug commonly used in cancer chemotherapy. Then, the as-obtained DOX-NPs were mixed with Sr-doped α-tricalcium phosphate and aqueous solutions enriched with natural polymers, in proper amounts to obtain calcium phosphate bone cements with setting times and drug release profile according to clinical need [1-5]. The biological performance of the DOX-loaded cements on triple negative breast cancer (TNBC) cell line MDA-MB-231 was also assessed by the mitochondrial reduction assay 3-(4,5-Dimethylthiazol-2-yl)-2,5-Diphenyltetrazolium Bromide (MTT) which is used to measure cellular metabolic activity as an indicator of cell viability, proliferation and cytotoxicity.

Results and Discussion
The drug release profiles from both DOX-NPs and DOX-loaded cements were performed at physiological pH in HEPES medium, showing concentrations according to the in vivo pharmacokinetics values. The biological results showed a significant decrease in the TNBC cell line proliferation rate cultured on DOX-NPs loaded cements compared to unloaded control.

Conclusion
The obtained results demonstrate the potential of DOX-NPs to be included in apatitic cements addressed to bone regeneration which can act as smart drug delivery systems, promising for more effective local treatment of bone cancer.

Strontium functionalisation of diatom frustules for bone regeneration

Andrew Reid¹, Fraser Buchanan², Matthew Julius³, Pamela Walsh²

¹ Queen’s University Belfast, Chemistry & Chemical Engineering, Belfast, GB; ² Queen’s University Belfast, Mechanical & Aerospace Engineering, Belfast, GB; ³ St Cloud State University, School of Biological Sciences, St Cloud, US

Introduction

Diatoms are a class of eukaryotic microalgaes¹ primarily found in aquatic environments. They are unique in that their cell walls (frustules), are composed of biogenic silica and have a very intricate structure. This structure is highly porous, nanopatterned and has a large surface area (~10 to 300 m²g⁻¹), which is identically replicated from generation-to-generation within the same diatom species. Additionally, it has been shown that diatoms have the ability to incorporate material other than silica into the frustule, allowing for diatoms to be doped to add functionality³⁻⁸.

Within our research we plan to modify the frustule of Cyclotella meneghiniana with Magnesium²⁺ and Strontium²⁺ ions using an in vivo feeding method as this could have the potential to be further developed into a novel implantable (bone tissue regeneration) technology. Research from within our own group has already shown that “diatom biosilica is non-toxic and does not invoke a pro-inflammatory response”¹. Magnesium and strontium were chosen as they have been shown to be beneficial for bone formation & health. We will characterise the doped diatoms with a vast array of analytical techniques, including SEM, EDAX, AFM, ICP & TGA in order to determine the extent & location of the ion incorporation. It is well documented within the literature that an “in-vivo feeding” approach has been successful in incorporating various metals, such as Calcium³⁻⁷,⁸, Germanium⁴, Iron⁵ and Titanium⁶ into the frustules of different species of diatoms, which is good supporting evidence for the viability of our research.

Bone regeneration therapies and implantable materials will be in increasing demand due to the increasing diagnosis rates of bone degenerative diseases such as osteoarthritis and osteoporosis. These conditions are often overlooked however their rates of diagnosis are on the rise due to a generally aging population⁹.

Experimental Methods

The diatom selected for this study is C. meneghiniana (which was isolated from the Mississippi River, USA), which will be cultured in D.I. H₂O enriched with Guillard F/2 solution containing the Mg & Sr 2+ ions in the form of their chloride salts. Silicon depletion of the diatoms will be carried out similarly to Hildebrand (et al.)¹⁰, in order to increase metal uptake. Post culturing, samples were cleaned to remove the residual organic material¹. Initial characterisation of the diatoms was be carried out, using Spectroscopy, Scanning Electron Microscopy (SEM) and Energy-dispersive X-ray spectroscopy (EDAX).

Results and Discussion

SEM images in Fig 1 (a and b) show the morphology of the frustules of C. meneghiniana prior to doping with a typical particle size of 12 to 14 mm. In the doped samples preliminary results have shown that Sr is being taken up into the diatoms’ frustules. EDAX results confirmed the uptake of strontium (Fig. 2a) whereas no Sr was detected in the control (Fig 2b). The concentration of Sr in the doped samples was quantified to be 4.08(±0.93) atomic weight percentage (n=10).

Work is now underway to fully characterise the doped diatom frustules using AFM, EDAX, SEM, ICP & TGA in order to assess their potential in bone repair.

Conclusion
In conclusion we hope to present the functionalisation of diatom frustules with magnesium and strontium ions. This may provide a potential new biomaterial for bone regenerative medicine.

The Effect of Needle Diameter on the Diameter of Electrospun PCL Microfibres

Moresche G. Bartley, Kathleen E. Tanner

Queen Mary University of London, School of Engineering and Materials Science, London, GB

Introduction
A successful Bone Tissue Engineering scaffold requires biocompatibility, mechanical properties, biodegradability or lack thereof and scaffold architecture. The attachment, migration and proliferation of cells are fundamental to the formation and regeneration of bone tissue (O’Brien et al., 2011). Electrospinning is a fabrication technique used to create fibrous scaffolds which can resemble the native structure of the extracellular matrix environment. In this study, we investigated the effect of needle diameter on the diameter of electrospun (Polycaprolactone) PCL microfibers.

Experimental Methods
15% w/v of PCL (80,000 Mw) in chloroform was used to prepare electrospun microfibers. Needle sizes 10, 12, 14, 16 and 18 gauge, giving internal diameters (ID) of 2.69mm, 2.16mm, 1.60mm, 1.19mm and 0.84mm respectively, were used. The electrospun fibres were collected on a rotating mandrel. Parameters such as flow rate (2ml/hr), voltage (19.2kV), humidity (50%), temperature (17°C), distance 13cm and the speed (350 rpm) of the rotating mandrel were optimised and then remained constant. Fibre mats were characterised using Scanning Electron Microscopy (SEM) at a magnification of x1,000 and the diameter of the microfibres and intra-fibre spaces, but not the nanofibres, were measured using ImageJ software.

Results and Discussion
The PCL fibres formed had microfibres diameters ranging from 0.8-27µm (Figure 1). The resulting electrospun fibres demonstrated that fibre diameter can be controlled by the ID of the electrospinning needle (Figure 2). Small needle diameters such as gauge 18 and 14 (0.84mm and 1.60mm ID respectively) produced thinner microfibres with minimal needle blockages during the electrospinning process. Furthermore, needles with large IDs such as gauges 10 and 12 (2.69mm, 2.16mm respectively) frequently developed needle blockages but resulted in larger fibre diameters. A mixture of micro and nanofibers were observed for needles with a small ID such as gauge 14 (1.60mm). The instability of the Taylor cones formed caused the electrified jets to form secondary branching, fabricating thinner fibres branched off from the main electrospinning jet.

Conclusion
The ID of an electrospinning needle influences the diameter of fibres within a scaffold. This is most likely controlled by the size of the jet released from the needle tip. Further work will focus on using stop motion imagery and high-speed photography to identify changes in the electrospinning jets and the resultant fibres.

Introduction
Cartilage lesions have become a major health problem worldwide because of the limited regenerative capacity of articular cartilage following trauma or chronic joint disorders like osteoarthritis (OA)¹. Despite multiple efforts in addressing this clinical need, there are no efficient and long-lasting therapies available for promoting cartilage regeneration². Tissue engineering approaches, combining a range of biomaterials, cells, and growth factors, could provide prospecting alternatives³-⁴. Several unanswered questions and aspects of this technology remain to be elucidated to expand its clinical application. There is still a lack of understanding of the role of specific biomaterials in modulating molecular signaling pathways during in vitro chondrogenic differentiation. Previously we have reported silk fibroin-gelatin (SF-G) bioink using progenitor cells or mature articular chondrocytes to make phenotypically stable engineered articular cartilage⁵. Therefore, we aim to identify the role of SF-G bioink in modulating in vitro chondrogenic signaling pathways in human bone marrow-derived stromal cells (hMSCs) using detailed proteomics analysis.

Experimental Methods
Silk gelatin-based 3D bioprinted constructs, composed of 5% bombyx mori silk fibroin (SF) and gelatin (G) were encapsulated with hMSCs through the bioprinting platform (3D Discovery, RegenHU). SF-G constructs were cultured with D-MEM high glucose with and without chondrogenic factors (GFs). Cell viability assessment and chondrogenic differentiation through histology, gene expression analyses by Real Time PCR and protein by immunohistochemistry and PANTHER and DAVID analyses were carried out. Chondrogenic differentiation was monitored at 1, 14 and 28 days.

Results and Discussion
SF-G 3D bioprinted constructs resulted biocompatible ensuring high percentage of cell viability. Gene expression analyses displayed a high expression of COL2, SOX9, COMP, ACAN and low expression of COL1 and COL10 in chondrogenic 3D bioprinted SF-G-compared to control. The interaction between SF-G bioink and hMSCs augmented several chondrogenic pathways, including Wnt, HIF-1, and Notch as explored with PANTHER and DAVID analysis. We elucidated the debatable role of TGF-β signaling in vitro, by assessing the differential protein expression by hMSCs-laden bioprinted constructs in the presence and absence of TGF-β3. We revealed a direct role of TGF-β3 in generating stable chondrogenic differentiation. hMSCs-laden bioprinted constructs contained a large percentage of collagen type II and Filamin B, typical to the native articular cartilage. Hypertrophic markers were not identified following TGF-β3 addition.

Conclusion
This is the first study reporting such extensive proteome profiling of the in vitro silk based bioprinted constructs. The SF-G bioink positively modulated the expression of cartilage-specific ECM components by emphasizing the regenerative potential of this 3D bioprinted SF-G bioink system for cartilage regeneration.

Effect of silane-containing gas flame surface pretreatment on the flexural strength of veneered Y-TZP ceramic before and after \textit{in vitro} aging

Katia Sarafidou\textsuperscript{1}, Eleni Siarampi\textsuperscript{1}, Lambrini Papadopoulou\textsuperscript{2}, Nikolaos Kantiranis\textsuperscript{2}, Eleana Kontonasaki\textsuperscript{1}, Petros Koidis\textsuperscript{1}

Introduction
A common design in prosthodontics consists of a zirconia restoration veneered with a feldspathic layer. The chemical composition of the two components is different and thus bonding techniques between the two materials, as well as the behavior of the interface, may control the mechanical properties of the bilayered restoration. Pretreatment of the zirconia surface could possibly improve the bond between core and veneering layer and the quality of the interface. Therefore, various surface treatment methods have been applied such as surface grinding, air-abrasion, application of ceramic liners or laser etching \cite{1}. Silane-containing butane gas flame (SGF) has been proposed as a pretreatment method because it can be easily applied and creates a silica rich layer on the interface that may enhance the bond strength \cite{2}. However there is no data in literature on how this method can affect the flexural strength of veneered zirconia specimens.

The aim of the present \textit{in vitro} study was to investigate the flexural strength of bilayered zirconia ceramics after SGF pretreatment of the zirconia core, before and after artificial accelerating aging.

Experimental Methods
Sixty bar-shaped specimens were manufactured out of a dental Y-TZP material and divided in two groups: in the first group specimens were layered with a liner (LINER) before application of a feldspathic veneering ceramic, while in the second group, the zirconia surface underwent pretreatment with SGF with the Silano-Pen device (SGF) before layering. Half of the veneered specimens in each group (n=15) underwent artificial accelerating aging for 10h at 122°C with 2.5 bars pressure, simulating more than 30 years of clinical time. A 4-point bending test was performed in order to determine flexural strength. Specimens were further analyzed using Scanning Electron Microscopy (SEM), X-ray Diffraction (XRD) and Fourier Transform Infrared (FTIR) Spectroscopy.

Results and Discussion
There was no statistically significant difference between the flexural strength for the LINER and SGF pretreated specimens before or after aging. However, qualitative analysis revealed that with the majority of the specimens pretreated with SGF, areas of the veneering material remained firmly attached to the zirconia core after flexural strength testing while the liner layer becomes completely detached following the veneering material after fracture. However, most of the specimens presented cohesive type of fracture. SEM analysis on the fractured surfaces revealed the presence of Zr and Y traces on the intaglio surface of the delaminated veneer suggesting that while fracture was occurring, the bond between core and veneer layer controlled the event and led to particles of the zirconia core to be detached and relocated on the veneering material. Cross sectional analysis revealed that even in cohesive failures, the veneering layer is detached from the zirconia surface suggesting a lower bond at the interface. Silane-containing gas flame coating may be beneficial for the veneer-zirconia bond strength since it affects the interface in a microscopic level. Artificial aging had a statistically significant impact on the flexural strength of the specimens, with values being higher after aging [LINER: t(28)=2.255, p=0.032, SGF: t(28)=3.362, p=0.002]. This may be explained by the fact that aging in an autoclave promotes an extensive tetragonal to monoclinic (t→m)
zirconia phase transformation. The $t \rightarrow m$ transformation may lead to a volumetric expansion around defects, which induces compressive stresses that consequently stop propagation of the microcracks [3].

**Conclusion**

The silica rich layer on the interface created after silane-containing gas flame pretreatment may enhance the bond strength between core and feldspathic layer, although it did not significantly increased the flexural strength of bilayered veneered specimens. Pretreatment of the zirconia surface may influence the mechanical behavior of all-ceramic restorations on the long-term. Thus, further clinical investigations are required in order to evaluate the mechanical properties after in situ function.

Periodontal Restoration Using Femtosecond Pulsed Lasers

Antonios Anastasiou¹, Animesh Jha²

¹ The University of Manchester, Chemical Engineering and Analytical Science, MANCHESTER, GB; ² University of Leeds, School of Chemical and Process Engineering, Leeds, GB

Introduction

Periodontitis is an inflammatory disease affecting the periodontium i.e., the tissues that surround and support the teeth. The pathogenesis of the disease begins when microorganisms adhere and grow on teeth surface forming microbial plaque. If left untreated, formation of pathological pockets around diseased teeth is observed which eventually can lead to tooth loss [1]. Many treatment strategies have been proposed so far but the most of them fail to achieve regeneration of the PD ligament or tissue reattachment mainly because of:

• The oral bacterial which are attached on the tooth surface and lead to contamination.
• The formation of a junctional epithelium which is not practically attached to the tooth surface. Here we propose the use femtosecond lasers in order to sinter, densify and bond a layer of ceramic biomaterial on the surface of the tooth and close to the periodontal pocket. Based on the properties of the new layer (regenerative potential and antibacterial properties) we aim to promote the regeneration of the periodontal tissues and to protect the new tissue from the formation of bacterial biofilm. To be successful, we need appropriate procedures for the irradiation and attachment of the new layer and to engineer suitable biomaterials with both antibacterial properties and enhanced regenerative potential.

Experimental Methods

All the calcium phosphate minerals used in this work have been synthesised through wet precipitation method at temperature of 37 °C and pH=5.4 for brushite and pH=8 for fluorapatite. To enhance the laser-biomaterials interaction, we doped the minerals with 10% Fe²⁺/Fe³⁺. We also introduced Sr²⁺ and Ce³⁺ into the crystal lattice in order to enhance the regenerative and antibacterial potential respectively. For laser irradiation experiments bovine enamel blocks have been coated with a mixture of chitosan solution and the corresponding mineral powder. Two different lasers have been utilised i.e. a femtosecond pulsed laser with repetition rate of 1 KHz and emission at 800 nm (System A: Ti:Shaphire, LIBRA) and an ultrafast femtosecond pulsed laser with repetition rate of 100 MHz and emission at 1040 nm (System B: Chromacity Ltd).

Results and Discussion

After experiments with the two lasers we managed to form compact layers of fluorapatite on the surface of dental enamel using system B. The thickness of the new layers is between 20 and 30 μm and after nano-indentation the mechanical properties found to be very close to that of dental enamel and natural bone. System A, because of the low repetition rate produces pulses of high energy causes ablation. After we identified the appropriate laser, our efforts were focused on optimising the laser energy. The minimum power where sintering is taking place is 0.2 W. Although there are alterations on the surface of the coating, the delivered energy is not sufficient for bonding the mineral to the enamel. Bonding can be achieved for average power higher than 0.45 W [2]. In this case there is strong attachment of our mineral with the enamel and after checking the cross sections of the samples we verified that the thermal damage is restricted in a zone of 5 μm below the enamel-coating interface. For higher energy considerable thermal damage to the enamel was observed.

In terms of materials we concluded that brushite isn't appropriate for this application. Upon heating, brushite losses two molecules of water and is transformed into monetite. Further heating results in the transformation to γ- and β-pyrophosphate. Similar transformations were also observed during the laser irradiation of the brushite coatings.
Because of the radical change in crystal structure, there was shrinkage of the sintered layers and formation of microporosity, leaving exposed the surface of the underlying enamel. On the other hand, fluorapatite, resulted in dense layers and thus we further investigated its biological properties.

Three types of fluoroapatites (undoped, Sr-doped and Ce-doped) were tested for regenerative potential and antibacterial properties. After experiments with four bacteria (i.e. *E. Coli*, *S. Aureus*, *B. Subtilis*, *B. Cereus*), it was found that the undoped and the Ce$^{3+}$ doped fluorapatites present better antibacterial response than the Sr$^{2+}$ doped material [3]. The synthesised minerals in powder form were then incorporated into chitosan scaffolds and tested with Dental Pulp Stem Cells (DPSCs) to check their regenerative potential. Both the scaffolds containing Ce$^{3+}$-doped and those with Sr$^{2+}$ doped fluoroapatite, presented high osteoconductivity leading to the differentiation of the DPSCs into osteoblasts [4]. Overall, it was shown that doping with Ce$^{3+}$ retains the good antibacterial profile of fluorapatite and enhances its regenerative potential, which makes it a promising option for the proposed application.

**Conclusion**

With this platform technology we aim to transform the tooth itself to the scaffold that will promote the regeneration of the PD ligaments and prevent the formation of bacterial biofilm.

Development of bioadhesive microcapsules as a new cellular treatment for the diffuse cartilage lesions

**Desiré V. Bustos**¹, Aurelio V. Castrillo², Matilde A. Rodrigo¹,³, José Carlos R. Cabello¹,³

¹ Universidad de Valladolid, CIBER-BBN, BIOFORGE (Group for Advanced Materials and Nanobiotechnology), 47011 Valladolid, ES; ² Hospital Clínico de Valladolid, Departamento de traumatología, 47003 Valladolid, ES; ³ Technical Proteins Nanobiotechnology S.L, 47011 Valladolid, ES

**Introduction**

Cartilage structures can be damaged causing two types of injuries: focal; the lesion is restricted to a concrete zone or diffuse; the lesion affects a broad area of the articular cartilage. This type of lesions appears due to the reduced self-healing capacity of articular cartilage. Diffuse damage is much more difficult to treat, usually restricted to palliative care or systemic anti-inflammatory treatments. As the damage progresses up to the point where the majority of the cartilage is lost, the only option available is the surgical replacement of the arthritic joint with a prosthesis. This type of diffuse lesions have a high prevalence as the common type of degenerative processes associated to aging and intense professional sport.

More recently, cell-based approaches using autologous chondrocytes or, specially, mesenchymal stem cells (MSCs) [1] have been tested and it can even be found in some clinics. However, the efficacy of such cell-based treatment is controversial (MSCs plays a palliative role more than a direct restoration of the lost cartilage) [2] where the main problem is the unconfinement of the cells used. In general terms, the applied cells stay in the injection site only for short periods of time, so their regenerative potential is greatly reduced. The most promising approach is the combination of such cells with a biomaterial-based carrier that can play that role.

The general objective of the project, in order to resolve the previous task, is the development of bioadhesive and injectable cell microcarriers with the ability to regenerate the articular cartilage. This aim is materialized in the fabrication of multibiofunctional capsules that are able to promote the cell cargo with selective adhesion and location on the articular surface (cartilage). To do so, special attention is paid to the cell-material interaction on both the inner and outer surface of the capsule by means of the inclusion of, on one hand, specific cell adhesion domains and, on the other hand, sequences that promote the adhesiveness to collagen II and chondroitin sulfate, two distinctive components of the hyaline cartilage [3].

The microcapsules are based on a novel kind of biomaterials, named Recombinamers that are polypeptide materials obtained by recombinant DNA technology. In particular, the core composition of the microcarrier is the Elastin-like Recombinamers (ELRs) [4].

**Experimental Methods**

Recombinant DNA techniques have proven to be very powerful tools for the development of novel protein-based biomaterials. This class includes ELRs, which are protein-based polypeptides that comprise repetitive units of the Val−Pro−Gly−X−Gly (VPGXG)n pentapeptide, in which X (guest residue) could be any amino acid except L-proline.

ELRs are inspired by elastin, showing excellent biocompatibility, and they exhibit thermo-responsiveness in aqueous media [5].

The cloning and molecular biology for gene construction were performed using standard genetic-engineering methods. Production was carried out by recombinant techniques using Escherichia coli as the cell system. Purification was performed by several cooling and heating purification cycles (Inverse Transition Cycling) following centrifugation; the ELRs obtained in this manner were dialyzed against MilliQ water and lyophilized.
The purity and molecular weight of the ELRs were verified by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Amino acid composition analysis and infrared spectroscopy (FTIR) were also performed.

Results and Discussion
Genetic-engineering methods allowed the synthesis of the genetic construct capable of synthesizing the desired biomaterial. Biopolymer adhesion to the hyaline-cartilage matrix was demonstrated measuring the adhesion forces between our biomaterial and surfaces with collagen II and chondroitin-sulfate versus control surfaces. Tailored layer-by-layer (LbL) approaches allowed the encapsulation of cell spheroids of autologous chondrocytes and MSCs.

In vitro and ex vivo assays were performed using cartilage explants from patients surgically intervened, this type of analysis showed the derivatized ELR adhesion efficacy to the articular surface and the final liberation of cell spheroids encapsulated hoping to demonstrate the cartilage regeneration.

Conclusion
In conclusion, a novel protein-based biomaterial with adhesion to the hyaline-cartilage matrix was synthetized. Besides, cell spheroids were encapsulated by the polymer. Hence, in this study could be possible overcome the limitations of the current treatments used in diffuse cartilage lesions and suppose an advance in regenerative medicine.

Polymeric Scaffolds reinforced with Graphene-Based Nanomaterials obtained by SLA: Preliminary study of the effect of nanofillers on curing and printability

Sara Lopez de Armentia¹, Silvia Fenández Villamarín¹, Juan C. del Real¹, Nicholas Dunne²,³, Eva Paz¹

¹ Comillas Pontifical University, Institute for Research in Technology, Madrid, ES; ² Dublin City University, Centre for Medical Engineering Research, Dublin, IE; ³ Dublin City University, School of Mechanical and Manufacturing Engineering, Dublin, IE; ⁴ Queen’s University of Belfast, School of Pharmacy, Belfast, GB; ⁵ Trinity College Dublin, Department of Mechanical and Manufacturing Engineering, Dublin, IE; ⁶ Dublin City University, Advanced Manufacturing Research Centre, Dublin, IE; ⁷ Trinity College Dublin, Advanced Materials and Bioengineering Research Centre, Dublin, IE; ⁸ Dublin City University, Advanced Processing Technology Research Centre, Dublin, IE; ⁹ Trinity College Dublin, Trinity Centre for Biomedical Engineering, Dublin, IE

Introduction

Despite the inherent capacity of the bone to regenerate and repair itself, when an irregular or a large defect appears, external solutions must be applied. Traditionally, autografts have been the gold standard; however, due to their drawbacks, like donor-site morbidity, alternative solutions have been explored. In this context, porous scaffolds hold great promise for bone tissue regeneration. They act as extracellular matrix that supports cell growth, promoting cell adhesion and proliferation. For an adequate performance, they must meet some requirements: e.g. biocompatibility, interconnected porosity, mechanical properties and biodegradability. Conventionally, different methods have been used for their manufacturing (e.g. electrospinning and freeze-drying). However, these methods do not allow an adequate control of geometry and porosity of the scaffolds.

The development of additive manufacturing techniques offers a promising solution since it allows the complete customisation and control of scaffolds geometry and porosity. To allow cells to adhere and proliferate on its surface, the material used to manufacture the scaffold must have a proper wettability. In general, polymers show a hydrophobic behaviour, which hinders cell adhesion. It has been proved that the incorporation of graphene (G)-based nanomaterials, like graphene oxide (GO) [1], improves hydrophilicity of different polymers. Furthermore, G-based nanomaterials present osteoconductivity and antimicrobial effect [2], besides, they reinforce the matrix from a mechanical point of view. It makes them suitable for being used as nanofillers to improve the properties of scaffolds. Amongst the different additive manufacturing technologies, stereolithography (SLA) shows many advantages: high accuracy, anisotropy, and liquid raw material, which favours the addition of nanofillers. However, when nanofillers are added to the resin, there is a competition in terms of light absorption between the photoinitiator and the nanofiller. Nanofillers may influence the UV curing process due to modifications in optical properties, which results in changes in absorbance or transmittance of the resin. They also can act as points for light scattering and shielding [3]. Besides, polymerisation may be influenced by nanofillers if they act as chain transfer agent, inhibiting the growth of polymer chain [4], or as free radical scavengers, cutting off the polymerisation process [5].

Therefore, the aim of this work is to study the effect of G-based nanofillers on the curing of an acrylic photocurable polymer.

Experimental Methods

As matrix, a commercial photocurable acrylic resin was used (Clear Resin Formlabs, USA). The matrix was reinforced with different G-based nanomaterials: G, GO and graphite nanoplatelets (GOxNP). Nanocomposites were prepared by ultrasonication with a load of 0.1 wt.% and viscosity was measured. Differential Scanning Calorimetry (DSC), Fourier-Transformed Infrared Spectroscopy (FTIR), hardness measurements and the extent of curing degree at
different ultraviolet exposure times were conducted. Finally, the printability using a SLA printer (Form 2, Formlabs) and dimensional stability of the different nanocomposites were examined.

**Results and Discussion**

An increase in the viscosity of nanocomposites was recorded for all nanocomposites investigated with the exception of G. The latter showed a reduction in the viscosity. This decrease in viscosity could be related with a poor dispersion of G within the resin.

The results demonstrated that nanofillers affects the curing of the matrix (R) to a different degree depending on the nanofiller type (Figure 1). Specifically, GO did not significantly affect the degree of curing, whilst GOxNP influence curing at low exposure times and G for all UV exposure times studied, which hampered the UV-curing of the resin. FTIR analysis and hardness test corroborated this trend, with a notable retardation in the UV-curing of the resin with the presence of G.

Printability tests were completed in accordance with curing study. G composite did not cure sufficiently to create the part, whilst the other composites did (Figure 2).

In terms of dimensional stability, it was found that the addition of GOxNP provided an improvement. However, the incorporation of GO did not affect dimensional stability.

**Conclusion**

It was found that the addition of GO and GOxNP to an acrylic resin do not affect the curing process or printability. Conversely, the incorporation of G affected both, probably due to the darker colour of this nanofillers, which absorbs more light and reduces the performance of the photoinitiator, negatively affecting the printability. Besides, GOxNP improved the dimensional stability of printed parts.

Introduction
Additive manufacturing and 3D printing are gaining an ever-growing importance in the biomedical field, due to the possibility to obtain personalized constructs in a cost-effective way when compared to traditional techniques. For this reason, optimized materials are needed in tissue engineering to combine the requirements of the printing processes with the bioactivity necessary for the native tissue repair and regeneration. Thanks to their general biocompatibility, non-toxicity and biodegradability, aliphatic poly(ester)s are widely used in this field; however, the stiffness of these materials is compatible only with the harder tissues present in the body (e.g., bone). In this sense, poly(ester urethane)s can offer an interesting solution. Indeed, their building blocks can be ad-hoc selected to tailor the mechanical and degradation properties of the resulting polymers, thus creating a plethora of materials suitable to replace also softer tissues (e.g., muscle and cardiac tissues).

In this work, a library of poly(ester urethane)s (PURs) based on poly(ε-caprolactone) and 1,6-hexamethylene diisocyanate has been developed. The effect of aliphatic chain extenders with different chain length (i.e., 1,4-butanediol, 1,8-octanediol, 1,12-dodecanediol) has also been analyzed. A surface modification protocol of the synthesized PURs has also been optimized to obtain more hydrophilic and cell-friendly substrates.

Experimental Methods
All PURs have been synthesized adapting a previously developed procedure [1]. The success of the process has been verified through Size Exclusion Chromatography (SEC) and Attenuated Total Reflectance Fourier Transformed Infrared (ATR-FTIR) spectroscopy. Thermogravimetric analysis (TGA), Differential Scanning Calorimetry (DSC) and rheological characterizations were also performed to study the suitability of these materials for Fused Deposition Modeling (FDM) printing applications. Mechanical characterization was also conducted through tensile tests on PUR films fabricated by solvent casting. To improve the hydrophilicity of the material surface, a plasma treatment in the presence of acrylic acid as monomer was optimized to expose -COOH groups. Wettability measurements were then performed on the treated samples and compared to the native PURs. Moreover, to obtain better biocompatibility and improve cell adhesion, the exposed groups were used to graft proteins and amino acids through carbodiimide chemistry. The grafting was verified through ATR-FTIR, \textsuperscript{1}H Nuclear Magnetic Resonance (\textsuperscript{1}H NMR) spectroscopy and colorimetric tests.

Results and Discussion
The PURs synthesized with the three different chain extenders exhibited a number average molecular weight comprised between 30 and 40 kDa. TGA, DSC and rheology characterizations showed that thermal and thermomechanical properties were in all cases suitable for processing through common FDM printers to obtain scaffolds for different tissue engineering applications. Mechanical testing showed that the use of 1,8-octanediol as chain extender resulted in a more elastomeric behavior of the final PUR, while 1,4-butanediol and 1,12-dodecanediol produced stiffer and more brittle materials. Surface modification through plasma treatment was successfully conducted on the PUR films, resulting in a relevant decrease in the contact angle values compared to non-treated samples, due to the introduction of carboxylic acid groups on the surface (Figure 1A and B). Gelatin was then effectively grafted on the plasma treated PURs, as verified...
by the presence of the gelatin peaks in the ATR-FTIR (Figure 1C) and $^1$H NMR spectra and indirectly by the bicinchoninic acid assay (BCA).

**Conclusion**

All the PURs synthesized in this work showed properties suitable for FDM printing processes. The different chain extenders used permitted to obtain differences in the mechanical properties of the materials, which can therefore be used to develop scaffolds for different types of tissues. The possibility to perform a post-processing surface modification of the PURs has also been demonstrated. The plasma treatment successfully exposed carboxylic acid groups, significantly improving the surface wettability and allowing for an easy grafting of biomolecules. In this way, the biocompatibility of the scaffolds produced with these PURs can be further enhanced. Indeed, PURs with similar composition and analogous modification have already demonstrated good interaction with cardiac primitive cells [2]. Moreover, the versatility of the carbodiimide chemistry used to graft proteins permits to ad-hoc select the most suitable biological cues (i.e. protein, amino acid, peptide) for the targeted application.

Exploiting the network topology of photo-crosslinkable PCL as tool towards improved light-based engineered tissue constructs

Quinten Thijssen, Sandra V. Vlierberghe

Ghent University, Department of organic and macromolecular chemistry, 9000, BE

Introduction
Poly(ε-caprolactone) (PCL) has been the subject of extensive research due to its biocompatibility, biodegradability and excellent rheological and mechanical properties. Especially its suitability for extrusion-based 3D-printing in order to obtain patient-specific implants has attracted significant attention. However, its application in light-based 3D-printing techniques remains scarce, mainly due to the brittleness associated with acrylate-mediated photo-crosslinking. Nevertheless, light-based 3D-printing techniques such as digital light processing offer distinct benefits in terms of throughput and resolution. Therefore, in order to overcome the drawbacks associated with acrylate-mediated crosslinking, the network topology of photo-crosslinked PCL is reported herein as tool to control the mechanical properties. Via the optimization of the structure of the oligomeric precursor as well as the thiol-based crosslinker, networks with various topologies have been designed and the influence thereof on the material properties was elucidated. Finally, the biocompatibility and light-based printability of the designed materials was elucidated.

Experimental Methods
Structure elucidation was performed through 1H-NMR spectroscopy and Fourier-transform infrared spectroscopy (FTIR). The thermal properties were studied by thermogravimetric analysis (TA instruments Q50) and differential scanning calorimetry (TA instruments Q2000). Degrees of swelling and gel fractions were calculated using the following formulas: Gelfraction= m(dry)/m(initial) × 100 (%), Degreeofswelling= (m(swollen)-m(dry))/m(initial). Tensile experiments were performed using a Tinius Olsen Model 1 ST apparatus. Photo-rheology was performed using an Anton Paar Physica MCR 301 rheometer equipped with a UV light-source (365 nm, 3500 mW/cm²) with a parallel plate set-up. DMA experiments were performed in tension using rectangular samples.

Results and Discussion
With the aim to develop thiol-ene photo-crosslinked PCL-based networks with different network topologies, PCL-diol (Mn = 2000, 4000, 6000 and 8000 g.mol⁻¹) was end-functionalized with alkene functionalities (i.e. allyl alcohol, allyl isocyanate or pentenoyl chloride) via urethane coupling chemistry or via the addition elimination reaction with acid chlorides. Successful modification was confirmed via 1H-NMR (nuclear magnetic resonance) spectroscopy and FTIR (Fourier transformed infra-red) spectroscopy. Furthermore, substitution degrees exceeding 80% were retrieved for all network precursors. The ene-terminated PCL was subsequently combined with a multifunctional thiol (i.e. pentaerythritol tetakis(3-mercaptopropionate) or trimethylolpropane tris(3-mercaptopropionate)) in order to obtain thiol-ene photo-crosslinked networks. Network formation accompanied by excellent network integrity upon UV irradiation was confirmed via photo-rheology as well as via gel fraction and swelling experiments. Photo-crosslinkable PCL-based oligomers with increasing molar masses of the oligomer and varying amounts of urethane functionalities (i.e. 0, 2 and 4 per chain) have been designed via this approach. Subsequently, the influence of the functionality of the thiol crosslinker was investigated. Finally, based on the designed network, the influence of the network topology on the material properties was assessed.

In-depth characterization of the thermal, mechanical and biological properties of the networks was performed through thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), tensile testing and cytotoxicity testing. As a result of the step growth polymerization mechanism inherent to thiol-ene crosslinking, homogeneous networks with improved mechanical properties were obtained, as compared to networks resulting from acrylate-mediated crosslinking.
crosslinking (elongation at break extended from 100 up to 700% and ultimate strength increased from 10 up to 21 MPa). Furthermore, a distinct influence of the hydrogen bonding as well as the crosslink density was established, characterized by an increased elongation at break and ultimate strength. Finally, their application in digital light processing, a light-based 3D-printing technique, was successful for several of the synthesized precursors. Throughout the study, acrylate-terminated PCL was applied as reference. The 3D-printed scaffolds are currently being evaluated for their potential to support cell growth of fibroblasts. The key findings will be presented at the conference.

**Conclusion**

Thiol-ene photo-crosslinked PCL-based networks offer distinct benefits over conventional acrylate-based crosslinking. Furthermore, control of the network topology via rational design of the photo-reactive oligomers and functionality of the thiol-based crosslinker was proven to be an effective approach to control the mechanical properties of resorbable PCL-based networks. As a result, the proposed materials have great potential to be exploited as starting materials for light-based 3D-printing to serve biomedical applications.

Design of polymeric structures based on chitin-glucan complex and biocompatible ionic liquids for biomedical applications

Inês Ferreira¹,², Diana Araujo¹, Andreia Rosatella³, Carlos Afonso³, Filomena Freitas², Luisa Neves¹

¹ LAQV/REQUIMTE, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Almada, PT; ² UCIBIO/REQUIMTE, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Almada, PT; ³ Instituto de Investigação do Medicamento (iMed.ULisboa), Faculty of Pharmacy, Universidade de Lisboa, Lisboa, PT

Introduction
This work aims to merge material design based on a microbial biopolymer - chitin-glucan complex (CGC) - with an innovative ionic liquid (IL) chemistry to develop polymeric structures in the form of films or hydrogels for biomedical applications.

Chitin-glucan complex (CGC) is a polysaccharide found in the cell wall of most fungi and yeasts, including, for example, Komagataella pastoris, Aspergillus niger, Schizophyllum commune, Gongronella butleri, Armillariella mellea and Saccharomyces cerevisiae. This natural co-polymer comprises a chitin moiety (N-acetyl-D-glucosamine units), which is covalently linked to a β-glucans moiety (glucose units), being biocompatible and possesses intrinsic wound healing and antimicrobial activity. However, its use is not widespread due to its insolubility in safe and biocompatible solvents.

In the last decades, ionic liquids (ILs) have been used as alternative solvents for the dissolution of natural biopolymers known for their intractability, such as chitin, cellulose, lignin and starch. ILs are compounds consisting entirely of ions, with an organic cation and an inorganic or organic anion. These solvents possess nonflammability, negligible volatility and their chemical and physical properties can be tuned by changing the cation or the anion in their structure, making them very attractive for a variety of applications, including as solvents for dissolution of biopolymers.

Experimental Methods
The novelty of dissolving chitin-glucan complex (CGC), from two fungal strains, Komagataella pastoris (CGCP) and Aspergillus niger (CGCKZ), using biocompatible ionic liquids (ILs) was explored in this work. Three cholinium-based ILs were tested, choline acetate, choline propionate and choline hexanoate.

Results and Discussion
Although all tested ILs resulted in the dissolution of the co-polymer at a concentration of 5 % (w/w), distinct polymeric structures, films or gels, were obtained from CGCP and CGCKZ, respectively. CGCP films were dense, flexible and elastic, with high swelling capacity (> 200 %). The IL anion alkyl chain length influenced the polymeric structures’ properties, namely, the CGCP films elongation at break and swelling degree. CGCKZ resulted in weak gels. For both polymeric structures, exposure to the ILs under the dissolution conditions caused significant changes in the co-polymers’ chemical structure, namely, reduction of their glucan moiety and reduction of the degree of acetylation, thus yielding chitosan-glucan complexes (ChGC) enriched in glucosamine (53.4 ± 0.3–60.8 ± 0.3 %).

Conclusion
Due to their biocompatibility and also tailorable physical and chemical properties by changing the IL used for CGC dissolution, both biopolymetric structures (films and gels) may be considered promising materials for biomedical applications.

Novel bioinspired GO-COOH decorated hybrid scaffolds based on natural polymers with potential application in tissue engineering

Jana Ghitman1, Elena I. Biru1, Gratiela Gradisteau Pircalabioru2, Horia Iovu1

1 University Politehnica of Bucharest, Advanced Polymer Materials Group, Bucharest, RO; 2 University of Bucharest, Microbiology Immunology Department, Bucharest, RO

Introduction

Bioinspired polymer-based scaffolds with nanofibrous architecture owing to their biomimetic microenvironments, appropriate guidance and mechanical support for cells adhesion and proliferation until hosts cells can repopulate and resynthesize a new natural matrix, are lately of particular importance to tissue engineering and regenerative medicine [1, 2]. The current research study deals with the design and investigation of novel bioinspired and biocompatible GO-COOH decorated hybrid polymeric scaffolds with nanofibrous architecture as biomaterials with highly proper features for functional restoration of damaged tissue. Gelatin (Gel) and alginate (Alg), two biobased - polymers with excellent biocompatibility, high microenvironment biomimicry and ability for proper guidance of cells development in combination with carboxylated graphene oxide (GO-COOH), embody the matrix of electrospun hybrid scaffolds (HAGS).

Experimental Methods

Following the design and characterization of GO-COOH decorated electrospun monocom-/bicomponent hybrid scaffolds based on Gel (GS), Alg (AS) or Alg/Gel (AGS), precursor mixtures consisting from Gel, Alg/polyethylene oxide (PEO) and Alg/PEO/Gel with two GO-COOH concentrations were prepared (Table 1) and subjected to electrospinning process.

The stability of electrospun biomaterials was achieved by crosslinking, using glutaraldehyde (GA) vapour to crosslink the monocomponent protein-based biomaterials; Ca2+ ions to mediate the ionic gelation of polysaccharide-based scaffolds, while for the bi-component hybrid scaffolds, the two-step crosslinking process was employed, generating the crosslinked scaffolds with interpenetrated hybrid network.

Results and Discussion

The nanometric fibrous architecture of scaffolds along with the presence of GO-COOH are established by SEM (Fig. 1, a). The structural investigations performed by FTIR, Raman and XPS spectrometry emphasized the occurrence of different non-covalent interactions (e.g., H-bonding) as well the formation of new chemical bonds between the functionalities of the system ‘components. The interpenetrated network of bicomponent structures determines a 10-
folds increase of Young’s modulus as compared to monocomponent counterparts, while the dispersion of GO-COOH significantly increases the elasticity of materials. The increasing trend in elasticity of designed hybrid nanofibrous scaffolds beyond the amount of dispersed GO-COOH might be correlated with the hindering effect graphene lattices which decreased the extend of interactions among the polymer chains accompanied with some re-aggregation phenomena which occurred during the crosslinking process. The in vitro biological assessments performed on NTC fibroblast highlight the highest biocompatibility and proliferation ability of HAGS-0.1 (MTT assay) (Fig. 1, c) as well the low cytotoxic potential of GO-COOH decorated hybrid nanofibrous scaffolds (LDH test) as well its potency support the cells adhesion, growth and proliferation in a certain concentration.

**Figure 1.** (a) – Schematic illustration of the main components and underlying principle in designing bioinspired GO-COOH decorated hybrid scaffolds; (b) - SEM micrographs of all electrospun mono-/bicomponent and GO-COOH decorated hybrid scaffolds with nanofibrous architecture; (c) - Viability and proliferation of NTC fibroblast seeded with nanofibrous scaffolds determined by MTT assay after 2 and 6 days in standard culture conditions.

**Conclusion**

In this work we have designed and characterized novel bioinspired GO-COOH decorated bicomponent hybrid scaffolds with nanofibrous architecture based on alginate/gelatin using electrospinning approach. The preliminary physico-chemical, mechanical and in vitro biological investigations suggest that various types of interactions that occur between the functionalities of the system’s entities and their synergy along with rational nanofibrous architecture might be the driving factors in designing bioinspired scaffolds with highly proper features for personalized medicine. Further studies concerning in vitro and then in vivo screening of biological behavior of the designed biomaterials to ensure their safety and potency beyond the academic/laboratory investigations as biomaterials with highly proper features and performances for tissue engineering, are mantadory.

Silk fibroin interaction with other polymers and hydroxyapatite for novel biomaterial development

Arita Dubnika\textsuperscript{1,2}, Karina Egle\textsuperscript{1,2}, Andra Grava\textsuperscript{1,2}

\textsuperscript{1} Riga Technical University, Institute of General Chemical Engineering, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre, Riga, LV; \textsuperscript{2} Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction
Silk fibroin (SF) is a fibrous protein derived from Bombyx mori cocoons, that can form natural hydrogels with good biocompatibility, mechanical strength, and relatively slow degradation time \cite{1}. In tissue engineering, SF is often used in combination with other biomaterials. Composite materials can be formed with bioactive ceramics, glass and polymers - synthetic or naturally occurring \cite{2}, such as hyaluronic acid (HA) - a glycosaminoglycan that is used for the production of potential carriers for cell transplantation \cite{3} and hydroxyapatite (HAp) - a naturally occurring mineral that is biocompatible and osteoconductive. The aim of this study was to investigate the ability of silk fibroin to form novel biomatertials with other polymers and HAp.

Experimental Methods
Bombyx mori silkworm cocoons and silk fiber were obtained from China (natural origin). SF solution was obtained by previously described extraction and purification method \cite{4} ensuring concentration of 13.4 ± 1.5 weight %. Interaction of various concentrations of hyaluronic acid (HA), chitosan (CHI) and gelatin (G) was evaluated. Samples were prepared with various ratios of HAp weight % (30-90 %). Different concentrations (0.5 - 3.3\%) of crosslinking agents - glutaraldehyde (GTA) and sodium tripolyphosphate (TPP) were used for preparation of hydrogels. Crosslinking was done at 37°C and 60°C temperatures. Swelling ratio, gel fraction, microstructure and physicochemical properties were analyzed.

Results and Discussion
The highest swelling ratio was observed for SF/HA samples crosslinked with GTA at 37°C temperature compared to physically crosslinked SF/HA hydrogels with no HAp addition. With addition of HAp, CHI or G, swelling ratio and gel fraction is dependent on the crosslinking method, especially order of TPP and ethanol treatment.

Conclusion
Crosslinking with GTA increased the swelling ratio of SF/HA hydrogels compared to physically crosslinked SF samples at all tested temperatures. When HAp and gelatin or chitosan is introduced in SF based samples, crosslinking with TPP and ethanol can be iterated to achieve desirable properties.

Introduction
The possibility of combining the mechanical strength of titanium (Ti) with the bioactivity of hydroxyapatite (HA) is attractive to develop high-strength and low-weight composite materials for the treatment of bone defects. However, the chemical reactions occurring during sintering of Ti in contact with HA have limited usefulness of such composites [1]. In this work, a new concept of achieving the goal is proposed based on the biomimetic precipitation of calcium deficient HA (CDHA) at physiological temperature to avoid the decomposition of both components. The load bearing robocast Ti scaffold was infiltrated with a self-setting CDHA foam and the structure, mechanical, and biological properties were studied. Moreover, to increase the adhesion strength with CDHA, and in turn strengthen the resulting composite, the functionalization of the Ti surface was explored.

Experimental Methods
Ti scaffolds were produced by robotic assisted deposition of an ink that was prepared by mixing of commercially pure Ti powder (ASTM Gd1 20-63 μm) with an organic binder, gelatine. A post-printing thermal treatment was optimized to eliminate the binder and maintain the purity during sintering. Scaffolds were sintered at 1300 and 1400 °C for 3 and 10 h in argon atmosphere using a tubular furnace. Part of the Ti scaffolds was functionalized with gelatine before the infiltration process. CDHA foams were produced by mechanical foaming of an alpha tricalcium phosphate self-setting paste [2], using either polysorbate 80 or gelatine as foaming agents. The obtained injectable foams were infiltrated into the sintered Ti scaffolds and allowed to set in water at 37 ºC for 10 days. The phases in the composites were evaluated by XRD and EDX analysis, additionally XPS and FTIR were used to characterize the functionalization of the Ti surface. The microstructural characterization was performed by optical microscopy, SEM, and μCT. Compression test and indentation adhesion test were used for the mechanical evaluation of the composites. The cytocompatibility of the Ti scaffolds was evaluated by the culture of SaOS-2 osteoblast like cells.

Results and Discussion
Debinding at 350 °C for 12 h was selected as optimal due to the maximum removal of the organic binder and the least thermal oxidation of Ti. The correlation between the consolidation conditions and the mechanical performance of the scaffolds was established. Sintering at 1400 °C for 10 h resulted in the strongest scaffolds, having a yield compressive strength of 61 MPa and a Young’s modulus of 1.2 GPa at 70 % of porosity. The Ti scaffolds showed an equiaxial grain microstructure of α-phase grains with the size of 75 μm (Fig. 1d) and had less than 2 wt.% of C and O. Normally, functionalization of Ti is performed on flat disks [3]. This work shows that functionalization can be done in scaffolds as the surface chemical analysis confirmed the incorporation of Si and N coming from silane and gelatine, respectively. Moreover, improved hydrophilicity was visually observed. The CDHA foams demonstrated the ability to retain a porous structure after infiltration (Fig. 1b, c) with the pore size of about 350 and 120 μm for polysorbate and gelatine, respectively. The crystalline composition of the composites after setting was hexagonal Ti and HA, and no secondary phases neither decomposition were observed by XRD, metallography, and EDX. CDHA had a nano-plate like microstructure (Fig. 1e). μCT reconstruction showed an interpenetrating phase composite of Ti, CDHA, and a pore network, all located continuously along the material (Fig. 1b). SaOS-2 cells growth and matured in the Ti scaffold. Page 1652 of 2028
scaffolds producing a lining layer on the strands and mineral deposits. Currently, the analyses of the CDHA/Ti interface, the mechanical strength, and cytocompatibility of the composites are ongoing.

**Conclusion**

Physiological temperature processing of CDHA/Ti composites without undesirable secondary phases is possible by the biomimetic setting of CDHA inside of Ti scaffolds. The composites exhibited a network of open pores with the size in the range optimal for bone regeneration and with mechanical strength suitable for moderate load bearing applications.

**Introduction**

Among natural polymers, cellulose represents a low cost, abundant and renewable polysaccharide with great versatility. This long chain biopolymer can be found in organized in hierarchical structures composed by nanofibers with high aspect ratio (3-4 nm wide and hundreds μm length). Among all the different methods to obtain cellulose nanofibers (CNFs) proposed in literature, TEMPO-mediated oxidation represents one of the most diffused. [1] From TEMPO-oxidized CNFs aqueous dispersions it is possible to obtain physically crosslinked hydrogels by means of the divalent cation addition. The realization of biocomposite hydrogels through inorganic nanoparticles incorporation can help in overcoming their lack in mechanical properties, mixing the softness of the gel and the hardness of the inorganic component. Moreover, the presence on inorganic components, such as calcium phosphates, can improve not only their mechanical properties but also the bioactivity of the gels. GO has also been tested as an effective treatment for cancer as it can specifically target cancer cells with a significant cytotoxic effect against osteosarcoma. [2,3]

The aim of this work is to design and characterize a TEMPO-oxidized cellulose nanofibers (TOCNFs) injectable hydrogel embedded with inorganic nanoparticles composed by calcium phosphates (CaP) and calcium phosphate and graphene oxide (CaP-GO) whose final application is the bone tissue regeneration.

**Experimental Methods**

TOCNFs aqueous dispersions were by oxidation of cotton linters cellulose, exploiting the NaClO/KBr/TEMPO oxidation system, followed by an ultrasonication step, as widely reported in literature. [1,4] Biocomposites were prepared by embedding the nanoparticles, synthetized at the IPCB (CNR; Naples), into the so obtained TOCNFs dispersion. The optimized final hydrogel composition was: TOCNFs with dry weight of 4% w/w on the final composite and CaP or CaP-GO with dry weight of 1% w/w on the final composite.

Gels were observed by SEM microscopy and the composition was evaluated by means of TGA, FT-IR and XRD analysis. Rheological characterization was performed by means of strain, frequency and shear rate sweep. The injectability of the hydrogels was evaluated by loading it into a 5 mL syringe mounted on a custom experimental setup and extruding it at 0.6 mm/sec for 15 mm through 18 G needle. [X]

Stability tests were performed by immersion in Dulbecco's Modified Eagle Medium (DMEM) up to 28 days. Mineralization tests were carried out in 1.5X simulated body fluid (SBF), incubated at 37°C under continuous shaking.

**Results and Discussion**

The embedding of CaP or CaP-GO in the gel proved that the nanoparticles act as physical crosslinkers interacting with the cellulose fibers, as proven by the rheological characterization, which reported an increase in the mechanical properties for the biocomposites and confirmed the thixotropic and shear-thinning behavior (Figure 1 a). The average load value registered in injection tests was in the range 1.5 - 4.4 N, far below 30 N, which is considered a reasonable injection force upper limit (Figure 1 b).

Stability assays in DMEM, results in an increasing growth in weight in the first 15 minutes; all the specimens registered the maximum increase (around 60%) after one day of immersion and were stable up to 28 days.
SEM and XRD analysis performed on the specimens before and after the mineralization tests suggested that gels incorporating CaP and CaP-GO nanoparticles show a greater bioactivity than TOCNF gels, accelerating the mineralization process and enhancing the formation of the apatite layer on the gel surface (Figure 2 a-d).

**Conclusion**

With the extensive characterization, this work demonstrated that the physico-chemical properties of TOCNF based dispersions could be enhanced through the addition of the inorganic phases within the polymer matrix. This yields a hydrogel that is easily injectable, with bioactive properties that promote mineralization of the hydrogel affordable for bone tissue regeneration. These properties can be easily modulated by modifying the amount of inorganic components depending on the final application.

Introduction
Blood contacting devices (BCDs) are daily used for the treatment of cardiovascular diseases. Currently used biomaterials still lead to complications such as thrombosis and infection, demanding improvements in this field [1, 2]. New insights have arisen when hydrogels with high-strength and stiffness were obtained by incorporating graphene oxide (GO) [3]. However, when tissue engineering approaches are desired, biodegradable materials with suitable haemocompatible and mechanical properties and small degradation products are still a hurdle [4]. The present work aims to develop a new biodegradable poly(2-hydroxyethyl methacrylate) (pHEMA) hydrogel to be used as a potential scaffold in a post-implantation tissue engineering approach. For that, a degradable crosslinking agent was incorporated to allow hydrogel degradation and oxidized graphene-based materials (GBM) with differing lateral size and thickness explored to potentiate mechanical reinforcement. The hydrogel performance regarding physical-chemical features and biological performance were evaluated.

Experimental Methods
Degradable pHEMA (d-pHEMA) films were produced by adding (0.25, 0.5, 0.75wt.%) of the cross-linking agent pentaerythritol tetra(is-3-mercaptopropionate), named as tetrakis, to the previously described formulation of pHEMA films [5]. d-pHEMA/GBM composites were produced by mixing with HEMA monomers 1% (w/v) of single-layer graphene oxide (GO) or few-layer GO with 5 or 15 µm lateral size (M5ox or M15ox). pHEMA polymerization was assessed by Fourier-transform infrared spectroscopy (FTIR), hydrophilicity of the films was evaluated by optical contact angle. Topography and porosity were analyzed by SEM and crioSEM, respectively, and the swelling behavior through water uptake capacity. Degradation studies were performed in vitro in PBS under 100 rpm over 6 months (ISO 10993:13) and in vivo using the chick chorioallantoic membrane (CAM) assays. Cytotoxicity of degradation products (24h and 6 months) was evaluated towards human umbilical vein endothelial cells (HUVECs), assessing cell metabolic activity (resazurin assay) and cell morphology (dapi/phalloidin staining and fluorescence microscopy). The non-fouling character of the hydrogels was evaluated by direct contact assay with HUVECs, platelets and bacteria. HUVECs (1x10⁴ cells/well) were incubated on top of the hydrogels, and after 24h and 7 days the cell metabolic activity and cell morphology assessed as described above. Platelets’ adhesion and activation (3×10⁸ platelet/mL) was assessed by SEM after incubation of hydrogels with human platelets for 1h (37 °C; 100 rpm). Methicillin-resistant *Staphylococcus aureus* (S. aureus) (ATCC MRSA 33591™) adhesion (1.3x10⁸ bacteria/ml) to hydrogels was visualized by SEM after incubation during 24h at 37 °C.

Results and Discussion

Page 1657 of 2028
Hydrogels polymerization was confirmed by FTIR, showing no evidence of unreacted HEMA monomers (C=C; 1635cm⁻¹). The use of tetrakis does not induce significant changes on swelling (≈80%) and hydrophilicity (≈40°) of the native pHEMA, maintaining its hydrogel-like behavior.

Independently of the amount, incorporation of Tetrakis in pHEMA allows full degradation of the hydrogels within 2 months. When GBMs are added, the stability of the hydrogels increase, degrading after 3 months for GO and 4 months for M5ox and M15ox. The 24h and 6 months degradation products revealed no cytotoxicity to over HUVECs. CAM assays confirmed lack of cytotoxicity and irritability in all hydrogels. Mechanically, incorporation of tetrakis decreased the Young’s modulus and tensile strength (UTS) of pHEMA in 50%. However, upon addition of GBMs, particularly M5ox, the UTS increased to 0.2 MPa, with an elasticity of 0.25 MPa, while keeping a strain of 20%, improving native pHEMA’s mechanical properties and reaching values similar to the ones from native small diameter blood vessels.

The non-fouling properties were confirmed, where no HUVECs adhered to d-pHEMA nor d-pHEMA/GBMs materials surface, after 1 and 7 days. Similarly, there is no platelets nor S. aureus adhesion to the surface of the hydrogels. Such features are promising when envisioning the production of a BCD, since thrombus formation and infection may be prevented.

Conclusion
Overall, this work has demonstrated that pHEMA can be turned into a degradable material by incorporation of Tetrakis, despite compromising the mechanical properties. The incorporation of GBMs can however counterbalance this, reestablishing the stiffness and strength, and simultaneously allowing the tuning of the degradation time. Furthermore, the intrinsic features of pHEMA were kept, such as its hydrophilic and non-fouling behavior. Hydrogels with 0.25% Tetrakis and 1% M5ox show suitable mechanical properties and degrade within 3 months, matching blood vessel remodeling. This new developed hydrogel can therefore be envisioned for applications in tissue engineering, namely as small diameter vascular grafts.

Gel/HA hydrogels as 3D in vitro breast cancer models

Matteo Pitton¹, Christian Urzì²,¹, Arianna Bossi¹, Nicola Contessi Negrini³, Silvia Farè¹,⁴

¹ Politecnico di Milano, Chemistry, Materials and Chemical Engineering Department, Milan, IT; ² UKC Bern, Department of BioMedical Research, Bern, CH; ³ Imperial College London, Department of Bioengineering, London, GB; ⁴ National Interuniversity Consortium of Materials Science and Technology, Florence, IT

Introduction

Adipose tissue (AT) is a highly complex connective tissue directly involved in several human functions [1]. Among diseases that affect AT, breast cancer is nowadays the most widely diagnosed pathology in women [2]. 3D in vitro models are emerging as valid tools to deeply understand mechanisms of breast cancer origin and development, and to test novel therapies in micro/nano scale, thanks to their capability in replicating tissue in vivo condition, compared to 2D cultures or in vivo animal models. In particular, natural hydrogels are promising materials to mimic physiochemical, mechanical, and biological properties of AT [3], since they are characterized by porosity, swelling ability, and tuneable mechanical properties. However, finely tuning the mechanical properties of natural-based hydrogels is still challenging and it represents a crucial feature to mimic both physiological and pathological AT conditions. Here, we developed gelatin (Gel) and hyaluronic acid (HA) hydrogels to realize a 3D in vitro breast cancer model. Gel aimed to replicate the collagen component naturally present in AT extracellular matrix (ECM), while HA simulated glycosaminoglycans in AT ECM.

Experimental Methods

Gelatin (Gel) and hyaluronic acid (HA) were functionalized by methacrylate groups (i.e., GelMA and HAMA, respectively), and the degree of functionalization (DoF) was assessed by ¹H NMR spectroscopy. Hydrogels were prepared upon light irradiation of polymer solutions (10 % GelMA and 1 % HAMA w/v). Two different photocrosslinkers were investigated and hydrogels crosslinked either by using UV irradiation (i.e., photoinitiator Irgacure I2959) or visible light (i.e., photoinitiator complex Ruthenium Ru and Sodium Persulfate SPS). Crosslinked samples were characterized by physical (i.e., stability tests in physiological-like solution 0.02 % w/v NaNO₃ in dH₂O, T = 37 °C, up to 3 weeks, n = 5), mechanical (i.e., compressive test, T = 37 °C, strain ramp = 2.5 % min⁻¹ down to 30 % and 5 % min⁻¹ up to 1 %, n = 3) and biological tests (i.e., indirect cytotoxicity, n = 3 per time point, UNI EN ISO 10993-5). GelMA hydrogels (10 % w/v) were characterized by performing same tests.

Results and Discussion

GelMA/HAMA hydrogels appeared less transparent than samples prepared only with GelMA (Figure 1.a), both after UV and visible light photocrosslinking. Weight variations curves (ΔW %) showed a higher increase in weight for blend hydrogels in the first 48 h (Figure 1.b), compared to GelMA samples (p < 0.05). This trend was associated to HAMA presence in hydrogels, since hyaluronic acid resulted able to retain huge amounts of water in ECM. Stress-strain curves showed that HAMA addition in GelMA hydrogels photocrosslinked by visible light exposure led to an increase in mechanical properties, such as elastic modulus (Figure 1.c.ii) and stiffness (Figure 1.c.iii), which resulted higher than other blend samples and respective GelMA hydrogels (p < 0.05). Ru/SPS crosslinked GelMA/HAMA hydrogels were approximately 3 times stiffer than respective GelMA samples (K⁺VIS = 103.2 kPa, K⁻VIS = 38.9 kPa), simulating pathological condition of AT [4]. Most breast tumours (i.e., fibroadenoma, low grade ductal carcinoma) exhibit indeed a 3-6-fold increased stiffness than native AT, while high grade ductal carcinoma shows an increase up to 13 times compared to physiological condition [4]. Moreover, HAMA addition allowed to enhance hydrogels stiffness involving low levels of photoinitiators. Higher photoinitiator concentrations could indeed increase material mechanical properties as well [5] but might lead to potential cytotoxic residual accumulations. Contrarily, GelMA/HAMA hydrogels...
photocrosslinked with I2959 showed a decrease in mechanical properties ($p < 0.05$), in comparison with both other blend and respective GelMA hydrogels ($K_{\text{b,UV}} = 9.6$ kPa, $K_{\text{g,UV}} = 53.2$ kPa). This trend was associated to an incomplete crosslinking of the polymeric network, which could be optimized by increasing UV time exposure. In vitro indirect cytocompatibility was thus performed on preadipocytes 3T3-L1 (Figure 2), after 1, 3, 7 days of samples incubation ($T = 37^\circ \text{C}, \text{CO}_2 = 5\%$). All the investigated formulations did not show cytotoxic effects on seeded cells (i.e., cell viability > 70\%).

**Conclusion**

HAMA addition to GelMA hydrogels allowed to increase the mechanical properties of the prepared hydrogels. Visible light photocrosslinking of GelMA/HAMA hydrogels resulted a promising approach for 3D in vitro breast cancer model realization, since led to an increase in stiffness, comparable to pathological AT condition [4]. Since no cytotoxic effects resulted from biological tests, breast cancer cells encapsulation could be further performed on investigated GelMA/HAMA hydrogels.

**Figure 1**

a) GelMA/HAMA and GelMA hydrogels images acquired by stereomicroscope (scale bar: 5 mm). b) Stability tests on GelMA/HAMA and pure GelMA hydrogels, up to 3 weeks. c) Compressive mechanical tests. Stress-strain curves of tested samples (i), elastic modulus obtained values (ii) and stiffness obtained values (iii). Statistical analysis was performed between blend formulations and significance was reported as ◊ (◊◊◊◊: $p < 0.0001$), while significance between blend hydrogels and respective pure GelMA samples was signed as * (**: $p < 0.01$, ****: $p < 0.0001$).
Indirect cytotoxicity on 3T3-L1 preadipocytes cultured with eluates obtained from GelMA/HAMA and pure GelMA samples, incubated (T = 37 °C, CO₂ = 5 %) for 1, 3, 7 days. All the investigated formulations did not exhibit cytotoxic effects on preadipocytes since cell viability resulted higher than 70 %, as UNI EN ISO 10993-5 reported.

Introduction

Aging populations in developed countries will increase the demand for implantable materials to support tissue regeneration. Protein-based eco-friendly biomaterials such as dairy proteins attracted great attention recently as substitutes for commercial materials for biomedical applications [1, 2]. Whey Protein Isolate (WPI), derived from dairy industry by-products, can be processed into hydrogels with the following desirable properties for applications in tissue engineering: (i) ability to support adhesion and growth of cells; (ii) ease of sterilization by autoclaving and (iii) ease of incorporation of poorly soluble drugs with antimicrobial activity, such as phloroglucinol (PG), the fundamental phenolic subunit of marine polyphenols. PG possesses antioxidative properties, which is expected to be beneficial for bone tissue engineering, as oxidative stress has been indicated to impede both the differentiation of osteoblasts and the resorption of bone by osteoclasts [3, 4].

In this study, WPI hydrogels have been enriched with PG at concentrations between 0 and 20% (w/v). PG solubilization in WPI hydrogels is far higher than in water. WPI-PG hydrogels supported the proliferation of and collagen production by human dental pulp cells (DPSCs), and less by osteosarcoma-derived MG63 cells. In summary, enrichment of WPI with PG may be a promising strategy to prevent microbial contamination while promoting cell attachment and growth of mesenchymal stem cells.

Experimental Methods

In this study 40% w/v WPI hydrogels modified with 0, 2.5, 5, 10, and 20% PG were prepared. DPSCs and MG-63 cells seeded on WPI hydrogels modified with different concentrations of PG were evaluated for their viability, proliferation, cell adhesion, morphology, potential to enhance extracellular collagen production and antimicrobial capacity. As this potential is expected to be different for cell lines and primary cells, physiological and cancer cell types, we performed a comparative in vitro biocompatibility study. Viability and proliferation of both cell types on the WPI hydrogels were quantified by means of the cell viability PrestoBlue™ assay, while cell morphology and attachment of both cell types on the modified hydrogels were assessed by means of scanning electron microscopy. Moreover, we determined the levels of collagen produced in culture supernatants as a marker of extracellular matrix (ECM) formation. Bacterial strains used in the study included Bacillus cereus, Enterococcus faecalis, Escherichia coli, Klebsiella oxytoca, K. pneumoniae, Pseudomonas aeruginosa, Staphylococcus aureus, S. aureus (MRSA), S. epidermidis, Streptococcus pyogenes. For susceptibility testing, the bacterial strains were grown overnight on nutrient agar at 37 °C.

Results and Discussion

Higher PG concentration in WPI hydrogels increased proliferation of both DPSCs and MG-63 cells. Compared to DPSCs, MG-63 osteosarcoma cells displayed a decrease of metabolic activity from day 4 to day 7 in all samples, indicating a downregulated proliferation potential of osteosarcoma cells cultured on WPI-PG hydrogels. After 7 days
of incubation, DPSCs adhered strongly into the surface and pores of the 10 and 20% WPI-PG hydrogels, whereas MG-63 appeared round and flat with an obvious decrease in cell density at the lower PG concentrations. Quantification of extracellular collagen as an indicator of ECM formation revealed that DPSCs enhanced the production of collagen at all time points relative to the PG-free WPI control hydrogel. MG-63 osteosarcoma cells exhibit significantly lower levels of collagen production with three-fold lower values compared to the DPSCs, indicating that mesenchymal stem cells cultured on WPI-PG samples favor ECM formation.

**Conclusion**

WPI-PG hydrogels demonstrate an excellent biocompatibility, allowing DPSCs and MG-63 cells to adhere, survive, and proliferate, favoring an enhanced growth and ECM collagen production by DPSCs compared to MG-63 cultures. The enrichment of WPI with various concentrations of PG did not adversely affect the mechanical properties of the hydrogels, while endowing them with antibacterial properties.

Accelerated Bone Regeneration by Rational Design of Magnesium Phosphate Cements

Friederike Kaiser1, Lena Schröter2, Jan Weichhold1, Svenja Stein2, Anita Ignatius2, Uwe Gbureck1

1 University Hospital of Würzburg, Department for Functional Materials in Medicine and Dentistry, Würzburg, DE; 2 University Hospital of Ulm, Institute of Orthopaedic Research and Biomechanics, Ulm, DE

Introduction
Calcium phosphates, e.g. hydroxyapatite, are commonly used as synthetic bone replacement material due to their high biocompatibility and similarity to natural bone tissue.1 However, a complete resorption of hydroxyapatite and replacement by bone tissue is rarely observed.2 Magnesium phosphates such as struvite (MgNH4PO4·6H2O) or newberyite (MgHPO4·3H2O) are a promising alternative, due to their higher solubility.3 In vivo studies in a sheep model showed an almost complete degradation of a struvite forming cement with a struvite content of ≈40% after 10 months.4 In the current study we aimed to further increase degradation rate by either forming K-struvite (MgKPO4·6H2O) or a mixture of struvite and newberyite during cement setting by changing both the composition and amount of the cement liquid.

Experimental Methods
Magnesium phosphate cements with different powder liquid ratios (PLR) were produced by mixing farringtonite (Mg3(PO4)2) powder with ammonium hydrogen phosphate (struvite cement) or potassium hydrogen phosphate solution (K-struvite cement). Cement paste was filled into silicone rubber molds (12 x 6 x 6 mm) and samples were hardened for 24 h at 37 °C and 100% humidity. The cements were characterized regarding compressive strength and phase composition. Initial setting time was determined by Gilmore needle test and porosity by mercury intrusion. The cements with PLR 1 were stored for 18 days in phosphate buffered saline to investigate passive degradation and in vivo degradation was studied by implantation in a partly-loaded tibia defect in sheep model.

Results and Discussion
The material characterization revealed that the replacement of ammonium ions by potassium ions in the cement only slightly influences compressive strength (Figure 1E), but noticeably extends the initial setting time (Figure 1A). XRD measurements (Figure 1B-D) show that the cements consist of (K-)struvite, farringtonite and newberyite. Although the struvite content in the corresponding cement is significantly lower than the K-struvite content in the corresponding cement, a high amount of newberyte was formed which is thought to further improve cement degradation. Both cement compositions degraded in vivo and new bone tissue was formed around the implants. Macroscopic images of the implantation site indicate faster degradation of the K-struvite forming cement (Figure 2).

Conclusion
Due to their large content of high soluble magnesium phosphate phases, sufficient compressive strength for partially loaded bone defects and their rapid in vivo degradation, the investigated magnesium phosphate cements are promising candidates for a bone replacement material.

Extraction and characterization of native type I collagen from aquaponics Tilapia skin

Nunzia Gallo¹, Maria Lucia Natali², Chiara Brunetti², Alessandra Quarta³, Antonio Gaballo³, Alberta Terzi³, Teresa Sibillano⁴, Cinzia Giannini⁴, Giuseppe E. De Benedetto⁵, Federica S. Blasi¹, Angelo Corallo¹, Alessandro Sannino¹, Luca Salvatore¹,2

Introduction

Collagen is the most abundant structural protein in humans [1]. Thanks to its properties, it is one of the most widely used biomaterials in health-related sectors [1]. The industrial production of collagen mostly relies on its extraction from mammals. However, immune reactions triggering, zoonosis transmission risks, cultural and religious issues limited its use [1,2]. In this perspective, in the last two decades marine organisms attracted interest as safe, abundant and alternative sources for collagen extraction [2]. Every year fish processing industry discards account for about 70-85% of the total catch weight and raise significant environmental pollution [2]. The possibility to valorize fish byproducts as collagen sources makes fish collagen eco-friendly and attractive in terms of profitability and cost effectiveness. Additionally, fish byproducts harvesting from eco-sustainable aquaponics systems allows to obtain fish biomass with controlled properties over time. In this work, the physical, chemical, structural and biological properties of type I collagen isolated from Nile Tilapia skin raised in a pilot aquaponic system were assessed and compared with those of a commercially available isoform.

Experimental Methods

Type I collagen (T) was extracted from the skin of Tilapia (Oreochromis niloticus) bred in the pilot aquaponics plant of the “Urban Farming Lab” of the Dept. of Innovation Engineering (University of Salento, Lecce, Italy) according to a method developed by Typeone Biomaterials Srl (Lecce, Italy). Briefly, Tilapia skin were cleaned up by flesh and scales, washed and cut. Skin pieces were then treated with NaOH to remove non-collagenous proteins, defatted with butanol, and incubated at acid pH. The viscous suspension obtained was centrifuged and the collected supernatant salted out. The resulting precipitate was then filtered, lyophilized and ground, in order to obtain type I collagen dry flakes. The extracted material was fully characterized in comparison with a commercially available type I collagen isoform (N) produced by Nippi Inc (Tokyo, Japan). The protein molecular weight was assessed by Polyacrylamide Gel Electrophoresis in presence of Sodium Dodecyl Sulfate (SDS-PAGE). The amino acid composition was investigated by Gas Chromatography - Mass Spectrometry (GC-MS). The structural integrity was examined by mean of Transmission Electron Microscopy (TEM), Fourier-Transform Infrared Spectroscopy (FT-IR), Wide- and Small-angle X-ray scattering (WAXS, SAXS). The material thermal properties and degradation resistance were investigated by Differential Scanning Calorimetry (DSC) and enzymatic degradation. Lastly, the cytocompatibility of T and N was preliminarily evaluated by assessing the morphology, the metabolic activity and the viability of NHI/3T3 murine fibroblast up to 6 days.

Results and Discussion

The protein identity and the preservation of its native structure were confirmed by all performed analysis. The electrophoretic pattern showed the presence of the two typical bands of type I collagen [3,4]. The absence of other bands indicated the purity of the material, suggesting how T was as pure as N. The identity of T was confirmed also by its amino acid composition that was found to be comparable to N and according to literature [3]. The presence of
the typical IR vibrations of collagen in T and N confirmed their structural integrity and the extraction procedure quality [3, 4]. Moreover, a high triple helical content for both and a slightly high native structure conservation in N were found. Accordingly, WAXS confirmed the retention of triple helical structure at molecular scale, however highlighting the directional orientation loss of molecules in their lateral packing in T than N. Furthermore, SAXS showed that its typical arrangement became less visible at the nanoscale. The fibrillar structure of collagen was confirmed by TEM, with the presence of fibrils of diameter of about 250 nm and length of ≈mm. The denaturation temperature was found to be of about 33°C [4]. Lastly, the viability and the morphology of NH1/3T3 cells on T and N confirmed their cytocompatibility since a stimulated cell growth and absence of significant death rates were observed. Additionally, cell imaging showed morphological diversity between T and N, suggesting that different dynamics of adhesion/proliferation occurred. Intriguingly, the development of 3D structures after 3 days on N and in a less extent and later on T deserved further investigation.

Conclusion

All analysis confirmed how the extraction process allowed to isolate type I collagen in native state from aquaponics-derived Tilapia skin. The slight differences observed between T and N may be due to different extraction procedures, resulting in changes in their bioactive conformational structure. The promising biocompatibility results confirmed how T could be used as an alternative biomaterial for the development of medical devices and how aquaponics could be a valid source of byproducts for collagen extraction.

Structural characterisation of a gelatin/silica hybrid material, containing calcium, strontium and boron.

José Carlos Almeida¹,², Paula Maria C. Torres¹, Susana Maria H. Olhero¹

¹ Universidade de Aveiro, CICECO, Aveiro, PT; ² Universidade de Aveiro, TEMA, Aveiro, PT

Introduction
During the last ten years an effort has been made to develop new hybrid materials capable to produce biodegradable scaffolds or films, targeted to tissue regeneration [1]. Among the various hybrid systems, the gelatin-silica system has presented interesting results, namely as a stand-alone material for scaffolds [2,3].

Experimental Methods
In the present work, a sol-gel preparation protocol was developed in a way to include, in the inorganic domains of the hybrid system, ions recognized for enhancing bioactivity, such as calcium, strontium and boron [4].

Results and Discussion
In the first phase of the work, the structures of the hybrid material were analysed by FTIR, ¹H MAS (magical angle spinning), ²⁹Si MAS, ²⁹Si-{¹H} CP-MAS (cross-polarization magical angle spinning) and ¹¹B HAHN-ECHO NMR. Hybrid materials in the gelatin–SiO₂–CaO–B₂O₃ system were successfully obtained using GPTMS (3-glycidoxypropyltrimetoxysilane) as a coupling agent between gelatin and silica.

Conclusion
The formation of hybrid bonds between the organic gelatin-GPTMS and the silica domains, as well as, the presence of borosiloxane bonds (B–O–Si) were confirmed. The presence of calcium and strontium acting as network modifiers changes the boron coordination from trigonal to tetrahedral.

Synthesis of amorphous calcium phosphate from different Ca source

Marika Mosina\textsuperscript{1,2}, Liga Stipniec\textsuperscript{1,2}, Janis Locs\textsuperscript{1,2}

\textsuperscript{1} Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; \textsuperscript{2} Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction

Different calcium phosphates are widely used as biomaterials. Formation of hydroxyapatites in the human body occurs through an amorphous precursor phase such as amorphous calcium phosphate (ACP). Due to the fact that ACP is highly soluble and has good remineralization ability, it is ascribed with excellent properties and promising forthcoming applications in the development of bone graft materials. Materials properties such as specific surface area (SSA) and Ca/P molar ratio are attributed to the response of cells in bone regeneration process and different synthesis parameters can influence these properties of materials. The aim of the study was to investigate the effect of different Ca sources, synthesis initial Ca/P molar ratio and synthesis end pH on properties of ACP.

Experimental Methods

ACP was synthesized with a modified wet precipitation method [1]. Two different Ca\textsuperscript{2+} ion sources, calcium oxide (CaO) and calcium chloride (CaCl\textsubscript{2}) were used. Orthophosphoric acid (H\textsubscript{3}PO\textsubscript{4}) was added to the starting solution. The initial Ca/P molar ratio of reagents was 1.5, 1.58 and 1.67. From calcium and phosphorous ion rich solution, ACP precipitation occurs with the rapid addition of strong base (NaOH). The synthesis was performed at end pH 9.5 and 11.5. Obtained precipitates were centrifuged, washed with deionized water, and lyophilized. If calcium oxide was used as a source to obtain the calcium and phosphorous ion rich solution, suspension was dissolved by the addition of hydrochloric acid (HCl). Products were characterized with x-ray diffraction analysis (XRD), Fourier transform infrared spectroscopy (FT-IR), Brunauer–Emmet–Teller method (BET) and gas pycnometry. Gallium content in all the obtained ACP samples was detected by inductively coupled plasma mass spectrometry (ICP-MS).

Results and Discussion

Synthesized ACP from different Ca\textsuperscript{2+} ion sources displayed characteristic amorphous structure (wide bump around 30 ° 2Theta in XRD pattern and wide rounded peak in FT-IR spectrum were observed). The characteristic amorphous structure remain also in different synthesis conditions that were employed. Ca/P molar ratio of obtained ACP was in the range from 1.50 to 1.57 which is lower than the initially observed molar ratio (1.5-1.67). However, higher synthesis end pH (11.5) lead to the increased Ca/P molar ratio in the product.

Conclusion

The correlation between synthesis parameters (pH and initial Ca/P molar ratio) and ACP microstructure parameters (SSA, density, particle size) was not observed. This is due to the fact that other parameters of synthesis could have influenced the properties of ACP.

**Understanding the Influence of Chemical Properties of Silicon-Substituted Hydroxyapatite on Angiogenesis**

*Else Ellermann, Ruth E. Cameron, Serena M. Best*

*University of Cambridge, Materials Science and Metallurgy, Cambridge, GB*

**Introduction**

Synthetic hydroxyapatite (HA) is used widely in orthopaedic surgery for bone tissue engineering due to its similarity in composition to the mineral component of bone. There has also been considerable interest in the modification of the chemistry of synthetic HA to optimise osseointegration and periosteal apposition *in-vivo* [1]. In particular, the substitution of silicate groups for phosphate groups in the HA lattice has been investigated. Over the years, silicon-substituted HA (SiHA) has been observed to induce enhanced osteoblast attachment and proliferation, promote bone mineralisation and increase the mechanical stability of calcium phosphates [2,3]. However, successful bone tissue engineering relies on both the osteogenic- and also the angiogenic potential of biomaterials and should, therefore, be considered as part of the biological performance.

To date, there have been few studies that have investigated the influence of SiHA on angiogenesis *in vitro*, and uncertainty remains about the mechanism by which silicon contributes to bioactivity. Since the addition of silicon does not only change the chemical composition of HA but also alters the physical properties, such as grain size and mechanical stability, it has been proven difficult to assess the direct effects of silicon on cell behaviour. The objective of this study is to establish the formation of vessel-like structures on SiHA and gain an understanding of the extent to which chemical properties contribute to the bioactivity of calcium phosphates.

**Experimental Methods**

Phase-pure HA and SiHA (1.5 wt%) powders were produced with a particle size of approximately 17 µm. Discs were prepared through uniaxial pressing at 124 MPa for 1 minute using powder calcined at 900°C, followed by sintering at 1250°C for 60 minutes. A co-culture of primary human osteoblasts (hOBs) and human dermal microvascular endothelial cells (HDMECs) was used. Discs were pre-coated with fibronectin for 2 hours, seeded sequentially at a hOB:HDMEC cell ratio of 70:30 and incubated for 8 Days. The formation of vessel-like structures was assessed via fluorescence microscopy using cell nuclei staining (DAPI) and HDMEC-specific cell markers (CD31 and vWF). To minimise the differences in surface topography, a number of discs were polished and subsequently scratched (PS) using a 30 µm lapping film to induce a controlled surface roughness required for cell attachment. Untreated and PS surfaces were visually inspected using Scanning Electron Microscopy (SEM). To assess the isolated effect of topography on cell behaviour, chemical properties of untreated and PS-treated samples were masked using an 8 nm thick gold-sputter coating (SC samples). Possible coating-induced topography modifications were examined using Atomic Force Microscopy (AFM).

**Results and Discussion**

AFM analysis showed that the layer of gold deposited sputter coating was sufficiently thin to avoid modification of the surface topography of the SiHA and HA discs. Visual inspection of SEM images revealed similar surface topographies between all PS samples, despite SiHA exhibiting a significantly smaller grain size compared to HA. Qualitative analysis showed vessel-like structure formation with multiple branching points on 2D SiHA and HA surfaces. The network obtained on the former material was observed to exhibit a higher level of complexity compared to the latter for both untreated and PS samples (Figure 1a). Quantitative analysis, presented in Figure 1b, showed that the number of tubular structures was significantly enhanced on SiHA compared to conventional HA. Although the differences in angiogenic potential observed between the two calcium phosphates reduced on PS discs, the vessel...
density remained significantly higher on PS-SiHA. Sputter coated (SC) and PS control samples showed no significant difference between the number of vessel-like structures indicating successful minimisation of the variability in surface topography between the samples.

**Conclusion**
The formation of vessel-like structures with multiple branching points was achieved on SiHA samples using a co-culture of hOBs and HDMECs. Topography was found to have a significant influence on the angiogenic potential of the calcium phosphates. The polishing and scratching method was found to significantly minimise the variability in surface topography as evidenced by similar cell behaviour on SC-PS samples. Although the difference in the density of vessel-like structures between SiHA and HA decreased on PS samples, a clear difference could still be observed, with a higher number of tubular structures observed on silicon-substituted samples. These findings indicate a direct influence of silicon on the biological performance of calcium phosphates.

Protein functionalized nano- and microporous ceramic biomaterials to tailor bacterial and cellular interactions

Deepanjalee Dutta¹, Jana Markhoff², Kurosch Rezwan³, Dorothea Brüggemann⁴

¹ University of Bremen, Institute of Biophysics, Bremen, DE; ² University of Bremen, Institute of Biophysics, Bremen, DE; ³ University of Bremen, Advanced Ceramics, Bremen, DE; ⁴ University of Bremen, Institute of Biophysics, Bremen, DE

Introduction
Surface modification of manifold biomaterial surfaces is important for orchestrating cell-ligand interactions during multicellular tissue repair. In particular, for ceramics-based biomaterials to be applied in soft tissue engineering such functionalization strategies are necessary to provide biochemical signals. Two essential proteins involved in tissue regeneration, namely collagen and fibrinogen, have been extensively used for the design of biomaterials for soft tissue repair, specifically to promote wound repair. Therefore, the fundamental aim of this study is to understand how ceramic biomaterials with variable topography can be modified with collagen and fibrinogen to tailor cell behavior and to prevent bacterial penetration.

Experimental Methods
As a model system for wound healing, we analyzed how 3T3 fibroblasts, HaCaT keratinocytes, and E. Coli bacteria interacted with protein-modified alumina nanopores and microporous alumina textiles for a possible regenerative therapy of the human body's largest organ, the skin. Using our established self-assembly routines of pH- and salt-induced self-assembly, alumina nanopores and microporous alumina textiles were silanized followed by modification with self-assembled collagen [1,2] or fibrinogen nanofibers [3-4], respectively.

Results and Discussion
Interestingly, collagen-modified alumina nanopores were able to prevent bacterial penetration. E. Coli bacteria died as a result of their inability to migrate through the membranes to access the underlying food supply (agar).[2] A very different behavior was found in fibrinogen-modified alumina textiles, with the textile surfaces being capable of acting as bacteria capture agents. Therefore, despite their microporous scaffold architecture, these textiles prevented bacterial infiltration, which is very interesting for protein-modified ceramics to be used as porous wound dressing materials that can promote adequate gas exchange and nutrient supply.

Further on, the interaction of skin cells, such as 3T3 fibroblasts and HaCaT keratinocytes, with protein-modified ceramics revealed the ability of both cell types to grow on these ceramics up to a period of 72 h. On the alumina nanopores, keratinocytes tended to mature in cell clusters [2], while on the microporous alumina textiles, a distinct difference in morphology was observed. Fibroblasts adhered well to the ceramics as well without noticeable changes in their morphology in response to the different topographies.

Conclusion
In summary, our results suggest a good potential of protein-modified ceramics with different topographies to mimic the microenvironment of native skin and other soft tissues and to enable the growth of various cell types via tailored biochemical cues.

The Influence of Formulation on the Release Kinetics of the Antibiotics from Biocompatible Ceramics

Rajan Choudhary¹,²

¹ Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; ² Riga Technical University, Baltic Biomaterials Centre of Excellence, Riga, LV; ³ National University of Science and Technology “MISiS”, Center for Composite Materials, Riga, LV

Introduction
Bone tissue reconstruction is often associated with bone infections such as osteomyelitis, septic arthritis, and prosthetic joint infections. *Staphylococcus Aureus* is found to be the most causative microorganism for these infections [1]. The bone-bonding ability of ceramics made them a potential biomaterial for bone tissue engineering, restoring bone defects, being an implant material, or coating over the metallic implants [2]. The regenerative potential of ceramics can be enhanced by using growth factors or antibiotics [3]. Therefore, ceramics have been explored as a drug carrier to deliver therapeutic molecules and prevent bone infections. One of the key terms in drug delivery is the drug release rate. The release rate of a drug is controlled by diffusion, dissolution, swelling, affinity, and ion exchange [4]. Also, material parameters can influence the drug release rate, such as pore size, surface modifications [5]. The current report attempts to study the influence of different formulations on the drug delivery behavior of biocompatible ceramics.

Experimental Methods
The microcrystalline hydroxyapatite was synthesized by a cost-effective sol-gel combustion method. The synthesized hydroxyapatite and commercially purchased zirconia were utilized as a drug carrier either in pure form or as a composite with biocompatible ceramic containing different amounts of polyvinyl alcohol (PVA) as a binder. The model drugs selected for comparison are ciprofloxacin hydrochloride and levofloxacin.

Results and Discussion
Ciprofloxacin hydrochloride shows a sustained release whereas levofloxacin shows burst release from the ceramic drug carrier. The percentage of polyvinyl alcohol added to the drug played a vital role as a higher concentration of the polymer affects the stability of the drug carrier. Hydroxyapatite/zirconia composite shows sustained release (29%) when compared to pure hydroxyapatite (43%) and zirconia (37%) after 6 hours of immersion in simulated body fluid.

Conclusion
Release kinetics shows that the nature of the drug, concentration of the binder, and the ratio of ceramics in the composites decides the release kinetics of the drug from the drug delivery carrier.

Amorphous Calcium Phosphate with Fluoride for Dental Restoration

Vita Zalite, Janis Locs

Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV

Introduction
Amorphous calcium phosphate (ACP) has been used as filler in ionomer cements, as colloidal suspensions in toothpaste, as ingredient in mouthwash and chewing gum, thus proving ACP remineralization efficiency in therapeutic dentistry [1]. Also there are some studies about ACP containing fluoride [2,3] to enhance anti-caries and remineralizing potential. However, wider application of ACP materials are limited due to thermal instability of this phase. Recently cold sintering process have been introduced [4] giving opportunity to sinter powdered materials without high temperature. This technique or its modification could be a key factor to produce ACP ceramic materials for dental hard tissue restoration. In order to obtain adequate mechanical strength and intensify anti-caries effect of the material we offer to incorporate fluoride into ACP structure (ACPF). The aim of this study is to produce ACPF ceramic as potential material for application in restorative dentistry.

Experimental Methods
ACPF was synthesized trough reprecipitation method, where CaO and H₃PO₄ were used as Ca²⁺ and PO₄³⁻ ion sources to precipitate CaP salt. 3M HCl was added to completely dissolve CaP salt and then 3M NaOH was used for reprecipitation of ACPF. The product was subjected to freeze drying. The ceramic ACPF tablets were obtained by uniaxial pressing (Ø 13 mm, 198 kN, 10 min), thus initiating cold sintering. To characterize obtained materials XRD, FTIR, picnometry was used, also bulk density and relative density were determined.

Results and Discussion
XRD pattern of synthesized ACPF powder showed only two humps characteristic of ACP phase. FTIR analysis revealed absorption bands attributed to [PO₄] group vibration in the range of 550-1000 cm⁻¹. [CO₃] group presence in the range of 1400-1520 cm⁻¹ and [HPO₄] group presence at 875 cm⁻¹ was detected. XRD data showed a very small amount of nanocrystalline phase presence in ACPF ceramic after sintering. There can be distinguished one peak with very low intensity at 28.6 2θ, that was strongly overlapped. The true density of the powder was 2.51±0.04 g/cm³. The bulk density of the ACPF ceramic tablets was 2.37±0.05 g/cm³ after pressing procedure and calculated relative density was 94.3%±0.6%.

Conclusion
In summary, by applying uniaxial pressure (1500 MPa) it is possible to obtain ACPF ceramic with relative density close to 100%. The preliminary results look very promising. However, mechanical testing should be performed in further study.

Biomimetic amorphous calcium phosphate biomaterials for in vivo guided biosynthesis of biomimetic hydroxyapatite

Jana Vecstaudza¹, Marika Mosina¹, Valentina Stepanova¹, Janis Locs¹,²

¹ Riga Technical University, Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga, LV; ² Baltic Biomaterials Centre of Excellence, Headquarters at Riga Technical University, Riga, LV

Introduction

Number of patients encountering musculoskeletal system traumas, bone related diseases and pathologies increases worldwide, therefore the need for effective biomaterials is still persistent. Such effective materials should copy both physical and chemical structure of the inorganic part of the bone tissue. Recently our group has developed synthesis route [1] for obtaining of amorphous calcium phosphate (ACP) with physical structure that is similar to the biological calcium phosphate (CaP) particles within the bone tissue. The similarity is attained by the nanostructures, that can be expressed as increased specific surface area (SSA) of the synthesized ACP (133-150 m²/g). The SSA of this ACP is much closer to SSA of the bone CaP particles (up to 240 m²/g [2]) as of other ACP materials reported in the literature. Further, to achieve the similarity of the chemical composition of the bone mineral, the ACP should be enriched chemically. Therefore, aim of the study is to obtain and characterize ACP with biomimetic chemical composition, where the biomimetic ions are carbonates, magnesium, strontium, sodium, potassium, chloride, fluorine and zinc. Introduction of such biomimetic ACP biomaterials into the body would ensure biosynthesis of biomimetic calcium phosphate, e.g., biomimetic hydroxyapatite, by dissolution and subsequent reprecipitation route.

Experimental Methods

ACP was synthesized using precipitation method [1], that was modified to enrich the composition with biomimetic ions. In brief, CaO was dissolved in hydrochloric acid and transparent solution was obtained. Then reagents containing biomimetic ions were added. Later being: MgO, SrCl₂, KOH, NaF and Zn(NO₃)₂. Next, under vigorous stirring stoichiometric amount of NaOH was added, thus inducing precipitation of biomimetic ACP. The precipitated product was rinsed with deionized water and dried at 80 °C temperature. The as-synthesized ACP was characterized using XRD, FT-IR in ATR mode, SEM-EDS, BET and DTA methods. Heat treatment (1100 °C/1h) was performed to determine quantitative phase composition and further use it to calculate Ca/P molar ratio of the biomimetic ACP. Furthermore, stability of the ACP phase in air atmosphere was studied in the course of 12 months using XRD. Stability in wet environment was studied as well in comparison with pure ACP. Parallelly three samples were obtained and characterized.

Results and Discussion

The modified precipitation method was successful for obtaining ionically enriched ACP. XRD patterns of respective samples demonstrated two wide humps characteristic to ACP (see Fig. 1). The FT-IR spectra confirmed presence of the carbonate ions. Next, the SEM-EDS confirmed the presence of the rest of the biomimetic ions: Mg, Sr, K, Na, F and Zn. The SSA of biomimetic ACP was 86±10 m²/g, which was slightly smaller than that of pure ACP obtained by the same method (133-150 m²/g [1]), however reason behind this is still unclear. Heat treatment produced biphasic mixture of HAp/β-TCP with ratio of 10/90 wt%, thus the calculated Ca/P molar ratio of the biomimetic ACP was 1.52. Crystallization temperature was determined with DTA; it was lower for the biomimetic ACP than for pure ACP: 620 °C and 650 °C, respectively. Regarding the ACP phase stability in air - it was stable for 12 months (study is ongoing). Further, it was found that
presence of biomimetic ions stabilizes ACP phase in water environment when compared to pure ACP. Pure ACP started to crystallize after 8-9 h, while for the biomimetic ACP crystallization was detected at 48 h (see Fig. 2).

**Conclusion**
- Biomimetic ACP with intended chemical composition was successfully obtained by a modified precipitation method.
- Addition of biomimetic ions to the ACP lowered its specific surface area and crystallization temperature, however specific surface area remained relatively high: \(86 \pm 10 \text{ m}^2/\text{g}\).
- At the same time stability in water environment for the biomimetic ACP was increased more than five times comparing to the pure one.
- Further studies include ACP phase stability tests in simulated body solutions and *in vitro* cell tests.

Role of borosilicate bioactive glasses in bone regeneration

Nefeli Vaporidou, Azadeh Rezaei, Tim Schaefer, Joel Turner, Aldo Boccaccini, Gavin Jell

1 University College London, Division of Surgery and Interventional Science, London, GB; 2 University of Erlangen-Nuremberg, Institute of Biomaterials, Erlangen, DE

Introduction
An ageing population means an increasing need for materials that can stimulate bone regeneration in patients with impaired bone healing. Boron has been reported to affect bone metabolism and a lack of boron is associated with impaired bone development. Boron deficiency in animal models can also result in reduced chondrocytes density in the growth plate and decreased bone volume fraction. The incorporation of boron into the bioactive glass (BG) network has been shown to promote osteoblast metabolic activity and angiogenesis. However, there is still relatively little known about the cellular mechanism of boron. In this study, using an in vitro bone nodule formation model, the effect of boron and boron bioactive glasses (BBG) is investigated with the aim of developing tailored BGs with an optimised ion release profile for patients with underlying bone diseases.

Experimental Methods
Calvarial osteoblasts were isolated from 3-day-old Sprague-Dawley rats and cultured in α-MEM supplemented with 2 mM β-glycerophosphate, 10nM dexamethasone, and 50μg/mL ascorbate for 21 days. Osteoblasts were treated with dissolution products of boron bioactive glass (provided by Prof. A. Boccaccini with a composition in wt%: 37.5 SiO₂, 22.6 CaO, 5.9 Na₂O, 4.0 P₂O₅, 12.0 K₂O, 5.5 MgO, 12.5 B₂O₃) diluted to achieve 0.3, 0.7 and 1mM of boron (referred to B1, B2 and B3 respectively) as determined by ICP. 45S5 bioactive glass (similar Si level to B1) was used as control. The proliferation (total DNA quantification), angiogenic response (VEGF ELISA) and alkaline phosphatase activity of the cells were measured. Bone nodule formation in response to the BG dissolution products was characterised using Alizarin Red calcium staining and transmission electron microscopy (TEM). Raman spectroscopy and interferometry (for quantitative size analysis).

Results and Discussion
Boron was released from the BGs within biologically relevant ranges. Boron Bioactive Glass dissolution products (within the range of 0.3-1mM boron) did not affect total DNA or VEGF expression after 7 days of culture (Figure 1). For the first time, results will be presented on the effect of boron on bone nodule formation.

Conclusion
Understanding how boron interacts with osteoblasts in vitro will allow the development of improved bioactive glasses, that release different therapeutic ion concentrations to target different stages of healthy bone regeneration.
Figure 1. Osteoblast VEGF expression in response to Boron Bioactive glass (BBGs) Dissolution products.

BBGs did not affect VEGF expression (7-day culture).

3D bioplotting of neonatal porcine islets in a plasma-based bioink

Sarah Duin¹, Susann Lehmann², Elisabeth Kemter⁴, Eckhard Wolf⁴, Anja Lode¹, Michael Gelinsky¹, Barbara Ludwig²,³

¹ TU Dresden, Centre for Translational Bone, Joint and Soft Tissue Research, Dresden, DE; ² University Hospital Carl Gustav Carus, TU Dresden, Paul Langerhans Institute Dresden of Helmholtz Centre Munich and German Centre for Diabetes Research, Dresden, DE; ³ University Hospital Carl Gustav Carus, TU Dresden, Department of Medicine III, Dresden, DE; ⁴ Ludwig-Maximilians University Munich, Gene Center, München, DE

Introduction
Diabetes mellitus type 1 is characterized by insulin-deficiency due to autoimmune-derived destruction of the insulin-producing beta cells in the pancreas. The common therapy is treatment with exogenous insulin, however the majority of patients develop major complications such as kidney failure in the long-term. To avoid those it would be preferable to make islet transplantation available for a larger number of patients. Human islets for transplantation are sparse, but donor shortage could be solved through use of xenogeneic islets, whereby neonatal porcine islets are an attractive candidate [1]. Especially for xenogeneic islets separation from the host’s immune system is crucial, yet supply with oxygen and nutrients as well as the ability to sense blood-glucose should not be impaired, which requires short diffusion distances. For easy retrieval macroencapsulation devices are preferable over microencapsulation of islets, yet the diffusion distances in these are large.

In a proof-of-concept study we were able to show that it is possible to create macroporous scaffolds with encapsulated functional murine pancreatic islets by using extrusion-based 3D bioplotting [2] with a biologically inert hydrogel blend of alginate and methylcellulose [3]. Preliminary work of our group indicated that this approach is also a promising tool for the bioplotting of neonatal porcine islet-like cell clusters (NICC), yet the system was limited by a lower viability than had been observed in murine islets and a progressive loss of function over time. In this study, the biologically inert hydrogel was adapted for use with human platelet lysate to study the hypothesis that growth factors from platelets, e.g. insulin-like GF 1, and plasma components such as serum albumin support cell survival and function in plotted scaffolds.

Experimental Methods
The hydrogel used for bioplotting consisted of 3 % medical-grade alginate dissolved in PBS or in platelet lysate (PL), prepared from platelet concentrate obtained from a local blood bank (Deutsches Rotes Kreuz - Blutspedendedienst Nord-Ost, Dresden, Germany), and 9 % methylcellulose (algMC or PL-algMC). Viscosity of the cell-free blends was analysed using a plate rheometer (Rheotest RN 4).

NICC were incorporated into the gels prior to bioplotting carried out on a BioScaffold 3.1 (GeSiM, Germany). Scaffolds with NICC were crosslinked with SrCl₂ and cultured in supple-mented Ham’s F-10.

To investigate distribution and cell viability, NICC were stained with MTT or calcein AM/ethidium homodimer, and cryosections of islet-containing scaffolds were stained with DAPI and TUNEL. Presence of insulin was studied via dithizone staining of whole scaffolds, and of immunofluorescence-staining for insulin and glucagon inside the islets in cryosections. To study glucose stimulated insulin response, plotted islet scaffolds and free control islets were incubated in Krebs-Ringer buffer supplemented with either 3.3 or 16.4 mM glucose and a long-lasting glucagon-like peptide 1 (GLP1) analogue. Insulin content was analysed by quantification of secreted insulin with ELISA and normalization to the DNA content determined after cell lysis by QuantFluor assay.

Results and Discussion
By comparison to algMC we were able to show that PL-algMC has a similarly high viscosity, yet incorporation of NICC into either blend did not impact their morphology. For both blends, MTT-staining demonstrated an even distribution and metabolic activity of NICC inside the plotted scaffolds. Live/Dead as well as TUNEL stainings indicated viability of encapsulated NICC for as long as 28 days, whereby the viability of those exposed to PL was increased compared to NICC encapsulated in plain algMC. Dithizone and immuno-fluorescence stainings confirmed that insulin and glucagon are continuously produced and adequately located in encapsulated NICC. Our data also suggest that, while GLP-1 receptor agonists are required for functionality of NICC independent of the hydrogel used for encapsulation, functionality was improved in bioplotted constructs prepared with PL.

**Conclusion**

This study introduces a hydrogel blend with platelet lysate for increased biological support of neonatal porcine islet-like cells clusters in 3D bioplotted constructs.

Development of biodegradable shape memory polymers towards minimally invasive, patient-specific breast reconstruction

Coralie Greant, Lana Van Damme, Sandra Van Vlierberghe

Ghent University, Polymer Chemistry & Biomaterials Group, Centre of Macromolecular Chemistry (CMaC), Department of Organic and Macromolecular Chemistry, Ghent, BE

Introduction
According to estimations of the Global Cancer Observatory, over 2.2 million women were diagnosed with breast cancer in 2020, worldwide. [1] While most often requiring surgical removal of the affected breast tissue, breast reconstruction following mastectomy remains a challenge. [2] Conventional reconstruction techniques, using synthetic prostheses or autologous tissue, are accompanied with risks and complications such as infection, prosthesis rupture, capsular contracture, donor site morbidity, uncontrollable resorption rates and the need for reinterventions. [3,4,5] Therefore, a strong research focus is directed towards regenerative adipose tissue engineering, shifting reconstruction strategies from tissue replacement to autologous tissue regeneration.

Experimental Methods
In the present work, a novel approach is introduced to enable minimally invasive, patient-specific, aesthetically elegant breast reconstruction. To this end, shape memory copolymers based on aliphatic polyesters were synthesized and functionalized into acrylate end-capped urethane-based polymers (AUPs) to enable chemical crosslinking. The materials were tuned by adjusting the ratio of building blocks and adapting the molar mass, in order to achieve a glass transition temperature below body temperature (30 - 35°C). The AUPs were characterized physico-chemically by nuclear magnetic resonance (NMR) spectroscopy, differential scanning calorimetry (DSC), thermogravimetric analysis (TGA) and gel permeation chromatography (GPC). Subsequently, a photo-sensitive resin was developed based on the synthesized AUPs, rendering them suitable for digital light processing (DLP). By varying the molar mass of the polymer, the acrylate content of the AUPs and the concentration of photoinitiator and photoabsorber, the resin was optimized towards efficient photo-crosslinking, which was confirmed by means of photo-rheology. Furthermore, the gel fraction was assessed and swelling tests were performed, to study the crosslinking efficiency and network density. Once optimized, the photo-sensitive resin was processed into porous scaffolds by means of DLP, as an appropriate porous architecture will enable (adipose) tissue infiltration and regeneration within the scaffold. The morphology of the obtained scaffolds was investigated using scanning electron microscopy (SEM) and micro-CT. The results indicated that stable scaffolds can be realized, with pore sizes around 1000 μm.

Results and Discussion
Furthermore, in vitro biocompatibility assays were performed, to assure the absence of cytotoxic components. To this end, adipose-derived stem cells were seeded onto tissue culture plates. The cytotoxicity was tested through an indirect assay in which the crosslinked materials were submerged during 24h, 72h and 7 days in culture media. The culture media, containing any leached components, was placed on top of the seeded cells in order to assess biocompatibility through a live/dead staining and MTS assay. Finally, a crucial aspect in this project is the shape memory property of the final scaffold. Based on the glass transition temperature of the AUP, which is right below body temperature, a shift in shape can be induced - from a temporary reduced size into a permanent large, patient-specific volume - upon implantation in the body. This assures the minimally invasive approach of the developed strategy. The study of this shape memory effect, as evaluated by shape fixity and strain recovery, as well as the mechanical characterization of the scaffold, is currently ongoing.

Page 1689 of 2028
Additionally, future experiments include a profound study of the effect of shape memory characteristics on cell behavior, by injecting cell-encapsulating gelatin-based hydrogels in the porous scaffold.

**Conclusion**

As a result, the developed porous shape memory scaffolds can be considered promising candidates towards minimally invasive, patient-specific adipose tissue engineering.

Introduction

Intrinsically conducting polymers (ICPs) have been largely applied to produce biomaterials. However, their use in neural tissue engineering is considerably restricted because of some intrinsic disadvantages, including their hydrophobicity and inadequate mechanical characteristics. In order to overcome these limitations, soft conductive polymer hydrogels (CPHs) have been explored, resulting in water-based platforms with optimal adhesion, biological and electrical features as well as comparable mechanical properties to the native tissues. Approaches providing the incorporation of ICPs as a conductive element into CPHs have been lately researched by synthesizing the hydrogel around ICP chains, resulting in an interpenetrating polymer network (IPN). Due to the efficient ICP integration into the hydrogel network, IPNs have shown some favorable properties including high chemical and mechanical stability, biocompatibility, electrical and electrochemical characteristics.

Experimental Methods

In this work, the interpenetrating polymer network hydrogel is designed and developed by the introduction of polythiophene (poly[6-(3-thienyl)hexanesulfonate], P3HT6S) into poly(N-isopropylacrylamide-co-N-isopropylmethacrylamide) (P(NIPAm-co-NIPMAm)) hydrogel network. The incorporation of P3HT6S as ICP aims to confer sufficient electrical characteristics to the final platform. In order to permit the production of the hybrid hydrogel in an aqueous medium, polythiophene monomers are modified and synthesized to guarantee the water-solubility. Upon dissolution of P3HT6S in water, NIPAm-co-NIPMAm constituents are added, resulting in the hydrogel precursor solution. The final system is established by synthesizing the P(NIPAm-co-NIPMAm) hydrogel interpenetrated with P3HT6S chains by UV light exposure in a cold environment, forming the IPN. Morphological, chemical, thermal, electrical, electrochemical, and mechanical characteristics of the IPN are examined to investigate the effect of different P3HT6S concentrations into the hydrogel formulation. Furthermore, human umbilical-derived mesenchymal stem cells and neural progenitor cells isolated from postnatal mouse brain sub-ventricular zone are selected to investigate the biological properties of P(NIPAm-co-NIPMAm)/P3HT6S hybrid hydrogel. Thus, the response of cells seeded and cultured on the conductive IPN is evaluated in terms of cell viability, proliferation, and neural differentiation. Finally, the suitability of the hybrid hydrogel as ink for 3D printing applications is assessed.

Results and Discussion

The influence of P3HT6S incorporation into the P(NIPAm-co-NIPMAm) hydrogel is evaluated in terms of morphological characteristics, evidencing similar properties of up to 2% P3HT6S concentrated hydrogels.
enhancements of electrical, electrochemical, and mechanical characteristics of the proposed P(NIPAm-co-NIPMAm)/P3HT6S hydrogel compared to the P(NIPAm-co-NIPMAm) pristine formulation are also reported. Hence, the suitability of the novel conductive hydrogel for promoting the conduction of neural electrical signals in physiological environments and inducing an optimal mechanical integration in the brain tissue is highlighted. Furthermore, the hydrogel's biocompatibility is proven by a high percentage of viable mesenchymal stem cells cultured onto the IPN platform. Additionally, the biological response of neural progenitor cells seeded onto P(NIPAm-co-NIPMAm)/P3HT6S reveals that the hybrid hydrogel supports the survival of neurons and astrocytes, as the two main cell types of the central nervous system (Figure 1). More in detail, it is evidenced that P(NIPAm-co-NIPMAm)/P3HT6S hydrogel can promote cell neural differentiation, as highlighted by the presence of a significantly higher quantity of neural cells on P(NIPAm-co-NIPMAm)/P3HT6S samples at late stages of culture. Lastly, the possibility to exploit the hydrogel solution as a printable ink for the fabrication of 3D biomaterials with tailored morphological and structural characteristics is illustrated.

Conclusion
In this study, a soft, low-impedance, and biocompatible P(NIPAm-co-NIPMAm)/P3HT6S hydrogel is designed and developed. Results reveal that the proposed platform is a suitable candidate for the design and production of 3D-printed conductive biomaterials, enlightening a promising potential for novel neural tissue engineering applications.

Nisin Z loaded wet-spun fibers: characterization and antibacterial features against *Staphylococcus aureus*

Natália C. Homem, Tânia D. Tavares, Catarina S. Miranda, Joana C. Antunes, Maria Teresa S.P. Amorim, Helena P. Felgueiras

*University of Minho, Centre for Textile Science and Technology (2C2T), Guimarães, PT*

**Introduction**

Microbial resistance against conventional antibiotics is being classified as a public health problem, with economic consequences worldwide. *Staphylococcus aureus* – a common opportunistic pathogen – induced infections are among the most prevalent, once *S. aureus* is resistant to multiple antibiotics. Thus, both the academia and the industry sectors have been devoting their efforts in finding solutions or alternatives to the widespread antibiotic resistance of *S. aureus*[1]. In this scenario, antimicrobial peptides (AMPs) are gaining more importance in pharmacology or biomedicine strategies as they can target multiple organisms with efficiency, are less likely to induce resistance, and are not just bacteriostatic but also bactericidal[2]. Nisin Z, an AMP which presents significant antibacterial activity against Gram-positive bacteria and low toxicity in humans, has been studied for food preservation applications, but very little research has been done to explore its potential in biomedical applications. In this context, the aim of this study was to engineer bio-based fibrous structures for the controlled release of Nisin Z, aiming to serve as platforms in the fight against *S. aureus*-derived infections. Single- and dual-polymer fibers, composed of sodium alginate (SA) and gelatin (GN), were produced via wet-spinning and subsequently loaded with Nisin Z. Loaded and unloaded fiber's controlled release kinetics and antimicrobial action was mapped, and their physical, chemical, and thermal properties were assessed. The long-term stability of the fibers was also evaluated.

**Experimental Methods**

Nisin Z peptide (Mw 3331.05, potency <38,000 IU/mg, Toku-E) was characterized via Fourier-transform Infrared Spectroscopy (FTIR) and its Minimum Inhibitory Concentration (MIC) against *S. aureus* was assessed by the broth microdilution method, in order to establish the loading concentration of peptide into fibers. SAGN spinning solutions were prepared by mixing SA (alginic acid sodium salt from brown algae, medium viscosity) and GN (type A from porcine skin, ≈ 300 bloom) under low stirring at a polymer ratio of 70:30 v/v (SA at 2 wt% and GN at ≈ 1wt% dissolved in distilled water). Then, SAGN fibers were produced by wet-spinning in a set-up composed of a syringe pump (NE-1600, New Era Pump Systems), a tray containing the coagulation bath (2wt% CaCl$_2$ aqueous solution at 21°C), and an 18-gauge (G) needle. The spinning was performed at a rate of 0.1 mL/min and room temperature, and the fibers were collected and stored in a cabinet desiccator. SA control fibers were produced in equal conditions, while SAGN-crosslinked and SA-free-crosslinked fibers (labeled as SAGNCL and GNCL, respectively) were produced via the removal of SA from SAGN fibers (immersion within PBS 0.25M solutions for 48h at 4°C) and subsequent crosslinking with glutaraldehyde (immersion in a concentrated PBS solution containing 2.5 wt% of glutaraldehyde for 1h at 4°C)[3]. The functionalization of SA, SAGN, SAGNCL and GNCL fibers with Nisin Z was achieved via adsorption (72h, 120rpm) at a loading concentration of 3xMIC, resulting in SAz, SAGNz, SAGNCLz and GNCLz fibers. The loading efficiency was confirmed by UV-VIS spectroscopy at 205 nm. The morphology (brightfield microscopy), chemical composition (FTIR), thermal resistance (Thermogravimetric analysis, TGA, and Differential Scanning Calorimetry, DSC) and degradation/release profile (SBF at pH 7.4, release via UV-VIS) of all fibers were assessed. In addition, the antibacterial activity against *S. aureus* of SA, GN, SAGN and Nisin Z solutions was acquired via the Kirby-Bauer method, while the unloaded and loaded fibers were evaluated via time-kill kinetics assay[4].

**Results and Discussion**

Page 1693 of 2028
FTIR results showed that SAGN fibers were successfully produced and that modifications to these fibers’ chemical stability and structure were introduced via PBS reactions, crosslinking with CaCl₂ and glutaraldehyde (GNCL and SAGNCL). Regardless of the chemical modification employed, all fibers were homogeneous both in size (≈ 243.55 µm) and shape (defect-free). SAGNCL fibers proved to be the most resistant regarding thermal resilience, assessed via TGA and DSC. Nisin Z was functionalized onto all fibers at an average concentration of 178 µg/mL. Nisin Z did not impact on the fiber’s morphology nor on their chemical/thermal stability. Its main effect was detected on the time-kill kinetics of the bacteria S. aureus. SAGNCLz and GNCLz were capable of progressively eliminating the bacteria, reaching an inhibition superior to 99% after 48h of culture. The peptide-modified SA and SAGN were not as effective, losing their antimicrobial action after 6h of incubation. Bacteria elimination was consistent with the release kinetics of Nisin Z from the fibers.

**Conclusion**

In general, data revealed the increased potential and durable effect of Nisin Z (significantly superior to its free, unloaded form) against S. aureus-induced infections, while loaded onto prospective biomedical wet-spun scaffolds.

Human-derived extracellular matrix solid foams for in vitro adipose tissue formation

Nerea Garcia Urkia¹, Iratxe Madarieta¹, Jose Ramon Pineda², Igor Irastorza², Gaskon Ibarretxe², Fernando Unda²

¹ Tecnalia, Basque Research and Technology Alliance (BRTA), Biomaterials, Donostia-San Sebastián, ES; ² Faculty of Medicine and Nursing, Basque Country University, Cell Biology and Histology, Leioa, ES

Introduction
Increased incidence of adipose-related diseases involves the need of in vitro models¹. The extracellular matrix (ECM) represents the suitable material for this purpose. In this work, we describe human-derived decellularized adipose tissue (hDAT)² processed as solid foams (SF) in combination with collagen type I (Col-I). The study is based on structural and human dental pulp stem cell (HDPSC)³ culture, as a cell type with the capacity to differentiate into adipocytes.

Experimental Methods
hDAT³ and Col-I-based SFs were obtained by freeze drying a 0,5 % (w/v) acid solutions (10 µl in an 4x 0,8 mm µ-slide) (Table 1). SFs microstructure (SEM), water absorption and HDPSC cultures⁴ (1.5 x 10⁴ cells/SF) were studied. After 3 days of culture, cell stained to determine viability (Calcein/Propodium Iodide) and proliferation (Ki67 antibody and Alexa 488) in the SF analyzed by fluorescent microscopy. The viable and proliferation rate was determined (positive cells/total cells) in 3 microscopic images of SF.

Table 1. Sample identification (ID) and hDAT/Col-I SF composition.

Results and Discussion
All SF no showed significant differences in physically characterization. SFs showed an interconnected porous architecture (100µm pore, fig. 1A) with Young modulus between 2043 ± 400 Pa (SF1) and 5858 ±871 Pa (SF4), and water absorption 96-97 %. HDPSC viability and proliferation results are shown in Fig. 1 (B and C) and Fig 2. HDPCS cells maintained viable (>95%) and proliferate (>7%) on the SFs. The highest cell proliferation rate was detected with high hDAT quantity.

Conclusion
Freeze dried SFs obtained by various formulations of hDAT and Col-I ECM materials, shown optimal physical and biological properties for HDPSC culture. The best hDPSC viability and proliferation results were shown in SFs obtained by 100% and 75% hDAT in formulation which are currently being analyzed to determine the biologic capacity of the SFs to differentiate hDPSC in adipocytes and ideally form new in vitro adipose tissue model.

Green antibacterial thermosensitive hydrogels based on corn silk extract, hyaluronic acid and nanosilver for wound healing application

Assunta Borzacchiello¹, Mario di Gennaro¹,², Pooyan Makwandi³, Ghareib W Ali⁴, Francesca Della Sala¹, Wafa I. Abdel-Fattah⁴, Luigi Ambrosio¹

¹ National Research Council of Italy, Institute of Polymers, Composites and Biomaterials, Napoli, IT; ² Università degli Studi della Campania “Luigi Vanvitelli”, Caserta, IT; ³ Istituto Italiano di Tecnologia, Centre for Micro-BioRobotics, Pisa, IT; ⁴ National Research Centre, Inorganic Chemistry Division and Mineral Resources, Refractories and Ceramics Dept., Biomaterials Group, Cairo, EG

Introduction
Hydrogels have attracted research attention for wound healing applications since hydrogel dressings are an excellent source for providing moisture to a dry lesion, monitoring fluid exchange from within the wound surface, helping to cool down a wound, as well as provide temporary pain relief [1]. Thermosensitive amphiphilic block copolymers, polyethylene oxide-polypropylene oxide copolymers (Poloxamers or Pluronics, PPO-PEO-PPO), thanks to their ability to undergo thermal gelation, to their good tolerability, and low irritancy/toxicity, have been used in the biomedical field for instance for tissue engineering and drug delivery applications [2]. Hyaluronic acid (HA) is naturally occurring glycosaminoglycan, presents in mammalian connective tissues. It has been demonstrated that HA promotes dermal regeneration and for this, it is widely used as dermal fillers, as wound dressings and substrates for dermal engineering applications [3]. It has to be highlighted that infection is a crucial and generally unsolved issue in wound healing. Therefore, materials containing antimicrobial compounds, such as Ag nanoparticles (Ag NPs) have shown the capability to inhibit or decline infections. Corn silk extract (CSE), a waste material of the crop, has been used for AgNPs biosynthesis as both a reducing and stabilizing/capping agent [4]. In addition, CSE possesses excellent antioxidant capacity [5]. In this context, we propose novel and green thermosensitive nanocomposites hydrogels based on HA, Pluronics and AgNPs for wound healing applications.

Experimental Methods
The corn silk were heat extracted. AgNPs were synthesized within CSE by microwave. The hydrogels were prepared by dissolving different amounts of Pluronics F127 and F68 in silk extract with and without AgNPs. Subsequently HA was added. The hydrogels composition was optimised by rheological analysis. The hydrogels were characterised for the rheological properties. The formation of AgNPs was confirmed by UV-Vis surface plasmon band while their morphology was evaluated by DLS and HRTEM. Bacterial cell suspensions were prepared, for each tested Gram-positive and Gram-negative, the cell growth of the tested bacteria was determined at the end of the incubation period, based on the optical density measurements at a wavelength of 620 nm. In vitro biocompatibility was performed by Alamar Blue assay on L929 fibroblast cells culture. The wound healing potential of the realized formulations was assessed by wound healing assay on Human Dermal Fibroblast (HDF) cells after 24 and 48 h of thermosensitive hydrogels incubation. Wound healing assay was performed by scraping the cell monolayer in a straight line to create a “scratch area”. Wound area, was calculated using the ImageJ public domain software. The migration rate can be expressed as the percentage of wound area reduction or wound closure.

Results and Discussion
Separate Pluronic F127 and F68 solutions do not show an appropriate Tgel but by formulating Pluronic F127/F68 blends at specific concentrations, it was possible to obtain a medium with a Tgel close to Tb. The addition of HA slightly affects Tgel, but very interestingly, improved significantly the final gel viscoelastic properties. AgNPs were spherical with average diameter of 8 nm (Figure 1A-D). The presence of AgNPs did not alter the hydrogels rheological
properties. The AgNPs hydrogels showed an excellent bactericidal activity against the tested Gram-positive and Gram-negative bacterial strains. The results confirmed the bactericidal activity of the samples in comparison with control. It has been demonstrated the biocompatibility of the hydrogel on L929 cells and that the presence of Ag does not modify the cell viability. The in vitro wound healing assay of the realized thermosensitive corn silk extract-nanosilver hydrogels was performed on HDF cells; the results (Figure 2A-C) have been demonstrated that the wound surface area decreases with the increasing exposure times (24 to 48h) of the tested hydrogels compared to the controls. Accordingly, the wound closure percentage increases with the increasing time after exposure to the injectable hydrogels. The individual biomaterials used in this assay could affect positively the wound healing process.

**Conclusion**

We developed a Novel and green thermosensitive injectable hydrogels based on HA, CSE and Ag NPs. In-vitro model of wound healing revealed that the nanocomposites allow faster wound closure and repair, compared to the control. The obtained results highlight the potential application of these novel injectable hydrogels as wound dressing.

Development of vitamin C loaded plant-based microfibers for wound healing applications

Fabrizio Fiorentini¹,2, Giulia Suarato¹,3, Rosalia Bertorelli³, Athanassia Athanassiou¹

¹ Istituto Italiano di Tecnologia, Smart Materials, Genova, IT; ² Università di Genova, DIBRIS, Genova, IT; ³ Istituto Italiano di Tecnologia, Translational Pharmacology, Genova, IT

Introduction
Wound healing is an articulated process, which consists of several biological and chemical events. Tissue repair mechanisms can be improved by (1) stimulating cell proliferation through the employment of microfibrous scaffolds, which can effectively mimic the 3D conformation of the extracellular matrix, and (2) applying bioactive molecules able to boost the cell ability to restore the wound area. Moreover, materials derived from natural resources are becoming an optimal choice to create alternative wound dressing. The purpose of this work was to fabricate natural 3D microfiber scaffolds loaded with vitamin C for the treatment of skin lesions, by combining four plant-based molecules: zein, an alcohol-soluble protein derived from corn; low-methoxy pectin, the most abundant hydrophilic polysaccharide in the plant cell wall; soy lecithin, used as emulsifier agent; and vitamin C, the bioactive molecule able to exert antioxidant activity and stimulate collagen synthesis.

Experimental Methods
The polymeric microfibers were produced through vertical electrospinning of emulsion solutions, obtained by blending in aqueous 80 % v/v ethanol solution the four plant-based molecules described above. The optimized electrospinning parameters consisted in a voltage of 20 kV, a flow rate of 2 mL/hour and a distance of 25 cm between the tip of the needle and the collector. Five samples (labeled ZPC_0, 1, 2, 3, 4) containing different concentrations of vitamin C (0 – 10 mg/mL) were fabricated and their cross-linking was optimized, in order to enhance their water resistance. Two strategies of cross-linking were tested: (1) immerse in aqueous CaCl2 15 % (w/v) solution for 5 minutes at room temperature (RT); (2) trifluoracetic acid treatment for 3 minutes at RT in a closed environment. Morphological analysis was performed by SEM while the chemical characterization of the samples was carried out by FTIR spectroscopy. An in vitro drug release assay was set up by incubating the samples in 3 mL of PBS (pH 7.4) in an oven set at 37°C and replacing the buffer with fresh one at each time point until 24 hours. Swelling and degradation rate was monitored by immersing the matrices, before and after cross-linking, in PBS alone or with protease XIV from Streptomyces griseus inside at 37°C for a week. The biocompatibility was evaluated on Human Dermal Fibroblast adult (HDFa) cells by MTS assay.

Results and Discussion
SEM micrographs showed ribbon-like microfibers morphology without the formation of any beads (Figure 1a-j). The increase of vitamin C content in the samples resulted in an expansion in the fiber average diameter, from 0.84 to 1.19 μm (Figure 1k). The SEM imaging of the cross-linked samples demonstrates that TFA cross-linking was able to maintain better the microfibers structure compared to the CaCl2 cross-linking. In vitro drug release indicated a burst release of the vitamin C from the microfibers within 3 hours of immersion. Degradation assay showed a higher weight loss of the samples when immersed in PBS with protease, compared to the immersion in PBS alone. In vitro MTS assay on HDFa cells resulted in good biocompatibility for each sample of the study, except for the microfibers cross-linked through TFA treatment, which led to a decrease in cell viability compared to the control (Figure 2). Although this decline was recorded, biocompatibility improved with increasing concentrations of the vitamin C loaded into the fibers.

Conclusion
Page 1701 of 2028
So far, the results confirmed that our plant-based electrospun microfibrous patches represent a suitable biomaterial for wound healing applications. Ongoing experiments are carried out to test other physico-chemical properties of the matrices, such as their mechanical resistance and their radical scavenging ability towards DPPH• radicals.

The Development of an Implantable Bioengineered Tracheal Scaffold for Respiratory Tissue Regeneration

Tehreem Khalid1,2, Sally-Ann Cryan1,3, Fergal O'Brien1,4, Cian O'Leary1,2

1 Royal college of Surgeons in Ireland, Tissue Engineering Research Group/School of Pharmacy and Biomolecular Sciences, Dublin, IE; 2 RCSI & Trinity College Dublin, Advanced Materials & Bioengineering Research (AMBER) Centre, Dublin, IE; 3 National University of Ireland, Centre for Research in Biomedical Devices (CÚRAM), Galway, IE; 4 Trinity College Dublin, Trinity Centre for Biomedical Engineering, Dublin, IE

Introduction

Attempted tracheal replacement efforts to date have had very little success, due to their inability to regenerate a protective layer of respiratory epithelium and often succumbing to stenosis within poorly-vascularised constructs [1, 2]. The major objective of this study was to optimise a bilayered collagen-hyaluronic acid scaffold (CHyA-B), which has shown to facilitate the growth of respiratory epithelial cells on its non-porous film layer and fibroblasts in its porous collagen sub-layer [3]. This redeveloped bilayered scaffold will be assessed for cellular biocompatibility, robust mechanical properties, and maximised submucosal blood vessel formation to produce an innovative tracheal medical device.

Experimental Methods

A biodegradable, thermoplastic polymer was used to 3D-print a tubular backbone which was integrated into the CHyA-B scaffold via lyophilisation. Construct design was optimised via multimodal mechanical assessment to assess compressive strength and scaffold flexibility. The composite scaffold’s vascularisation potential was determined by assessment of cellular viability and angiogenesis using a previously optimised delayed co-culture model of Human Umbilical Vein Endothelial Cells (HUVECs) and Human Mesenchymal Stem Cells (hMSCs) [4]. In vitro vessel formation and infiltration visualisation was assessed using confocal microscopy and angiogenic growth factor release was assessed via ELISA and qRT-PCR.

Results and Discussion

The 3D-printed backbone was successfully incorporated within the CHyA-B scaffold by lyophilisation, producing a composite scaffold with a mean pore size of 300μm, ideal for vascularisation. The construct mimicked native tracheal mechanics with a compressive modulus of 0.09 to 0.19 MPa and flexural moduli of 0.13 to 0.29 MPa. The composite scaffold enhanced cell growth, expressing 2-fold higher levels of double stranded DNA than control materials and similar levels of cellular metabolic activity compared to control. Notably, angiogenic growth factor release (VEGF and bFGF) and angiogenic gene upregulation (KDR, TEK-2 and ANG-1) was detected in composite scaffolds and remained sustainable up to 14 days. Additionally, the presence of vessel like structures were observed in samples stained with CD-31 antibody using confocal microscopy. Furthermore, scaffolds placed within chick chorioallantoic membrane (CAM) assay confirmed the infiltration of blood vessels was not hindered by the presence of the 3D-printed backbone via histological sectioning.

Conclusion

By addressing both the mechanical and vascularisation requirements of a tracheal scaffold, this work has begun to pave the way to solve the critical components required for clinically-successful, next-generation implants for tracheal regeneration. Ongoing experimental work is looking to optimise culture conditions for facilitating growth and differentiation of primary respiratory epithelial cells in addition of HUVECs and hMSCs to obtain an epithelialised and vascularised tracheal scaffold.

Introduction
Chronic wounds are affecting more than 40 million people worldwide. Current treatments consist on wound debridement, infection control, compression and the use of wound dressings (gauzes, hydrogels, etc). In the last years, advanced wound dressings carrying active ingredients such as cytokines, antibacterial compounds or growth factors (GFs) have been developed. In this sense, mesenchymal stem cells (MSCs) secretome has shown its efficacy in wound healing [1]. Secretome is a dynamic combination of soluble molecules (GFs, cytokines, chemokines, hormones) and extracellular vesicles (transporting RNA, lipids, proteins, DNA, etc) released to the extracellular space. Secretome derived from MSCs has shown therapeutic effect in tissue engineering, having angiogenic, anti-apoptotic, anti-inflammatory, immunomodulatory and anti-fibrotic. Although secretome can be directly administered in the target site, its fast clearance is still challenging. Therefore, new efforts have been made to create delivery platforms that sustain secretome release and increase its retention time [2].

The aim of this work is to encapsulate human umbilical cord MSCs (hUcMSCs) secretome into nanoparticles (NPs) to achieve a sustained release and to evaluate their potential in chronic wound healing.

Experimental Methods
Secretome was obtained by culturing hUcMSCs under hypoxic conditions during 48h to increase the expression of proangiogenic molecules [2]. The content in angiogenic factors was determined using a protein array. Secretome was encapsulated in poly(lactic-co-glycolic) (PLGA) NPs by a double emulsification/evaporation method using two polymers concentrations (50 mg/mL PLGA50 and 25 mg/mL PLGA25). NPs size and zeta potential were measured using a Zetasizer. The loading content and release was evaluated using a microBCA. Secretome integrity was assessed by ELISA. NPs cellular cytocompatibility was studied using human dermal fibroblasts and keratinocytes (empty NPs were used as negative controls).

Results and Discussion
The most expressed proangiogenic molecules detected in the secretome were TIMP-2, MCP-1, IL-6 and RANTES; all involved in the healing process stimulation. NPs successfully encapsulated secretome, ranging from 7.2-10.2 µg/mg NPs. NPs have sizes of 300-400 nm and zeta potentials below -20 mV. NPs sustained the delivery of the cargo for 7 days, releasing from 2 to 4.0 µg/mg depending on the PLGA concentration used (Fig 1A). This allowed the modulation of the secretome release according to the therapeutics needs. Moreover, the released secretome maintained its integrity (Fig. 1B). NPs were biocompatible with skin cells at the range of the concentration tested.

Conclusion
The secretome composition evidenced its potential in wound healing. Secretome was successfully encapsulated in the NPs, showing a sustained release. Our results indicate that these nanoplatforms are promising chronic wound healing agents.

Functionalized hydrogels as therapeutic contact lenses for the controlled delivery of anti-inflammatory peptides

Nadia Toffoletto¹, Ana S. Silva-Herdade², Miguel A. R. B. Castanho², Benilde Saramago¹, Ana Paula Serro¹,³

¹ Instituto Superior Técnico, University of Lisbon, CQE, Lisbon, PT; ² University of Lisbon, Faculty of Medicine, Institute of Molecular Medicine, Lisbon, PT; ³ Instituto Universitário Egas Moniz, Centro de Investigação Interdisciplinar Egas Moniz, Caparica, PT

Introduction
Peptides have gained interest as drug candidates for the development of novel and safer medicines. They demonstrated to overcome most of the safety issues related to classic formulations, avoiding cytotoxicity and damage on microcirculation [1]. Kyotorphin (L-Tyr-L-Arg) is a small endogenous neuropeptide, which exhibited analgesic activity. To improve its membrane permeability and reduce enzymatic degradation, some derivatives (i.e. KTP-NH₂, Ibuprofen-KTP, Ibuprofen-KTP-NH₂) were previously designed. These derivatives also demonstrated to inhibit the liberation of pro-inflammatory cytokines in the inflammatory cascade [1,2]. The development of permeable drugs for topical application, able to provide a therapeutic effect in the back of the eye without need of intraocular injections, is a trending topic in ophthalmology. The use of KTP derivatives as anti-inflammatory and permeative peptides constitutes a novelty in the field. Herein, a KTP derivative (KTP-NH₂) was selected as a model peptide to investigate the possibility of its loading and release from therapeutic contact lenses (CLs), which could act as drug-reservoirs for the daily sustained release of the peptide.

Experimental Methods
Two CL materials (i.e. HEMA and HEMA-NVP-TRIS hydrogels) were investigated as potential CL backbone. HEMA is a hydrophilic monomer commonly used in commercial CLs, while HEMA-NVP-TRIS has been previously suggested as a hybrid CL material able to optimize oxygen permeability and water uptake [3]. Autodock software was used to model the molecular interactions between the monomers and the peptide, and identify potential functional monomers able to tune the release profile. Polymerization was performed at 60 °C for 24h. Then, hydrogels were washed to remove unreacted monomers and cut into 14 mm diameter discs to mimic the dimension of commercial CLs. Loading was performed by soaking dry discs (N=3) in 500 µL peptide solution (1 mg/mL) in PBS at 4 °C for 72 h. The concentration of the loading solution was measured over time to detect the amount of drug loaded in the hydrogel discs. Then, hydrogels were rinsed and immersed in 3 mL of PBS to investigate drug-release in vitro. At regular intervals (i.e. hourly for 8 h), 300 µL aliquots of the release medium were collected for quantification and replaced by fresh PBS. Peptide quantification was performed by UV-vis spectroscopy at 275 nm. To investigate their swelling behavior, discs (N=3) were weighted in dry state and after hydration in water or in the peptide solution (1 mg/mL). Light transmittance was assessed in the 200-700 nm range to prove the optical suitability of the materials.

Results and Discussion
Molecular docking with acrylic acid (AAc) and methacrylic acid (MAA) resulted in the lowest values of inhibition constant among the tested monomers (i.e. 10-13 mM) and the most negative values of the free energy (i.e. -2.6 Kcal/mol). These values indicate a predominance of the peptide-monomer complex over the two separate species and a strong interaction between the two. Therefore, AAc and MAA were incorporated in the prepolymer mixture as functional monomers. The presence of the functional monomers significantly increased the amount of peptide loaded during the soaking phase for both HEMA-based (i.e. from 1.54 µg/mg to 4.78 and 4.66 µg/mg of dry HEMA-AAc and HEMA-MAA discs, respectively) and HEMA-NVP-TRIS-based hydrogels (i.e. from 2.56 µg/mg to 4.72 and 4.57
µg/mg of dry HEMA-NVP-TRIS-AAc and HEMA-NVP-TRIS-MAA discs, respectively. HEMA-NVP-TRIS-based hydrogels released the loaded peptide within the first hour in vitro (Figure 1). HEMA-based hydrogels sustained the release for about 8h. The incorporation of functional monomers increased the amount of drug released over time. Despite the presence of the hydrophobic TRIS monomer, the swelling of HEMA-NVP-TRIS lenses (≈ 65%) was higher than for HEMA-based lenses (≈ 45%) due to the high water uptake of NVP [3]. The swelling of functionalized hydrogels increased in the peptide solution (i.e. ≈ 60% for AAc- or MAA-functionalized HEMA discs and ≈ 80% for AAc-functionalized HEMA-NVP-TRIS discs). All hydrogels exhibited a light transmittance higher than 90% at 500 nm, which is considered the minimum requirement for optical devices. Transmittance in the visible range was not affected by the presence of the functional monomers or by the loading with KTP-NH₂.

Conclusion

AAc and MAA, selected as functional monomers due to their high molecular affinity with KTP-NH₂ peptide, increased the amount of peptide loaded in both HEMA-based and HEMA-NVP-TRIS-based hydrogels. All designed hydrogels showed suitable physical properties (i.e. water uptake, light transmittance) for their use as contact lens materials. HEMA-based hydrogels sustained the release of KTP-NH₂ for about 8h in vitro, which is compatible with the use of daily therapeutic lenses for the treatment of inflammatory ocular conditions. Further investigation is needed to assess the peptide permeation to the back of the eye.

Skin drug delivery bio-based polymeric structures using ionic liquids

Noemi Jordao, Joana Galamba, Luisa Neves

Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Departamento de Química, LAQV-REQUIMTE, Caparica, PT

Introduction
Nowadays, different efforts for the development of novel and innovative biomaterials, which can be used in several research areas, have been increased. Indeed, biomaterials derived from biopolymers, which are abundant and obtained from renewable sources, present outstanding properties such as biodegradability, biocompatibility and biological properties [1]. However, their application for medical field can be limited mostly due to their poor solubility in water and in most biocompatible organic solvents [1,2]. To overcome this limitation, ionic liquids (ILs) as low-melting organic salts appears as an interesting alternative for biopolymer valorization. In the last decade, different works that explores the ILs as alternative solvent for biopolymer dissolution have been reported [1-5]. In this context, the present work explores the use of functional ionic liquids, which are designed to be capable to disrupt hydrogen bonds but also have biological properties, to dissolve microcrystalline cellulose (MCC) and the development and characterization of valuable polymeric structures, in the form of films and gels. Different ILs composed by benzethonium and didecylidimethylammonium cations, which can exhibit anti-bacterial or anti-microbial properties, and short linear carboxylate anions have been developed.

Experimental Methods
The selected ILs were prepared by acid-base reaction, after previously preparation of the desired cation in their hydroxide form through adequate ion-exchange resin. All prepared ILs were analyzed by NMR (1H and 13C), ATR-FTIR spectroscopies, and elemental analysis to check their structure and relative purity levels. Also, thermal proprieties (DSC and TGA) were evaluated. The developed films and gels were analysed by ATR-FTIR spectroscopy, thermal analysis (TGA and DSC), and rheological studies.

Results and Discussion
Carboxylate ionic liquids (ILs) containing benzethonium (BE) and didecylidimethylammonium (DDA) as cations have been sucessful prepared to be used for the first time as dual functional solvent for microcrystalline cellulose (MCC) dissolution. The selected synthetic methodology to prepare the desired ILs consisted in two followed steps: i) preparation of hydroxide form of the desired cation, through an anion exchange resin method (Amberlite A26-OH form exchange resin). In general, all prepared ILs are liquid at room temperature, their structural and thermal properties have been evaluated. After optimized the dissolution conditions, it was observed that all tested ILs have been able to dissolve MCC up to a concentration of 4 % (w/w), resulting in different polymeric structures as gel or film depending on the type of IL and ratio between MCC and IL.

Conclusion
In conclusion, all tested ILs showed ability to dissolve MCC up to 4 % (w/w) of biopolymer concentration. In this sequence, different polymeric structures through phase inversion method as film or gels have been prepared, which can be correlated with the type of ionic liquid used as well as the ratio between MCC and IL. The developed films and gels were analysed by ATR-FTIR spectroscopy, thermal analysis (TGA and DSC), and rheological studies. Furthermore, according to ATR-FTIR spectroscopy, the obtained gels and films showed that some IL remains in the polymeric structures, enhance their application in biomedical field, namely for skin drug delivery.

Novel ternary organic/inorganic sol-gel derived hybrid biocomposite: A multifunctional platform towards bone cancer therapy and regeneration

Ashkan Bigham, Ines Fasolino, Alessandra Soriente, Luigi Ambrosio, Maria Grazia Raucci

National Research Council, Institute of Polymers, Composites and Biomaterials (IPCB-CNR), Naples, IT

Introduction

As a minimally invasive therapeutic approach, phototherapy is an effective substitute for traditional cancer therapies; in the exposure of light irradiation, a photocatalytic agent generates heat and reactive oxygen species locally culminating in the cancer cells death. Black phosphorus (BP) with excellent photothermal effect has recently drawn a considerable attention in bone cancer therapy. It is mainly composed of a single phosphorus giving BP a high degree of homology with natural bone. However, there are some bottlenecks revolving around BP—being highly prone to oxidation and a high aggregation tendency in the presence of salts; these issues, which limit the BP’s applicability and efficiency, are still the hotspots in the field.

Bioactive glass (BG)-based sol-gel derived hybrid materials are of particular interest in bone tissue regeneration. These materials are endowed with recapitulating the advantages of polymers and ceramics into a package. As calcium is vital for BG’s bioactivity and osteoblasts activities, its incorporation into the BG hybrids is still problematic. Due to lack of thermal treatment for organic/inorganic BGs, calcium ions cannot diffuse into glass structure and so it is a real challenge.

Considering the mentioned issues, we successfully gave birth to an innovative, stimuli-responsive, regenerative hybrid biocomposite composed of pluronic-F127/BG/BP (Figure 1). This hybrid is prepared in a non-aqueous solution in which the F127 molecules would self-assemble around BP nanoparticles followed by formation of a BG shell on the BP-encapsulated F127 liquid crystals. Putting the extraordinary regenerative properties of BG beside the photothermal effect of BP yielded a multifunctional platform for bone cancer therapy and regeneration.

Experimental Methods

The hybrid, which is composed of F127/BG/BP, is synthesized through evaporation-induced self-assembly sol-gel technique followed by being in the exposure of a microwave irradiation (Biotaage Initiator). The F127 is first dissolved in the mixture of ethanol/HCl followed by addition of 2D BP nanosheets with different concentrations. The mixture is then exposed to a two-step microwave irradiation. Finally, the solution is poured in a Petri dish to dry at room temperature. It is noteworthy that different calcium precursors (nitrate, chloride, and alkoxide) and microwave irradiation are applied to assess their effects on the physicochemical and biological properties of hybrid biocomposite. The samples without F127 and any calcium precursors are prepared to shed light on their effects as well. The XRD, Raman spectroscopy, FTIR, SEM equipped with EDS and elemental mapping, TEM, AFM, ICP, and thermal analysis are performed to characterize the physical and chemical properties of prepared hybrid. In the case of biological properties, the bioactivity in simulated body fluid (SBF), degradability in phosphate buffer saline (PBS), and the BP release at different temperatures (25 °C and 37 °C) are assessed in vitro. Moreover, the cytotoxicity was evaluated on murine fibroblast cell line L929 (ISO10993-5), meanwhile the in vitro anticancer activity on healthy osteoblast and osteosarcoma cells was also investigated.

Results and Discussion

The obtained results indicated that the F127 had a key role in homogenous distribution and controlled release of calcium ions from the hybrid. The samples without F127 induced toxicity when exposed to L929 due to burst release of calcium ions. The microwave irradiation had a stronger effect on the chemical stability and the samples treated with it showed a significant increase in the cell viability. The BP structure is turned out to be intact after the hybrid
preparation because of being encapsulated in F127 liquid crystals and no oxidation was observed attributed to synthesis environment. Regarding to thermo-responsivity of F-127, the encapsulated BPs were released faster when temperature raised to 37 °C. The bioactivity potential of hybrid with and without BP was assessed in SBF and the ternary hybrid outperformed the other one in deposition of newly formed calcium phosphate stemming from the released BP. The cell studies implied that the ternary hybrid selectively target cancerous cells without inducing toxicity towards healthy cells and also the encapsulated-BP exhibited a powerful photothermal effect when exposed to NIR against cancerous cells.

**Conclusion**

Two issues in the field are successfully addressed as follows: homogenous distribution of calcium ions in the sol-gel derived hybrid BG structure followed by the ions controlled release and *in situ* preparation of hybrid BG containing BP nanoparticles without being oxidized. Taken together, the thermo-responsive biocomposite can be exploited in simultaneous bone cancer therapy and regeneration.

**In vitro** biocompatibility and inflammation response of β-glucan based mixture extracted from barley for wound healing treatment

**Alessandra Soriente**¹, Maria Grazia Raucci¹, Giovanna Gomez d'Ayala¹, Donatella Duraccio², Hussman Razzaq³, Ines Fasolino¹, Luigi Ambrosio¹

**Introduction**

Over the past few years, β-glucans have met with great interest as potential multifunctional modulators of wound healing, alone and/or incorporated in a polymeric matrix [1]. β-glucans represent the major components of bacteria, fungi, yeast and cereals, mainly oat and barley’s cell walls, revealing a source-dependence of structural and biological properties. Among them, barley β-glucans are extensively studied as they have shown interesting antimicrobial and wound healing features [2]. In this study, β-glucan based mixtures (containing proteins, fats and other polysaccharides, such as starch) were extracted from barley at different pH, through a very simple and low cost extraction process [3]. The obtained mixtures were then employed for film preparation and the cell biocompatibility was studied. To this aim, different cell lines involved in wound healing, human dermal fibroblasts (HDF) and human umbilical vein endothelial cells (HUVEC), were used for **in vitro** biological studies. The results suggested that β-glucan films are biocompatible and support **in vitro** cell proliferation and migration. Moreover, these films are able to modulate the inflammation process in terms of pro-inflammatory and anti-inflammatory cytokines levels.

**Experimental Methods**

The β-glucan films were prepared and characterized to evaluate their biological properties. A simultaneous extraction of polysaccharides and proteins from barley flour was performed in alkaline medium, according to a procedure previously described [2]. The water soluble extract was recovered by centrifuging the extraction suspension at 7000 rpm for 20 minutes. Films (100 µm-thick) were obtained by casting at RT from a 5% (w/v) solution and subsequently conditioned at RT and 65% RH for 5 days, before analyses. Molecular mass of β-glucan was measured by MALD-MS.

In order to study the films effects on cell adhesion, proliferation and inflammation reaction, HDF and HUVEC were used. The viability and migration of fibroblast and endothelial cells were analysed by using the **in vitro** scratch wound healing assay. The cell–material interaction and spreading were determined by confocal laser scanning microscopy (CLSM) by staining the cells with cell tracker™ deep red dye, meanwhile Alamar blue assay was used as redox indicator to investigate the cell biocompatibility. Furthermore, the effect on inflammation response modulation, was carried out on a murine macrophage J774 cell line in order to assess the effects of β-glucan based mixtures on inflammatory and anti-inflammatory cytokines production (i.e. IL-6, IL-10, IL-1β), nitrites and reactive oxygen species (ROS) produced after cells stimulation by lipopolysaccharide (LPS).

**Results and Discussion**

**In vitro** biological studies showed that β-glucan films support cell survival, adhesion and migration. In particular, cell biocompatibility test evaluated through direct and indirect assays, demonstrated that β-glucan films are able to support fibroblast viability up to 72 hours of cell culture. In addition, these films promoted endothelial cell viability of HUVEC up to 48 hours. Furthermore, qualitative wound healing assay hinted β-glucan films’s capability of reducing the scratch area of 50% from quantitative point of view (within 24 hours of cell culture). As concerning morphological studies by confocal microscopy (cell tracker™ deep red dye), the β-glucan film treatment induces a cell spreading by...
reducing cellular shape. Finally, the materials are able to modulate inflammatory response in terms of ROS levels, IL-6, IL-10 and IL-1β secretion triggered by LPS in macrophages cell line.

Conclusion
The obtained results demonstrated a good biological properties of β-glucans based mixture as promising candidates for wound healing treatment.

Drug-eluting casein hydrogels for wound dressings

Leonor Garcia¹, Andreia S. Oliveira¹,²,³, Ana P. Serro¹,³, Benilde Saramago¹

Introduction

Chronic wounds represent a challenge to wound care professionals and are responsible for the consumption of numerous healthcare resources around the globe. In Europe wound treatment represents 2% to 4% of the medical expenses.

Drug loaded hydrogel dressings are considered promising candidates for the treatment of different types of wounds, since they present a 3D-structure that mimics the skin extracellular matrix (ECM), namely in what concerns the water content, being able to ensure a moist environment to the wound.

The present work aims to develop drug-eluting casein-based hydrogels for wound dressings. Due to their biocompatibility, mechanical properties, ability to interact with soft biological tissues, and presence of many functional groups susceptible to chemical modifications, casein hydrogels have been used in a vast range of biomedical applications, including wound dressings [1].

Hydrogels can be loaded with drugs which, if released in a controlled way, may contribute to the healing process. The release profile will depend on the hydrogel's characteristics such as the crosslinking degree, hydrophilicity, and affinity to the drug. In this work the produced hydrogels were loaded with octenidine dihydrochloride and polyhexanide, two antiseptics with a broad spectrum of effectiveness that represent an alternative to older substances such as chlorhexidine, polyvidone iodine or triclosan.

Experimental Methods

Casein hydrogels were prepared through free radical polymerization of acrylamide and coagulation of casein micelles. The pH of the casein solution was adjusted to 6 by the addition of NaOH. After casein dissolution, acrylamide and N,N’-methylenebisacrylamide were added. Ammonium persulfate and tetramethyleneethylenediamine were used, respectively, as radical initiator and crosslinking accelerator for acrylamide. The functional monomer N-(3-aminopropyl)methacrylamide hydrochloride was also added to the formulation to establish preferential interactions with octenidine dihydrochloride and improve the drug release profile. Subsequently, the solution was poured into a glass mould, exposed to UV for 4 h and then left for 22 h at 36 °C for casein gelation. After proper washing, the hydrogels were dried in the oven at 36 °C for 8 h.

The hydrogel's swelling was assessed in water and in both drug solutions. The mechanical behaviour was studied through tensile tests on hydrated samples. The hydrogels were soaked for 48 h in Octiset® (1 mg/mL of octenidine dihydrochloride and 20 mg/mL of 2-phenoxyethanol) and polyhexanide solution (0.5 mg/mL) at room temperature. After drug loading, the release kinetics was obtained in sink conditions in PBS at 34 °C and 180 rpm. Sterilization was carried out in autoclave at 121 °C for 20 minutes. Antimicrobial properties against S.aureus and P.aeruginosa were also studied.

Results and Discussion

The casein hydrogels showed high values of swelling, around 2100 % in water and 1038 % and 992 % in Octiset® and in polyhexanide solution, respectively. Tensile tests led to a Young module of 0.0156 MPa. Polyhexanide loaded samples were able to release the drug in a controlled way during 48 h (Figure 1), in contrast with the ones loaded with Octiset®, which led to a burst release. The drug-loaded hydrogels showed good antimicrobial properties.

Conclusion

Page 1716 of 2028
Further investigation in order to improve the release profiles of the Octiset® components (octenidine dihydrochloride and 2-phenoxyethanol) is under way.

Introduction

Augmenting anterior cruciate ligament (ACL) repair using synthetic scaffolds to promote ligament healing is a new emerging surgical strategy for the treatment of ACL ruptures. With the increased interest for regenerative medicine, many studies are now focusing on the development of bioactive and biodegradable synthetic ligaments [1]. For this application, Polycaprolactone (PCL) is a well-known biocompatible and biodegradable polymer that presents the advantage of slow degradation depending on its molecular weight. Biointegration of such candidate scaffolds for ACL repair augmentation is a key property to address, as lack of osseointegration has been incriminated in long-term failures of ACL repair. PCL does not present any bioactive activity by itself, but its functionalization with poly(sodium styrene sulfonate) (pNaSS) has proven to enhance \textit{in vitro} cell adhesion and metabolic activity of fibroblasts [1-3]. The aim of this study was then to evaluate \textit{in vitro} and \textit{in vivo} the biocompatibility and osseointegration properties of PCL ligaments grafted with pNaSS.

Experimental Methods

\textbf{In vitro study:} The \textit{in vitro} osteoblast (MC3T3-E1 cells) response was evaluated on grafted and non-grafted PCL films and knitted portions of the PCL ligament. Cells viability and proliferation were evaluated, as well as the expression of alkaline phosphatase and the calcium deposition.

\textbf{In vivo study:} The osseointegration of knitted PCL ligaments was investigated \textit{in vivo} in a rat ACL repair augmentation model by histological evaluation. Following transection of the ACL, rats received either the pNaSS-grafted knitted PCL ligament (G group, N=12), the non-grafted knitted PCL ligament (NG group, N=12) or the flexor digitorum longus tendon autograft (AG group, N=12, control group). Three months after surgery, operated tibial bones were harvested and submitted to non-decalcified histological evaluation using a previously established modified ligament-to-bone core based on interface width, bone formation within the ligament, cellularity and inflammation [4]. Scoring was performed by two investigators blinded to the grafted or non-grafted status of the specimen.

Results and Discussion

\textbf{In vitro results:} Grafted knitted substrates showed statistically higher viability when compared with non-grafted analogs ($P < 0.05$), confirming the positive influence of pNaSS presence on the viability of the cells, as evidenced before on other polymeric surfaces [5]. Grafted knitted PCL fibers induced higher MC3T3-E1 cell proliferation (Fig.1), ALP activity and calcium deposits than their nongrafted counterparts and than grafted PCL films.

\textbf{In vivo results:} Three months after implantation, all groups showed histological evidence of osseointegration of the PCL ligaments or the autograft (Fig.2). Histological scores quantifying osseointegration of the PCL ligaments were higher in the G group compared to the NG group, arguing for a beneficial effect of pNaSS grafting on osseointegration of knitted-PCL ligaments into the tibial bone tunnels.

Conclusion
This small animal study is the first evaluation of the synthetic ligament performance. It provides encouraging in vitro and in vivo results on the effect of pNaSS grafting on bone formation and biointegration of knitted-PCL ligaments.

Introduction
Breast cancer therapies have been constantly improving year by year, but a comprehensive, uniform cure for this disease with minimal side effects is still a long way off. Hence, there is a need to develop a more efficient therapeutic approach to improve breast cancer prognosis and enhance its survival rates. Gold nanoparticles (GNPs)-based delivery systems offer many advantages due to their unique chemical and physical properties, that make them biocompatible, easy to modify, and functionalize with cancer-specific biomolecules. GNPs can accumulate in tumor tissue either passively via the EPR effect or actively via their conjugation with a targeting molecule.\textsuperscript{[1]} Thus, GNPs conjugation with drugs can enhance drug uptake into cancer tissue. Among GNPs, gold nanostars (GNSs) are emerging as promising tools for cancer photothermal therapy (PTT).\textsuperscript{[2]} Due to their anisotropic spiked shape, they exhibit Near InfraRed (NIR) plasmon resonances with high thermal release efficiency as well as a high surface to volume ratio available for conjugation and functionalization. The study aimed to synthesize and characterize a novel Herceptin (H) conjugated polyethylene glycol-gold nanostars (H-PEG-GNSs) to be used as a selective PTT platform against HER2 (human epidermal growth factor receptor-2) expressing breast cancers.

Experimental Methods
GNPs were synthesized, pegylated, and characterized using Transmission electron microscopy (TEM), Dynamic Light Scattering (DLS), UV-Vis spectrophotometry, and Thermogravimetric analysis. The conjugation between PEG-GNSs and Herceptin was carried out using the previously reported EDC-NHS protocol.\textsuperscript{[3]} The conjugated GNSs were then characterized using UV-Vis spectroscopy absorption studies, DLS, Bicinchoninic acid (BCA) analysis, and dot-blot assay. Viability (MTT assay) and uptake studies were carried out to verify the interaction of Herceptin conjugated PEG-GNSs with the target breast cancer cells.

Results and Discussion
PEG-GNSs showed an intense LSPR (Localized Surface Plasmon Resonance) absorption with the maximum wavelength in the bio-transparent window (750-950 nm), making it a suitable tool that can be used for deep tissue PTT. Next, H-PEG-GNSs were prepared and characterized using DLS and UV-Vis spectroscopy: Herceptin conjugation resulted in particle size increase, less negative zeta potential, and UV-Vis absorption spectrum redshift of PEG-GNSs. The presence of Herceptin on the surface of GNSs also revealed by BCA and dot blot assays. The targeting and anti-proliferative properties of the nanosystems were observed by \textit{in vitro} studies against HER-2 overexpressing cells (SKBR-3 cell line) and compared to a healthy fibroblast cell line (NIH-3T3). Viability assays and uptake studies demonstrated an anti-proliferative efficacy of Herceptin conjugated to GNSs and internalization into target cancer cells, which were both evidence of its active function in recognizing the tumor cells.

Conclusion
Although preliminary, all data gathered showed the successful formation of Herceptin-PEG-GNSs conjugate. Currently, experiments are ongoing to explain other aspects related to the efficacy and the uptake mechanism of the
nanoconjugate systems in the target tumor cells. 3D cancer models and in vivo studies are required to assess the toxicity and efficacy of this PTT nanoplatform against HER-2 positive breast cancers.

Introduction

Current electrodes for electrical recording and stimulating cells generally exhibit high rigidity and harmful chemical composition. When used in implants, the tissue reaction to these characteristics can lead to glial encapsulation of the electrode, which will increase its overall impedance [1]. In addition, if the electrode material degrades, it might generate toxicity in surrounding cells and tissues, again negatively influencing the electrical signal transmission. Extracellular experiments and medical devices require planar electrodes to register or stimulate neural activity in the surrounding neurons. To improve current electrodes, we have developed low-disturbance and low-impedance, flexible, nanostructured planar electrodes based on vertical metallic nanowires standing over a flexible gold base [2] to obtain more efficient and biocompatible stimulation electrodes. Alternatively, to register single neuron activity, intracellular in vitro recordings can be performed by using the patch clump technique [3]. To decrease the damage produced to cells by the micropipette in this technique, we are developing conic shaped electrodes with a nanometric apex based on vertical metallic nanowires that will stand over the surface, minimizing cell invasion and reducing the membrane cell perforation size and the medium exchange.

Experimental Methods

Fabrication of either planar or sharp electrodes is based on the anodization process and the template-assisted electrodeposition technique. We use the first to oxidize the surface of the material and obtain an ordered nanoporous template. We have chosen aluminium as initial material to generate the template because of the highly ordered pore arrangement that it acquires once oxidized. Afterwards, the template pores are filled to obtain the vertical metallic standing nanowires on the electrode substrate. To do so, we use the template-assisted electrodeposition technique. Subsequently, nanowires are released from the membrane. The electrodes are then characterized by cyclovoltammetry and electrical impedance spectroscopy. Finally, the electrodes are tested in vitro with neural progenitor cells from rat embryos cerebral cortices to determine their biocompatibility. Electrodes surface is functionalized with a poly-L-lysine (PLL) coating (30-70 KDa) and then cells are cultured up to 14 days to study their morphology, viability and neural differentiation.

Results and Discussion

For planar electrodes, we have grown gold-based nanowires electrodes. Results showed proper neural cell adhesion, growth and differentiation on our gold-exposed electrodes. When compared with equivalent flat gold electrodes, we observed a more intimate contact of the nanostructured ones with the neuron axons. We also verified the lower impedance of the nanostructured electrodes compared with flat ones.

Regarding the sharp electrodes for intracellular recordings, we proposed a completely new electrode architecture which is still under study, preliminary experiments show proper neural cell adhesion, growth and differentiation.
Conclusion

While the cell survival and differentiation of neural cultures grown over nanostructured and flat electrodes is equivalent, a more intimate contact with neurons and a lower density of glial cell was observed for nanostructure electrodes, which also present a lower impedance.

Multi-targeted therapeutic single-patch for intestinal wound healing

Marco Araújo¹, João Silveira¹,²,³, Aureliana Sousa¹,², Mafalda Bessa-Gonçalves¹,²,⁴, Susana G. Santos¹,²,⁴, Cristina C. Barrias¹,²,⁴

¹ Instituto de Investigação e Inovação em Saúde, Porto, PT; ² Instituto Nacional Engenharia Biomédica, Porto, PT; ³ Faculdade de Engenharia Universidade do Porto, Porto, PT; ⁴ Instituto de Ciências Biomédicas Abel Salazar, Porto, PT

Introduction
Wound healing is a highly regulated complex process comprising several overlapping phases: hemostasis, inflammation, neo-tissue formation/remodelling [1]. Chronic wounds result from an abnormal WH process dominated by a persistent inflammatory condition. They can occur either as external or internal ulcers, the latter commonly associated to the stomach and intestine. In the past years, particular attention has been given to inflammatory bowel disease (IBD), which emerges as a global disease affecting ~10M people worldwide, with special incidence in young people (15-35 yrs old), bearing substantial costs to the health care system and society [2]. IBD, including ulcerative colitis and Crohn’s disease, are chronic, disabling, and progressive disorders characterized by a persistent inflammatory condition that leads to damage of the bowel wall. Current IBD therapies reduce inflammatory symptoms and prevent relapse episodes, but do not promote mucosal restitution, which should be key for effective healing. Herein, we propose a multi-targeted therapeutic strategy, based on a bioinspired multifunctional hydrogel-based patch combining both anti-inflammatory and pro-regenerative potential, as a disruptive approach for chronic intestinal wound healing.

Experimental Methods
Multifunctional hydrogel-based scaffolds were obtained from a pre-gel solution containing functionalized alginate, Irgacure 2959 and biopolymeric nanoparticles (BNP). The pre-gel solution was transferred to a glass slide containing 250 µm spacers and samples were irradiated using a BlueWave® 200 curing spot lamp for the desired time periods, inducing polymerization and entrapment of the BNP. Scaffolds were analysed for their mechanical properties by rheology, whereas swelling and degradation behaviour were investigated in PBS and in a cocktail of collagenases (Collagenase type II + Collagenase type IV). Their anti-inflammatory potential was evaluated in-vitro by analysing the conditioned media (CM) from Lipopolysaccharide (LPS)-stimulated macrophages, and the pro-regenerative ability was assessed in the presence of two relevant intestinal cell types (Caco-2 cells and human intestinal fibroblasts - HIF).

Results and Discussion
We achieved to produce softer-to-stiffer hydrogel matrices, with stiffness between G’= 145 – 3300 Pa. Importantly, the viscoelastic properties were maintained upon freeze-drying and rehydration, highlighting the versatility of the material to be applied either in the form of hydrated or freeze-dried hydrogel. This is an attractive feature regarding a clinical application, since the scaffold can be easily stored and rehydrated in situ upon implantation. Although the entrapped BNP reduced scaffolds hydrophilicity, the 3D sponges still exhibited a high swelling ratio, confirming their ability to be rehydrated under physiological conditions. The scaffolds were able to maintain 75% of their initial weight after 14 days incubation in a Collagenase mixture that mimics the enzymatic activity in inflamed tissue of patients suffering from IBD, suggesting their suitable application as therapeutic patches for IBD. The scaffolds were able to normalize the CM from LPS-stimulated macrophages, reverting the inflammatory condition to levels similar to the non-stimulated control. Importantly, the same scaffold could be reused up to 3 times while maintaining this regulatory performance, which is advantageous in an IBD scenario, where disease relapse frequently results in an...
accentuated increase of inflammatory response. HIF seeded on the top of the scaffolds migrated through the pores to their interior and produced ECM components, namely fibronectin, increasing deposition along time. Caco-2 cells seeded on top of the matrices were also able to adhere, grow and migrate into the macropores.

Conclusion
This work highlights the development of an innovative multifunctional therapeutic platform that targets two important processes of wound healing: inflammation and tissue regeneration. The developed biomaterial demonstrated ability to normalize the inflammatory environment promoted by LPS-stimulated macrophages and supported invasion, proliferation and de novo extracellular matrix deposition by intestinal fibroblasts and epithelial cells. Our results suggest that this multi-targeted therapeutic platform may find potential application as an innovative treatment for IBD, disrupting with current symptom-driven therapies.

Differently Modified Nanoporous Titania Coatings as a Material for Smart Drug Delivery Systems

Saskia Zailskas¹, Philipp Abendroth¹, Hannah Christmann¹, Katharina Doli², Henning Hartwig², Meike Stiesch², Peter Behrens¹

¹ Leibniz Universität Hannover, Institut für Anorganische Chemie, Hannover, DE; ² Medizinische Hochschule Hannover, Klinik für Zahnärztliche Prothetik und Biomedizinische Werkstoffe, Zentrum Zahn-, Mund- und Kieferheilkunde, Hannover, DE

Introduction
Although tooth implants are a common treatment in dentistry nowadays, peri-implantitis remains a major health issue. Due to late infections bacteria may form biofilms on the implants’ surface which unfortunately leads to high implant failure rates (>10%).[1] To cure these undesirable infections at an early state, occurring bacteria have to be effectively eliminated. A controlled drug delivery system directly located on the implants’ surface offers a promising opportunity to achieve the required antibacterial effect. A stimuli-response system is desired in order to ensure the release of an antibacterial drug not directly after the implantation but only when an infection occurs. For this purpose, a nanoporous titania coating can be attached to the implant surface. The nanopores functions as a depot for local drug release and the surface offers the possibility for chemical modification to construct a stimuli-response release system. Considering that bacterial biofilms often produce an acidic milieu, a pH-responsive polymer can be used to generate a stimulated release. A corresponding system has already been accomplished for nanoporous silica nanoparticles.[2]

Experimental Methods
The first step to transfer the system to titania surfaces is the establishment of nanoporous titania films by utilizing an adjusted cathodic electrodeposition method of Hu et al.[3] In a further step, the surface is modified with phosphonic acid derivates, which form strong chemical bonds to titania and can therefore introduce functional groups.[4] The attachment of a pH-responding polymer is carried out using a reaction route described by Menzel and co-workers.[5] Cell culture investigations are performed in regards to cytocompatibility and antibacterial behavior.

Results and Discussion
The resulting titania coatings were characterized as porous materials; layer thicknesses could be adjusted by the number of cycles during the deposition. We were able to successfully attach different phosphonic acids to these electrodeposited titania coatings. First studies with the antiseptic chlorhexidine show that the release kinetics could be adjusted by surface modification. Cell culture investigations indicate a high potential for future usage in dental implants.

Conclusion
Nanoporous titania coatings modified with different phosphonic acid derivates show a high potential to design smart drug delivery systems for dental applications.

From supramolecular polymers to bioprinting of tough hydrogels

Matthew Baker

Maastricht University, MERLN Institute; Complex Tissue Regeneration Department, Maastricht, NL

Introduction
Reengineering the cell’s extracellular matrix (ECM) and the 3D spatial positioning of cells in tissue are necessary in order to create complex tissue constructs. While materials scientists have made significant progress in uncovering and recapitulating the complexities of the ECM, engineers have created sophisticated techniques which allow for complex 3D living structures to be fabricated. Supramolecular hydrogels provide an opportunity to mimic the fibrous structure and the self-assembled construction of the native ECM. Synthetic supramolecular hydrogels provide the opportunity to systematically control the mechanical properties (stress relaxation, stiffness) and self-assembly of the matrix; however, the control of the hydrogel properties and their translation to advanced fabrication technologies has remained a challenge.

Experimental Methods
Recently, we have explored molecular engineering of hydrogels based on the supramolecular polymerization of 1,3,5-benzenetricarboxamide (BTA) macromers. Via new synthetic pathways, and characterization of the supramolecular macromers, we can create a library of rationally designed structures. By characterizing the self-assembly of these structures (cryo-EM, Nile Red encapsulation, microscopy) and the resultant materials properties of the hydrogels (rheology, self-healing, tensile) we can begin to create structure/property relationships. In addition by exploring the effect of the materials properties on cell viability, cell aggregation, and printing performance, we can begin to create property/function relationships. In this talk, I will focus on the creation and optimization of the dynamics of these supramolecular polymers for use in cell culture and bioinks.

Results and Discussion
All target compounds were able to be synthesized and isolated in good yield and purity, showing the power of our new synthetic desymmetrization strategy. We observed that the amount of hydrophobics on the exterior of the macromer dictated the dynamic rheological properties (stress relaxation) over 4 orders of magnitude without significantly affecting the stiffness. Furthermore, we could engineer toughness and stretchability into the materials with select molecular units. All materials were cytocompatible and some showed excellent performance as bioinks.

Conclusion
By tuning of the dynamic and viscoelastic properties of the hydrogels we can closely tune the properties and create viable bioinks, even very tough and elastic hydrogels. With careful control over the (supra)molecular structure, we can move from soft, liquid-like supramolecular polymers to highly functional materials for tissue engineering.

Supramolecular BTA polymers allow control of viscoelastic hydrogel properties and 3D printing.
Tough fibrous mats prepared by electrospinning and photo-crosslinking mixtures of methacrylated poly(trimethylene carbonate) and methacrylated gelatin

Jia Liang1, Honglin Chen2, Dirk W. Grijpma1, André A. Poot1

1 University of Twente, BST, Enschede, NL; 2 South China University of Technology, Institute for Life Sciences, School of Medicine, Guangzhou, CN

Introduction
Materials prepared from combinations of synthetic and natural polymers are interesting for use in tissue engineering applications. Poly(trimethylene carbonate) (PTMC) is a synthetic non-crystallizing flexible polymer that degrades in vivo by surface erosion. Crosslinked PTMC networks are flexible, elastic and tough. Gelatin is a natural material that is widely used in biomedical engineering. It has excellent biological properties, but lacks mechanical resilience. By preparing hybrid networks from methacrylated PTMC and methacrylated gelatin (GelMA), materials that combine the advantageous properties of both can be prepared [1]. The aim of the current work is to prepare tough fibrous mats by electrospinning and photo-crosslinking mixtures of methacrylate-functionalized PTMC and GelMA.

Experimental Methods
Three-armed PTMC (20 kg/mol) and gelatin (50-100 kg/mol) were functionalized by reaction with methacrylic anhydride. The degrees of functionalization of PTMC-trimethacrylate (PTMC-tMA) and gelatin-methacrylate (GelMA) were 98% and 90%, respectively. PTMC-tMA and GelMA were dissolved in HFIP/AcOH (20/1, v/v) at different ratios (10/0, 8/2, 6/4, 3/7, 1/9 and 0/10, wt/wt). The mixtures (12.5%, wt/v) were stirred overnight at RT. Irgacure 2959 (5 wt% relative to the macromer) was added to the mixture and stirring was continued for 30 min before electrospinning. The mixture was transferred to a syringe equipped with a blunted 27G stainless-steel needle. Electrospinning was performed using a syringe pump (Multi-Phaser, Model NE-1000) at a rate of 1.0 mL/h and an applied voltage of 16 kV. The working distance from the tip of the spinneret to an aluminium collector plate was set at 15 cm. Two UV light bulbs (365 nm, 0.32 mW/cm²) were positioned at a distance of 10 cm from the fibers, which were continuously irradiated during spinning (2.5 hours). The collected mesh was subsequently immersed in ethanol containing Irgacure 2959 (3%, wt/v) for 1.5 hours and then post-cured in a UV box (365 nm, 7.0 mW/cm²) at 5 cm distance to the lamp for 40 min. The mechanical properties of the PTMC-tMA/GelMA electrospun mats were investigated by tensile testing and the proliferation of human smooth muscle cells (hSMCs) on the fibrous mats was evaluated by use of the CyQuant assay.

Results and Discussion
The tensile properties of crosslinked PTMC-tMA/GelMA and GelMA electrospun fibrous mats are shown in Table 1. Fibrous mats made from 8/2, 6/4, 3/7, and 1/9 PTMC-tMA/GelMA mixtures showed an outstanding toughness of 1023 ± 59, 539 ± 43, 33 ± 6, and 15 ± 4 N/mm², respectively. These values were significantly higher than that of a fibrous mat made from 100% GelMA (3 ± 1 N/mm²). Porosities of the 8/2 – 0/10 PTMC-tMA/GelMA fibrous mats ranged from 88 – 94%. After 7 days of culturing hSMCs on the fibrous mats, cell numbers on the 6/4, 3/7 and 1/9 PTMC-tMA/GelMA fibrous mats were similar as those on the 100% GelMA mats, and significantly higher than on the 100% PTMC-tMA specimens (shown in Figure 1).

**Conclusion**

We have demonstrated the preparation of tough electrospun fibrous mats from homogeneous PTMC-tMA and GelMA solutions with a wide range of compositions. The addition of GelMA to PTMC-tMA yields stable photo-crosslinked hybrid structures upon electrospinning and enhances the proliferation of hSMCs on the fibrous meshes. Such structures have potential to be used in vascular tissue engineering.

Retinol-crosslinked Supramolecular Hydrogels for Tissue Regeneration and Antioxidant Delivery

Antonio Feliciano, Matthew Baker

Maastricht University, MERLN, Maastricht, NL

Introduction
Bioengineered corneas have been fabricated using a variety of synthetic or natural materials to transplant corneal keratocytes. However, control of keratocyte phenotype remains a challenge. If a regenerative construct activates a fibroblast-like phenotype then unfavorable ECM akin to scar tissue is produced which will adversely affect transparency and ultimately impair vision. All trans-retinoic acid (RA), as a supplement, has been shown to promote favorable non-scarring phenotype and keratocyte proliferation. We hypothesize that supramolecular materials formed via host-guest inclusion of retinol and cyclodextrin can recapitulate dynamics of the ECM but also act as an injectable drug-delivery scaffold. Herein, we confirm the complexation between retinol and beta/gamma cyclodextrins and proceed to use this interaction to build a supramolecular system with cyclodextrin functionalized alginate.

Experimental Methods
Alginate was functionalized with cyclodextrins by EDC/NHS and characterized by NMR, GPC, and rheology. Complexation between cyclodextrins and retinol was characterized by phase solubility diagrams and association constants were calculated. Complexation was also confirmed by NOSY NMR. Material properties after the complexation were analyzed by UV-VIS, rheology (oscillatory and shear tests), and drug release of retinol.

Results and Discussion
We present host-guest complex characterization, synthesis of functionalized alginate, tunable stiffness of hydrogel, and cumulative release of retinol. In addition, we show supramolecular hydrogel behavior for example self-healing and shear thinning character from this interaction through rheological tests.

Conclusion
A supramolecular environment built with bioactive molecules like retinol which form a 2:1 association could be used in a variety of injectable tissue engineering applications. In addition, the release of retinol could enhance keratocyte proliferation in hydrogel constructs that deliver a sustained release of retinol.

Enzymatic crosslinked hydrogels based on gelatin loaded with maleoyl-chitosan/poly (aspartic acid) nanocarriers as potential therapeutic scaffolds for tissue engineering

Alina G. Rusu1, Aurica Chiriac1, Loredana E. Nita1, Liliana Tartau-Mititelu2

1 Institute of Macromolecular Chemistry "Petru Poni" Iasi, Natural Polymers, Bioactive and Biocompatible Materials Laboratory, Iasi, RO; 2 "Grigore T. Popa" University of Medicine and Pharmacy, Iasi, RO

Introduction
In the field of tissue engineering and regenerative medicine, researchers’ attention has been focused on the developing ideal biomaterials that mimic the architecture and composition of the extracellular matrix (ECM), and their further use as therapeutic scaffolds. In this regard, hydrogels have known a substantial expansion due to their unique properties, being developed for utilization in many technological and medical applications like scaffolds for tissue engineering. Owing to their excellent compatibility hydrogels can embed different nanoparticle systems and thus creating new materials with unique properties, such as hierarchically porous structure, high surface area, and tunable water affinity and biodegradability. Therefore, in this study, enzymatic crosslinked hydrogels based on gelatin loaded with maleoyl-chitosan/poly (aspartic acid) (MAC5/PAS) nanogels containing an antimicrobial drug, namely amoxicillin, were prepared and characterized from the point of view of their structural, morphological and biological properties (swelling, biodegradability and in vitro cytotoxicity).

Experimental Methods
For the preparation of the hydrogels, two transglutaminase (TGase) concentrations related to gelatin (2U/g protein and 5U/g protein) were used. Also, in these types of enzymatic crosslinked hydrogels, nanogels based on MAC5 and PAS were incorporated to function as building blocks and nanocarrier of bioactive compounds (antimicrobial amoxicillin). The enzymatic crosslinking reaction and the interactions between nanogels and gelatin were investigated by FT-IR spectroscopy. SEM analysis was utilized to assess and compare the morphology of the hydrogels based on gelatin with the one of the materials enzymatic crosslinked loaded with MAC5/PAS nanogels. Additionally, the swelling capacity, biodegradability and in vitro cell viability were evaluated.

Results and Discussion
Crosslinking by TGase and addition of MAC5/PAS nanocarriers reduced the solubility of gelatin hydrogels as compared to the conventional protein systems. The gels also exhibited controlled biodegradability and in vitro biocompatibility. In general, degradation products from all investigated systems based on gelatin and nanogels did not show cytotoxicity; Specifically, drug-loaded hydrogels showed the highest cell viability, further confirming the suitability of these systems as a biocompatible cell matrix in tissue engineering.

Conclusion
The overall results showed that the nanostructured hydrogels are promising therapeutic scaffolds for tissue engineering with controlled degradability and drug delivery capacity.

Analysis of reproducibility in free radical polymerisation of thermosensitive pNIPAm nanogels

Alena Vdovchenko, Karin Somby, Marina Resmini

Queen Mary University of London, Department of Chemistry, London, GB

Introduction
Thermo-sensitive nanogels based on poly(N-isopropylacrylamide) (pNIPAm) are widely investigate for potential applications in many fields such as drug delivery, sensing, tissue engineering or emulsification systems. [1] The most common approach for the preparation of nanogels is free radical polymerization of NIPAm and methylenebisacrylamide (MBA) which serves as a crosslinker of the polymer network. [2-5] The random character of the radical polymerization raises questions on the reproducibility of the synthetic methodology, and subsequently on the potential variability in the physico-chemical properties of the resulting nanomaterials. An interesting question is related to the crosslinker, and whether its concentration in the feeding solution has an impact on the overall monomer conversions, chemical yields and thermo-responsive behaviour. The potential application of pNIPAm nanogels in medicine requires these material to have well defined characteristics and the degree of reproducibility of the synthetic method is a priority.

Experimental Methods
The following study is focused on the statistical analysis of experimental data obtained in our research group by several researchers. The experimental data studied include chemical yields, monomer conversions obtained by 1H NMR, particle size determined by dynamic light scattering and volume phase transition temperature calculated though UV spectroscopy characterization.

Results and Discussion
The data analysis suggests the existence of a strong correlation between the amount of the crosslinker used during polymerization and the variability of the properties of nanomaterials.

Conclusion
Overall, the following study reveals that the statistical analysis of the reproducibility of the synthetic methodology is essential in the case of random polymerization, which is widely used in the preparation of nanomaterials for medical applications.

Electron Beam Mediated Synthesis and Material Properties of Gelatin/PEGDA Hydrogels with and w/o Ag Nanoparticles for Wound Dressings

Tugce Sener Raman, Catharina Krömmelbein, Stefanie Riedel, Stefan Mayr, Bernd Abel, Agnes Schulze

Introduction
Hydrogels are three-dimensional networks made of hydrophilic polymer chains that can retain a large amount of water or biological fluids in their swollen state [1]. They can be applied especially in biomedical applications, such as contact lenses, drug delivery systems, tissue engineering, and dressings for burn wounds [2]. Considering various merits, such as nontoxicity, ability to absorb exudates from wounds, [3] and ability to provide a moist environment good for wound healing, they have optimal properties to be used as wound dressings [4].

Hydrogels can be classified into natural hydrogels and synthetic hydrogels based on their source. Whereas natural hydrogels such as gelatin are highly desirable biomaterials for application in drug delivery, biosensors, bio actuators, and extracellular matrix components due to strong biocompatibility and biodegradability, insufficient mechanical properties are disadvantages of these natural materials [5]. However, hybrid hydrogels made from synthetic and biological polymers possess both suitable mechanical properties, and biocompatibility [6].

Nowadays silver is the most adopted antibacterial agent on various supports, due to its high biocompatibility, excellent resistance to sterilization conditions, effectiveness on different bacteria, and long-term durability of its antibacterial effect. Silver nanoparticles (AgNPs) in combination with hydrophilic, biocompatible polymers can be the basis of the new generation of antimicrobial materials [7-8].

Experimental Methods
In this study, Gelatin/PEGDA hybrid hydrogels and Gelatin/PEGDA hybrid hydrogels with Ag nanoparticles in the various concentrations were synthesized to provide biocompatibility, high mechanical strength, and sterilization required for biomedical applications (especially wound dressing). They were synthesized by electron beam polymerization since electron irradiation promises high efficiency as well as precise and fast crosslinking while not inducing cytotoxicity [9]. Also, the mechanical properties of hydrogels that are irradiated at different doses have been investigated, since crosslinking density can be easily adjusted by applying different irradiation doses. Gelatin/PEGDA hybrid hydrogels and Gelatin/PEGDA hybrid hydrogels with Ag nanoparticles composed of different concentrations which were applied to electron beam irradiation at various doses were synthesized to study the resulting mechanical properties of these hydrogels. The swelling ratio, rheology, and crosslinking ratio were investigated to determine the mechanics of the hybrid hydrogel.

Results and Discussion
The results of this study, the degree of crosslinking of the hydrogels was found to increase with an increasing irradiation dose. Additionally, although the hydrogels with AgNPs and the hydrogel without AgNPs have been prepared equally regarding concentration and irradiation, the hydrogels with AgNPs possess a different crosslinking density compared to hydrogels without AgNPs was adsorbed to reduce Ag(I) to AgNPs, therefore, the hydrogels...
without AgNPs were polymerized with a larger irradiation dose, which created an increased crosslinking density of the hydrogels.

**Conclusion**

In conclusion, it was determined that increased gelatin and decreased PEGDA concentration of hydrogels with AgNPs and without AgNPs affect the crosslinking density and swelling ratio of hydrogels. Electron irradiation demonstrated the ability to precisely tune the hybrid hydrogel properties by the selection of dose and concentration.

Formation of macroporous cell-laden hydrogels with thermosensitive chitosan-salts mixtures

Phuong Anh Dang\textsuperscript{1,2}, Carla Palomino-Durand\textsuperscript{2}, Pierre Marquaille\textsuperscript{1}, Etienne Decencière\textsuperscript{3}, Sophie Norvez\textsuperscript{1}, Emmanuel Pauthe\textsuperscript{2}, Laurent Corté\textsuperscript{1,4}

\textsuperscript{1} ESPCI Paris, PSL University, C3M laboratory, Paris, FR; \textsuperscript{2} CY Cergy Paris University, ERRMECe, Neuville sur Oise, FR; \textsuperscript{3} Mines ParisTech, PSL University, Centre for Mathematical Morphology, Fontainebleau, FR; \textsuperscript{4} Mines ParisTech, PSL University, Centre des Matériaux, Evry, FR

Introduction

Cell-laden thermosensitive hydrogels are highly valuable encapsulation matrices for 3D cell culture, bioprinting or cell delivery. In such materials, the interconnectivity and the size of the pores are key parameters that govern migration, proliferation and potential colonization of encapsulated cells [1]. Despite many efforts and progress, elaborating systems that remain liquid at room temperature and form a macroporous matrix in the presence of cells at body temperature is still a challenge [2]. Here, we explore the potential of thermosensitive mixtures composed of chitosan (CS) and phosphate salts such as beta-glycerophosphate (βGP) [3] and ammonium hydrogen phosphate (AHP) [4]. These systems can be held liquid at room temperature and neutral pH while exhibiting a fast sol/gel transition at body temperature. Most interestingly, this gelation results from a phase separation which spontaneously produces concentration fluctuations over several tens of micrometers. We hypothesize that such mechanism could be advantageously used to make cell-laden thermosensitive hydrogels having the macroporosity required for cell activity.

In our approach, CS/βGP/AHP mixtures were prepared, which pH, osmolarity and gelation kinetics can be finely tuned to be suitable with cell encapsulation. Cell behavior was assessed by in vitro encapsulation for two cellular models: pre-osteoblast MC3T3 and primary human gingival fibroblast HGF. Using a quantitative image analysis based on confocal microscopy (LSCM), we characterized the macroporosity as a function of the CS concentration. Furthermore, observations in cell-laden formulations provided a way to address key questions such as the homogeneity of the cell distribution and their possible influence on the pore formation.

Experimental Methods

Thermosensitive CS/βGP/AHP solutions: Ratios of βGP and AHP were adjusted to satisfy pH = 7.4 and osmolarity of 300 mOsm.L\textsuperscript{-1} for CS concentrations ranging from 0.5 to 0.8 wt%. Each CS solution was chilled in an ice bath for 5 min, βGP and AHP solutions were added and the mixture was vortexed for 30 s between each step. Fluorescently labelled CS with AlexaFluor488 was synthetized and mixed with regular CS before mixing with salts.

Cell staining and encapsulation: (1) Cells were stained with MemBright560 and mixed with CS/βGP/AHP solutions at a final concentration of 10\textsuperscript{6} cells. mL\textsuperscript{-1}; (2) Solutions with or without cells were dispensed into cell culture plates and incubated at 37°C and 5% CO\textsubscript{2} for 1 h to allow gelation; (3) After 1 h of incubation, culture medium was added. The viability and metabolic activity of cells were evaluated by Live/Dead and AlamarBlue assays.

LSCM analysis: Images were acquired using lasers at 488 nm and 561 nm with x40 magnification (LSM 710, Zeiss) at 1 h and 24 h post-encapsulation. Stacks of images were deconvoluted and binarized to determine the porosity as the ratio of white and black pixels. 2D images were analyzed with the morphological sieve technique to estimate the pore size distribution [5].

Results and Discussion

Formulations having physiological pH and osmolarity were produced with CS concentrations varying from 0.5 to 0.8 wt%. They all remained liquid at 21°C for more than 2 h and formed a gel within 2 min at 37 °C. Macroporous
hydrogels are obtained with porosities ranging from 63 ± 2 % to 75 ± 5 % (Figure 1a-b). Within this concentration range, large distributions in characteristic pore size were measured with maximum pore size up to 30 µm with mean values of 5-8 µm (Figure 1c for hydrogel prepared with 0.8 wt% of CS).

Encapsulation studies of MC3T3 and HGF cells showed good viability of at least 80% up to 24 h post-encapsulation. Cells were distributed homogeneously along the observable depth and can be localized within the microstructure (Figure 1c). We found that the formation of the macroporous structure is barely affected by the presence of cells. Both the porosity and the distribution in pore size are the same as for the hydrogels formed without cells (Figure 1d).

Conclusion
Thermosensitive CS/βGP/AHP mixtures were developed having cytocompatible pH and osmolarity. By varying CS concentration, we show that these systems form a gel within minutes and develop a network of interconnected macropores having sizes of tens of micrometers. Cells distribute themselves homogeneously within these gels without altering the formation and the morphology of the macropore network. Such results and methods bring a valuable insight into the complex cell-matrix interactions occurring during the gelation process. Furthermore, these systems provide an interesting platform to design thermosensitive scaffolds for 3D cell culture and cell delivery.

A comparative study of AUP-based hydrogel wound dressings and commercial dressings for the treatment of exuding wounds

Manon Minsart¹, Arn Mignon², Aysu Arslan¹, Iain U. Allan³, Sandra Van Vlierberghe¹, Peter Dubruel¹

¹ Ghent University, Polymer Chemistry and Biomaterials Research Group, Department of Organic and Macromolecular Chemistry, Ghent, BE; ² KU Leuven, Surface and Interface Engineered Materials, Campus Group T, Leuven, BE; ³ University of Brighton, School of Pharmacy and Biomolecular Sciences, Brighton, GB

Introduction
Wounds are a global medical concern [1]. The international advanced wound care market is expected to exceed €18 billion by 2024 [2]. To date, a wide range of wound dressings is commercially available with hydrogel-based dressings being the most relevant for exuding wounds due to their strong exudate uptake capacity. Unfortunately, hydrogels often suffer from inferior mechanical strength.

To this end, our research focuses on the development of a novel hydrogel-based wound dressing with tunable mechanical strength and high exudate absorption capacity using acrylate-endcapped urethane-based precursors (AUPs). The selection of a dressing is of paramount importance as inappropriate wound management and dressing selection can delay the wound healing process. Not only can this be distressing for the patient, but it can also contribute to complications such as maceration and (subsequent) infection. Malodorous wounds, which typically display high levels of exudate, can be especially distressing and thus negatively influence the patients’ wellbeing.

The novelty of our work is situated on two levels. On the one hand, we propose the application of a novel hydrogel-based wound dressing. The potential to apply the AUPs together with activated carbon into wound dressings for malodorous wounds was also assessed. Secondly, we realized an in-depth benchmarking of our newly developed materials relative to the most commonly applied commercial dressings.

Experimental Methods
Acrylate-endcapped urethane-based precursors (AUPs) [3] with a varying poly(ethylene glycol) backbone molar mass (2–20 kg/mol) and (multi-)acrylate endcaps were selected. The syntheses of the different AUP polymers were performed according to standard in-house protocols [4]. The precursors were processed both into UV-cured sheets and electrospun membranes. Both synthesized and commercial dressings were mainly characterized in terms of exudate absorption capacity and mechanical properties. The materials containing activated carbon (AC) were further assessed in terms of sorption potential using colorimetry with crystal violet as model compound. The morphology of each material was studied with scanning electron microscopy (SEM).

Results and Discussion
The results can be subdivided according to the applied processing technique. The swollen AUP UV-cured hydrogel sheets (30 wt%) elegantly combined mechanical strength (up to 0.63 MPa) and high exudate uptake capacities (up to 34.9 g_{water}/g_{material}) along with high gel fractions (> 85%). The commercial dressings exhibited inferior swelling capacities (up to 24 g_{water}/g_{material}). However, several dressings revealed a higher mechanical strength given their multi-layered character and/or hydrophobic nature. Interestingly, upon processing the hydrogel precursors through electrospinning, SEM indicated a homogeneous fiber morphology with fiber sizes in the 0.7–1.5 μm range. The fibrous commercial dressings had diameters ranging between 10 and 25 μm. The hydrogel sheets containing 0.5 wt % AC showed a strong sorption of the model compound crystal violet (> 90% after 24 hours). Finally, indirect cell tests with human dermal fibroblasts confirmed the in vitro biocompatibility of all materials.

Conclusion
The present work offers a profound overview, characterization and comparison of various essential properties of the synthesized and commercial wound dressings. The tested commercial dressings exhibit either a high strength or a high swelling, suggesting the strong potential of dressings combining both a high strength and a high swelling capacity. In this respect, the herein developed AUP materials offer great potential with a superior swelling capacity as compared to the commercial dressings and tunable mechanical properties.

No. 12Z2918N).

Processing of the AUPs into UV-cured sheets and electrospun membranes for wound healing purpose
This research focuses on the development of a novel hydrogel-based wound dressing with tunable mechanical strength and high exudate absorption capacity using acrylate-endcapped urethane-based precursors (AUPs). In this work, AUP-based hydrogels were synthesized with a varying backbone (poly(ethylene glycol) molar mass and (multi-acrylate) endcaps and processed into UV-cured sheets and electrospun membranes.

Production and characterization of dual-stimuli nanofibrous membranes

Adriana M.L. Gonçalves, Filipe V. Almeida, Paula I.P. Soares, João P. Borges

CENIMAT | i3N, Department of Materials Science, Caparica, PT

Introduction
Cancer is one of the main causes of death worldwide and its occurrence has been increasing over the years. Due to the therapeutic inefficiency and severe side effects of conventional cancer treatments, the development of new cancer treatment options has been one of the most studied research areas. The development of new multifunctional systems that deliver therapeutic agents locally to the tumor site allows a more personalized and effective treatment. The present work focuses on the development a dual-stimuli responsive device composed of Fe₃O₄ magnetic nanoparticles and PNIPAAm microgels embedded in electrospun polymeric fibers capable of providing a simultaneous and local combinatory cancer treatment: chemotherapy and magnetic hyperthermia. The incorporation of microgels and nanoparticles in electrospun nanofibers allows the localization of these systems in the tumor region in a sufficient concentration to enable a more effective treatment [1].

Experimental Methods
Fe₃O₄ nanoparticles (mNPs) were synthesized by chemical co-precipitation technique and later stabilized with dimercaptosuccinic acid (DMSA) and oleic acid (OA) [2]. Thermoresponsive PNIPAAm microgels were obtained by surfactant-free emulsion polymerization (SFEP) [3]. Poly(vinyl alcohol) (PVA) was used as fiber template and 10 wt. % of PNIPAAm microgels and 8 and 10 wt. % of mNPs were incorporated in the fibers through colloidal electrospinning technique to produce dual-stimuli nanofibrous membranes. The membranes were characterized and their mechanical properties, swelling ability, and heating ability were evaluated.

Results and Discussion
Fe₃O₄ nanoparticles with an average diameter of 8 nm were synthesized and successfully stabilized with DMSA and OA. Thermoresponsive PNIPAAm microgels were also successfully synthesized. At room temperature, the microgels are in a swollen state with a hydrodynamic diameter of around 1 μm. Above 32 ºC, their hydrodynamic diameter decreases and at higher temperatures the collapsed state of the microgels takes place, confirming their negative temperature response and Lower Critical Solution Temperature [4]. PVA fibers with a mean diameter of 179 ± 14 nm were obtained and both mNPs and PNIPAAm microgels were successfully incorporated. A bead-on-a-string morphology was observed, as shown in Figure 1. The presence of PNIPAAm microgels and Fe₃O₄ nanoparticles in the electrospun fibers decreases the swelling ratio of the membrane and increases the material stiffness, raising its Young's modulus when compared to the plain PVA membrane. A higher concentration of nanoparticles in the membrane also leads to an increase in this parameter. Also, DMSA coated nanoparticles appear to have a slight impact in the rise of rigidity of the membrane when compared to the OA coated nanoparticles. Magnetic hyperthermia assays show that a higher concentration of nanoparticles leads to a higher heating ability, as expected. The composite membrane with the most promising results is the one incorporated with 10 wt. % DMSA coated mNPs, since it shows the highest temperature variation, 5.1 ºC. If we consider a body temperature of 37 ºC, a temperature variation of 5.1 ºC is enough to reach the desired 42 ºC in magnetic hyperthermia treatment making this membrane a viable option in this type of cancer treatment. In order to evaluate the cytotoxic effect of PNIPAAm microgels and mNPs incorporated in PVA membranes, cytotoxicity assays were performed. All assays reveal that PVA membranes incorporated with PNIPAAm microgels and mNPs do not present any type of cytotoxicity and therefore could be used in biomedical applications.
Conclusion
In the present work, a dual-stimuli responsive system was successfully developed. This system is composed of magnetic nanoparticles and thermoresponsive microgels, which in turn were incorporated into PVA electrospun fibers. Results show the potential of this multifunctional device in magnetic hyperthermia applications as an alternative cancer treatment. In addition, the developed system also presents a special interest in drug delivery applications in which the device can be remotely triggered by an external stimulus like temperature variation. Drug delivery assays will be performed in the future.

In vitro simulation of extracellular vesicles delivery from thermosensitive nanocomposite hydrogel for regenerative medicine

Maria A. Grimaudo, Giada Bassi, Arianna Rossi, Monica Montesi, Silvia Panseri, Franco Furlani

National Research Council of Italy, Institute of Science and Technology for Ceramics, Faenza, IT

Introduction
Extracellular vesicles (EVs) have recently emerged as promising pleiotropic tools in regenerative medicine. EVs play a key role in cell-to-cell immunomodulation and, it has been recently demonstrated in preclinical neurotrauma models (e.g. spinal cord injury and traumatic brain injury), their role in functional recovery and neurovascular plasticity. For this reason, their delivery in situ will be beneficial for the recovery of damaged neural tissues. The aim of this work was to design an injectable thermosensitive nanocomposite hydrogel for the controlled delivery of a synthetic model of EVs.

Experimental Methods
Synthetic model of EVs was prepared by injecting 0.1 ml of organic phase containing 25 µl of 20 mg/ml cholesterol ethanolic solution, 12.5 µl of 40 mg/ml α-phosphatidylcholine ethanolic solution and 62.5 µl of pure ethanol into 1 ml of sterile water. Mimetic vesicles were then encapsulated into polymeric nanogels obtained by mixing 0.25 ml of 1.5 mg/ml sodium tripolyphosphate aqueous solution and 1 ml of 1 mg/ml chitosan (base, low MW) acid solution (0.1% w/v acetic acid aqueous solution). Encapsulated mimetic vesicles were prepared substituting the aqueous phase with 1.5 mg/ml sodium tripolyphosphate aqueous solution. Obtained systems were physically characterized by dynamic light scattering, while cells internalization assays were carried out by fluorescent labeling (Topfluor® PC, 3.6 µg/ml) or doxorubicin encapsulation into systems. In vitro release patterns from mimetic vesicles and hybrid systems were studied by dialysis membranes. Thermosensitive hydrogels were prepared by mixing 25 mg/ml chitosan (base, low MW) acid solution (1% w/v acetic acid solution) and 470 mg/ml disodium β-glycerophosphate salt hydrate (β-GP) aqueous solution (1:1 vol/vol ratio) at 4°C. Hydrogels were then casted overnight at 37°C. The addition of sodium hyaluronanate (1.6 MDa) to thermosensitive hydrogel was also evaluated. Polymeric mixtures were studied to evaluate gelation temperature by frequency sweep test (1 Hz, 0.01 strain, 1°C/min, from 5°C to 37°C), and swelling behaviour examined in vitro by hydrogel immersion in cells culture complete medium.

Results and Discussion
Synthetic EVs showed 133±25 nm, 0.149±0.021 and -21±6 mV, as dimensions, polydispersity index and net charge, respectively. EVs encapsulation into polymeric nanogels led to hybrid systems of 235±43 nm, 0.327±0.045 and +33±3 mV as size, polydispersity index and net charge, respectively.

Gelation temperature of thermosensitive hydrogel composed of chitosan and β-GP was found 36.6°C, while casted hydrogels showed the capability to swell up to 100% (weight ratio) after 6 h full immersion in cells culture complete medium. Successfully, cells assays demonstrated that labeled synthetic EVs were efficiently internalized by cells either in free form or encapsulated in polymeric nanogels. In vitro release studies revealed that doxorubicin, used as biomolecule model, was completely released from isolated synthetic EVs and hybrid systems in 24 h. Interestingly, uptake efficiency of doxorubicin in MG63 cells was superior for loaded hybrid systems in comparison to loaded synthetic EVs, while loaded chitosan coated EVs showed an intermediate behavior.

Conclusion
This study demonstrated the possibility to wrap EVs in a nanocomposite hydrogel that will work as EVs reservoir, and the chance to release EVs in a controlled manner, ascribable to the degradation kinetic of the nanohydrogel
itself. These data addresses the smart delivery of EVs as natural therapeutics useful in regenerative medicine applications.
Optimisation of a Thermoresponsive, Shear-Thinning Collagen-Hydroxyapatite Scaffold as a Platform for Structurally Complex Bone Repair

Introduction
The most severe clinical consequences of osteoporosis are fragility fractures, with an estimated occurrence of one every 3 seconds[1], with a significant portion of these occurring in the vertebrae. To alleviate pain and immobility associated with osteoporotic vertebral fractures, kyphoplasty and vertebroplasty structurally reinforce fractured vertebrae using a bone cement, however peripheral vertebrae are still weakened and remain at a 5 times greater risk of secondary fracture[2]. The intricate geometry of osteoporotic bone, pathological reduction in bone production and delicate nature of vertebral bone make a minimally invasive tissue engineering approach an attractive solution. Smart/responsive hydrogel based biomaterials offer the potential to conform to complex geometries found in osteoporotic bone, and provide surrogate ECM environments to promote cellular infiltration and proliferation[3]. Furthermore, these biomaterials can be functionalized with materials and cell signals to direct endogenous cells to repair local tissue[4]. Herein, we report the development and characterisation of a thermoresponsive methylcellulose collagen-hydroxyapatite(Ha) hydrogel as a minimally invasive delivery platform for spatially complex bone repair. Specifically, the objectives were to 1) investigate the effect of Ha particle size and concentration on the rheological and thermoresponsive properties of formulated hydrogels, 2) determine the ability of the hydrogels to support osteoblast viability and osteogenesis.

Experimental Methods

Hydrogel Fabrication: Collagen-Ha slurries were mixed with high viscosity methylcellulose (MC) (4000cP) to yield gels of 2.5% w/v MC and 0.1% w/v collagen with either nano or micro Ha content ranging from 50-200%w/collagen. The samples were lyophilized at -40°C for 25 hours, sterilised by ethylene oxide, before being rehydrated in a 5.6 w/v β-glycerophosphate solution adjusted to physiological pH (~7.2) using 0.1M HCL.

Rheological analysis: Gelation temperatures were assessed by measuring the storage(G’) and loss modulus(G”) while increasing temperature from 20-40°C, applying 1Pa of stress at a frequency of 1Hz. The samples were given 1 min to thermally equilibrate before measurement. The point of gelation was defined as when the ratio of G”/G’ =1 or Tan δ= 1.0. Gelation behaviour was also observed using G’ at 37°C over 30 minutes. Injectability of the hydrogels was demonstrated by measuring force (N) required to extrude scaffolds through a 25G Luer Lock needle.

Cell Viability: MC3T3s were cultured in MEMα containing 10% FBS, 1% Pen/Strep and 1% l-glutamine. 1ml of each hydrogel was pipetted to cover the bottom of a 24 well plate, followed by gelation at 37°C for 30 minutes. MC3T3s were seeded on top of each hydrogel at a density of 70,000 cells per well with a total media volume of 1ml per well. At days 1, 3, 7 & 14, well cultures were lysed and dsDNA was quantified using Quant-iT™ PicoGreen™ dsDNA Kit (Invitrogen™) according to the manufacturer’s protocol.

Results and Discussion
A range of thermoresponsive collagen-Ha hydrogels were successfully developed. Addition[CM(1)] of nHa and mHa resulted in a concentration dependent reduction of gelation temperature with the exception of nHa 200%(Fig 1.A).
This reduction was not significant and all sol-gel transitions occurred between room temperature and body temperature (at~30°C), indicating appropriate thermoresponsive properties for in situ application. At room temperature shear thinning properties enabled easy hydrogel extrusion through a 25G needle (Fig 1.B) demonstrating Ha content will not impede minimally invasive application. Upon exposure to 37°C for 30 minutes all hydrogels displayed increasing elastic modulus meaning physical crosslinking continues beyond sol-gel transition point (Fig 1.C). The speed and extent of hydrophobic interaction is reduced by higher Ha content with the exception of mHa 50%. Interactions responsible for gelation (Fig 2.B) between methylcellulose polymer chains could be interrupted by nano Ha interference. Hence we observe that larger Ha particles and lower Ha concentrations allow stronger gelated stiffness.

Our recent work includes successful cell culture of MC3T3s on hydrogel surfaces showing biocompatibility with no reduction in dsDNA observed (data not shown) over 7 days. Future work will involve further exploring cellular interaction and osteogenic potential of the hydrogels. Moreover, in anticipation of further improving osteogenesis we will investigate drug loading and release potential of anabolic agents for restoring bone structure and strength.

**Conclusion**

Overall, the hydrogels’ properties indicated appropriate characteristics to serve as a platform for minimally invasive and spatially complex bone application. The results suggest the ceramic element of these gels can be tuned in terms of particle size and concentration while retaining minimally invasive character and in situ fixation which could be significant for drug loading and cellular interaction.

Introduction
Osteoarthritis (OA) is a chronic joint pathology characterized by the degradation of articular cartilage, which incidence has been increasing over the last decades due to the population aging and the increasing prevalence of obesity. One of the most common approaches in severe stages of cartilage degradation is the total or partial removal of the damaged tissue and its replacement by synthetic materials. Hydrogels are very promising replacement materials for this purpose since they present similar structure and properties to articular cartilage. Besides, their high capacity to absorb water and dissolved substances turn them potential platforms for the vehiculation of drugs and other therapeutic agents. Polycarbonate urethane (PCU) has been used in several applications in the orthopedic field due to its high toughness and flexibility, long-term biocompatibility and bio-durability [1,2]. Some works demonstrated that cellulose acetate (CA) may be added as a reinforcement material to improve the mechanical properties of other polymeric materials [3]. This work aims to develop PCU hydrogels reinforced with cellulose acetate able to release diclofenac in a controlled way, in order to replace damaged articular cartilage and minimize the inflammatory postsurgical reactions.

Experimental Methods
PCU samples with 10\%, 15\% and 25\% of CA were produced by solvent exchange and compared with non-reinforced PCU, concerning the equilibrium water content and mechanical behaviour (compressive and tensile tests). The best performing material was further characterized in terms of wettability (captive bubble method), morphology (scanning electron microscopy) and friction coefficient (pin-on-plate tests against stainless steel 316L in phosphate buffered solution with hyaluronic acid (3 mg/mL)). Finally, the hydrogel was loaded by soaking with diclofenac and its release ability was compared to that of non-reinforced PCU, and the hydrogel's cytotoxicity was studied.

Results and Discussion
The water content of all the materials was similar, falling in the range of 62-67\% which mimics natural cartilage (water content < 80\% [4]). Regarding mechanical properties, the best results were obtained for PCU+15\%CA, with a compressive and tensile elastic modulus increase of 240\% and 12.5\% relatively to PCU. Besides, the ultimate tensile strength became approximately 20\% higher compared to PCU. PCU+15\%CA revealed to be quite hydrophilic, presenting a porous structure, with pores of different sizes heterogeneously distributed along the materials' structure. Although the friction coefficient (COF) slightly increased relatively to PCU, the values were of the same order of magnitude, being lower than 0.25. It was also observed that COF changed with the applied load: the higher the load, the higher the COF. Regarding the drug release behavior, PCU+15\%CA released a higher amount of the anti-inflammatory than PCU and led to a more controlled release kinetics, ensuring a sustained release for at least 48h (Figure 1). Finally, the cytotoxicity assays demonstrated that PCU+15\%CA is a biocompatible material, with a cellular viability close to 100\%.

Conclusion
Overall, the results showed that it is possible to produce PCU-based hydrogels for cartilage replacement with suitable mechanical properties, that should be able to control diclofenac release during at least the 48h.

In situ sequential co-delivery microparticle/hydrogel system for drug delivery in cancer therapeutics

Henrique Carrêlo, Maria T. Cidade, João P. Borges, Paula Soares

NOVA/FCT, Departamento de Ciências dos Materiais, Lisbon, PT

Introduction
Systemic delivery of cytotoxic chemotherapeutic agents is known to cause many negative side effects that diminish the patient’s quality of life. Local delivery of chemotherapeutic drugs has been the topic of many studies in recent years. This study focuses on the development of a thermoresponsive injectable microparticle/hydrogel for chemotherapeutic drugs co-delivery system for in situ injection. The embedding of microparticles within a hydrogel matrix will allow a more localized drug delivery with a sustainable and prolonged release [1].

Experimental Methods
Composite microparticles of gellan gum and sodium alginate were produced with a coaxial air flow technique. The precursor solution was extruded to an ionic crosslinking bath with calcium ions. Afterwards, microparticles were embedded in a Pluronic hydrogel to produce a thermoresponsive composite system. Mechanical properties, swelling, gelation time and rheological properties were determined by comparing the composite system with the hydrogel alone.

Results and Discussion
Air flow had a statistically significant impact on the size of the particles. A higher ratio of gellan gum diminished the particle size distribution most likely due to an increase in the viscosity of the precursor solution. Injectable hydrogels sensitive to temperature allow in vivo administration, through a minimally invasive procedure, and can serve as excellent support for the particles [2].

Conclusion
This system was designed to serve as a sequential drug co-release system with a potential synergetic effect [3]. In the near future, it is expected to load the hydrogel and microparticles with drugs suitable for cancer treatments, followed by its drug load and drug release characterization. Drugs loaded directly in the hydrogel will have an earlier release compared to the ones loaded within the microparticles. The different release patterns allow a sequential co-release of drugs that will increase the efficiency of the treatment. The proposed composite system is a promising composite for in situ drug delivery to tumours.

Investigation of Parameters Influencing Tubular-Shaped Chitosan-Hydroxyapatite Layer Electrodeposition

Mariusz Mąkiewicz¹, Katarzyna Nawrotek¹, Radosław A. Wach²

¹ Lodz University of Technology, Department of Environmental Engineering, Łódź, PL; ² Lodz University of Technology, Institute of Applied Radiation Chemistry, Łódź, PL

Introduction
Recent developments have introduced electrodeposition as a method for obtaining chitosan-based tubular deposits. In this process, the action of electric current on chitosan solution results in deposit formation on the electrode. Although the literature is lacking in explanation of the electrodeposition phenomenon, properties of chitosan-based deposits obtained in electrodeposition are widely described. Chitosan is a biomaterial widely studied in tissue engineering applications. Tubular shape chitosan-based deposits can be employed as implants in peripheral nerve injuries treatment. The aim of this work is to investigate parameters influencing the electrodeposition process from chitosan-hydroxyapatite colloidal solution and characterise the obtained tubular deposits.

Experimental Methods
Electrodeposition from chitosan, hydroxyapatite and chitosan-hydroxyapatite colloidal solutions containing lactic acid was conducted in a cylindrical stainless steel reactor with an inner rod serving as a cathode. In order to investigate the process, the following parameters: amperage, volume of evolved gas and gain in deposit thickness were recorded over time for different values of set voltage. Properties of applied colloidal solutions, e.g average size and zeta potential of particles were determined by dynamic laser scattering (DLS) and electrophoretic light scattering (ELS). The structure of deposits was assessed using scanning electron microscope (SEM) and Fourier transform infrared spectroscopy (FTIR).

Results and Discussion
Among the three investigated solutions, only electrodeposition in chitosan-hydroxyapatite solution results in tubular deposit formation on the cathode. Hydroxide ions, resulting from water electrochemical reduction, deprotonate –NH₃⁺ groups of chitosan and may react with calcium ions derived from hydroxyapatite which are coordinated by deprotonated chitosan chains. Changes of amperage recorded during the process reveal intricate character of investigated phenomenon. A possible explanation for these results is hydrogel deposition over time as well as gas evolution, which constantly changes resistance of the system. Rate of gain in deposit thickness and gas evolution is determined by set voltage. However, it does not influence deposit thickness for the process lasting over 20 minutes. The obtained results of properties of colloidal solutions indicate that the average size of particles and zeta potential values in chitosan-hydroxyapatite solution are higher than in chitosan and hydroxyapatite solutions. It suggests formation of new interactions between chitosan chains and hydroxyapatite. Morphology assessment of deposit surface via SEM indicates high surface irregularity for samples received at higher set voltage. Additionally, FTIR spectra present molecular differences between inner and outer side of the received tubular deposit. Obtained data indicates heterogeneous structure of the deposit. Outer and inner side of deposit is characterised by bands of chitosan chains and hydroxyapatite-derived species. However, bands assigned to chitosan chains are more pronounced for the outer side.

Conclusion
Electrodeposition from chitosan-hydroxyapatite solution is based on electrochemical reduction of water and formation of interactions between calcium ions coordinated and chitosan chains. As a result, the deposit is created on the cathode. Set voltage of the process has influenced the ratio of gas evolution and gain in deposit thickness.
Consequently, surface morphology of deposit is determined by set voltage. Reported results may serve as a valuable tool for manufacturing of biocompatible implants dedicated to treatment of peripheral nerve injuries.

A silated hyaluronic acid hydrogels platform with bioinspired properties for skeletal tissue engineering

Killian Flegeau\textsuperscript{1,2}, Hélène Gautier\textsuperscript{1}, Gildas Rethore\textsuperscript{1}, Anthony Bresin\textsuperscript{2}, Pascal Bordat\textsuperscript{2}, Pierre Weiss\textsuperscript{1}

\textsuperscript{1} Université de Nantes, RMES U 1229, Nantes, FR; \textsuperscript{2} HTL Biotech, Javené, FR

Introduction

Tissue engineering is a promising approach to regenerate damaged skeletal tissues. In particular, the use of injectable hydrogels alleviates common issues of poor cell viability and engraftment. However, uncontrolled cell fate, resulting from unphysiological environments and degradation rates, still remain a hurdle and impedes tissue healing. We thus aim at developing a new platform of injectable hyaluronic acid (HA) hydrogels with a large panel of properties (stiffness, degradation...) matching those of skeletal tissues. For bone regeneration, Biphasic calcium phosphate (BCP) granules are osteoconductive biomaterials used in clinics to favor bone reconstruction. We incorporated BCP granules into in situ forming silanized hyaluronic acid (Si-HA) hydrogels.

Experimental Methods

Si-HA is prepared by amidation of the carboxylic acid functions of HA \cite{1}. To improve osteoconduction properties, calcium phosphate ceramics particles (40-80 µm) (Biphasic Calcium Phosphate; BCP\textsuperscript{®}, Biomatlante) has been added to the high pH (12.4) viscous Si-HA solution. Si-HA-BCP has been adjust to a final concentration of 3% w/v Si-HA in a 4:1 volume ratio with sterile HEPES buffer (pH 3) using Luer-lock syringes. Subsequently, different HA were functionalized with silylated moieties and formed hydrogels upon injection through a sol-gel chemistry occurring at physiological pH.

Results and Discussion

Upon solubilization and pH adjustment, the low-viscosity precursor solutions are easily injectable through fine-gauge needles prior to in situ gelation. Rheological characterization demonstrated that these hydrogels set within 5 to 20 minutes at 37°C. Tunable mechanical properties (stiffness from 1 to 40 kPa) and associated tunable degradability (from 4 days to more than 3 weeks in vivo) are obtained by varying the degree ofsilanization (from 4.3% to 57.7%) and molecular weight (120 and 267 kDa) of the hyaluronic acid component. Following cell encapsulation, high cell viability (>80%) is obtained for at least 7 days. Finally, the in vivo biocompatibility of silanized hyaluronic acid gels is verified in a subcutaneous mouse model and a relationship between the inflammatory response and the crosslink density is observed.

We have developed hybrid silated HA/biphasic calcium phosphate granules hydrogels and demonstrated a mechanical reinforcement (E = 0.1 MPa) while maintaining similar degradation rates. In vivo implantation in a rabbit femur model finally assessed their efficacy as bone substitutes (Figure 1) in comparaison to an silated HPMC composite.

Conclusion

Collectively, these results suggest that these hydrogels with a large panel of ECM-like properties offer promising outcomes for skeletal tissue engineering.

**Fabrication of Bovine Hair Keratin/ Halloysite Bionanocomposite Hydrogels**

**Ezgi Ismar, Oguzhan Polat, Aysegul Uzuner Demir, Aykut Sancakli**

*Kazlicesme R&D Center and Test Laboratories, Istanbul, TR*

**Introduction**

During the conventional leather process, bovine hair is come out as a waste due to the de-hairing process. Bovine hair is destroyed with acidic treatment which makes it difficult to uptake from the wastewater. Thus, the enzymatic process for de-hairing the bovine leather is followed to obtain hairs from the discharged wastewater. Waste valorization in means of keratin is possible after obtaining the hair from the stream, the first removal of fat and other impurities should be followed with the addition of surfactant and obtained keratins are dried. Halloysite is a natural clay which’s chemical formula is $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$. It has a tubular shape with an outer part siloxane and aluminol inner part and it is a naturally occurred nanotube [1],[2],[3].

**Experimental Methods**

After de-hairing process of the leather, hair is collected from the wastewater and treated with SDS, and dried. To create the composite hydrogel structure cross-linking is added to keratin solution different halloysite ratio was studied to find the optimum ratio [4]. After the reaction process hydrogel is lyophilized and stored [5].

**Results and Discussion**

TEM is used to observe the halloysite distribution inside the hydrogel, SEM is used to characterize the sponge-like structure of the hydrogel, and FTIR and SDS-page are used to characterize the properties of the keratin. Thermal properties of the bionanocomposites are investigated via TGA and DSC. Swelling properties of the hydrogels were recorded for different pH environments.

**Conclusion**

Waste valorization of keratin is successfully applied and Keratin/ Halloysite bionanocomposite hydrogels are obtained. They can be a good candidate for biomedical applications.

Introducing external triggers to bioinspired hydrogels design for flexible cell encapsulation

Minye Jin¹², Alisa Gläser¹, Supun Mohotti¹, Julieta I. Paez³

¹ INM-Leibniz Institute for New Materials, Dynamic Biomaterials, Saarbrücken, DE; ² Saarland University, Chemistry Department, Saarbrücken, DE; ³ University of Twente, Developmental BioEngineering, Enschede, NL

Introduction

Hydrogels are used as extracellular matrix mimics in biomaterials field, including 3D cell culture, drug delivery and tissue engineering. Recently, our group developed a bioinspired covalent crosslinking strategy for hydrogel formation in the presence of living cells, via a condensation reaction between 2-cyanobenzothiazole (CB) and aminothiol (AT) groups, rendering stable adducts. The resulting CB-AT hydrogels showed rapid and tunable gelation kinetics, were mechanically stable, homogeneous at the microscale and cytocompatible.¹ To achieve fine tuning of gelation onset and kinetics, implementing other external cues to trigger the CB-AT gelation on demand is desirable. The aim of the present work was to explore variations of the CB-AT design and equip this system with redox and enzymatic triggers that enable fine tuning of the gelation onset and kinetics. Our strategy involved the use of “masked” AT precursors that can be unmasked under mild conditions by action of a reducing agent or a protease, thus triggering the CB-AT condensation on demand (Fig. 1a). Inspired by previously reported masked AT groups,²³ here we present the synthesis of novel protected AT polymer precursors and the investigation of condition reactions to trigger the CB-AT gelation with convenient rate (seconds to minutes) and adjustable mechanical strength under redox and enzymatic regulation, while keeping good cytocompatibility.

Experimental Methods

4-arm, 10 and 20 kDa poly(ethylenglycol) (PEG) macromers carrying either CB groups, or thiol-masked (R= SEt and SBu), or amine-masked (R' = furin or caspase-3 labile peptides) AT groups were synthesized in high yields and purity. Solutions of CB and masked-AT precursors (2-10 wt% in 20 mM HEPES buffer) were prepared and used for gel formulation under physiological conditions. Triggering of gelation was investigated in the presence of diverse reducing agents (TCEP, glutathione, DTT) or enzymes (furin, caspase-3), under variable polymer concentration (3.3-5 wt%), diverse trigger concentration and working pH (7-8). Gelation kinetics and mechanical properties of the resulting hydrogels were characterized by shear oscillatory rheology, to determine the effect of molecular design and working media parameters on materials properties. Swelling ratio of the gels was determined following established protocols.⁴

Results and Discussion

With redox triggering, PEG hydrogels via the CB-AT condensation reaction were successfully prepared at working pH range of 7.0 to 8.0. Hydrogels at 5 wt% polymer concentration showed gelation kinetics from seconds to minutes depending on the thiol-masking groups of AT precursors (R, Figure. 1b). The gelation rate trend observed was R=SEt > R= StBu at both pH 7.0 and 8.0, as revealed by in-situ rheology. This reflects the relative rate of reductive cleavage of disulfide bonds. The gelation kinetics was also tuned by varying pH, regardless from the molecular structure of masking group (Figure 1b). The pH change from 8.0 to 7.0 enabled a slower gelation process from a few seconds to minutes, in agreement with obtained results before.¹

In addition, the influence of reductant type on gelation kinetics was investigated (Figure 1c). The resulting CB-AT(SEt) gels were formed at 3.3 wt% concentration in 20 mM HEPES buffer at pH 8.0 using variable reducing agents (i.e. TCEP, DTT and GSH), keeping a constant (1:1) reductant: SR ratio. The use of TCEP produced a faster gelation time in seconds range while the use of GSH and DTT resulted in slower gelation times of 5 min and 15 min, respectively.
respectively. However, the final mechanical strength of the gels did not differ significantly. This indicates that the variation of reducing agent in this system allows tuning of gelation time between seconds to minutes without altering final gel mechanics.

Enzymatically triggered experiments were performed with peptide-masked AT precursors in the presence of furin and caspase-3 proteases in corresponding buffers. Unexpectedly, no gel formation was observed after 1 day. This is probably due to the steric hindrance of the PEG-peptide conjugate, which impeded adequate enzymatic recognition at the active site.

**Conclusion**

Two strategies to externally trigger CB-AT crosslinking were explored under physiological conditions. Redox triggering of the gelation was achieved successfully, gel formation was efficient and gelation kinetics could be fine-tuned from seconds to minutes range by varying molecular structure of masking groups of AT precursors, pH, polymer concentration and reductant type. Attempts to achieve enzymatic triggering proved unsuccessful under tested conditions, probably because of steric hindrance of the PEG-peptide conjugate that impeded adequate enzymatic recognition at the active site. In the future, the redox-triggerable CB-AT hydrogels presented here will be further developed as injectable and printable formulations for applications in tissue engineering and regenerative medicine.

**Introduction**

*Helicobacter pylori* is a Gram-negative bacterium that colonizes the stomach of nearly 4 billion people, i.e., half of the worldwide population [1]. Chronic infection with this bacterium can lead to chronic gastritis, peptic ulcers and, in some cases, gastric carcinoma. In fact, *H. pylori* infection accounts for 89% of all diagnosed gastric cancers [1], the 5th most common and 4th deadliest [2]. Although there is an antibiotic-based treatment, it fails in 20%-40% of the cases, prompting the need for newer therapeutic strategies [3]. Previously, our team showed that nanostructured lipid carriers (NLC) are efficient in eradicating *H. pylori* [4]. Still, to achieve complete bacterial clearance, NLC bioavailability must be improved, namely by increasing their gastric retention time. For that, development of a pH-responsive system to act as carrier appears as a good strategy to boost NLC performance.

**Experimental Methods**

Herein, low acyl gellan gum (LAGG) hydrogels with different polymer concentrations (1%, 1.5% & 2% w/v) were screened as possible NLC carriers. Hydrogels production was adapted from Silva-Correia et al. [5]. Briefly, after LAGG powder dissolution in deionized water, at 90°C, PBS (10% v/v) was added. Then, the solution was transferred to a Petri dish where the gelation process occurred. Finally, small discs were cut with a 9 mm diameter puncher. The mechanical behaviour of LAGG hydrogels and LAGG hydrogels with NLC (10% v/v) (NLC-LAGG) were analysed by dynamic mechanical analysis, using a compression test for 30 minutes. The hydrogels degradability was evaluated in different pH (7.4, 6.0, 4.0, 2.6 and 1.2) over 24h, at 37°C and 150 rpm, by tracking changes in weight and diameter of both LAGG and NLC-LAGG hydrogels. *In vitro* release of NLC was studied using LAGG hydrogels with NLC marked with coumarin-6 (cNLC-LAGG), which were incubated under the same settings used for the degradability test. At different time points, supernatants were collected and fluorescence readings were performed using a wavelength of 420 nm for excitation and 490 nm for emission. Confocal microscopy was used to evaluate NLC distribution on the cNLC-LAGG hydrogels. Finally, 1.5% and 2% NLC-LAGG hydrogels were immersed in pH 2.6 and 7.4 and, at different timepoints (24, 48 and 72h), extracts were collected. Then, extracts’ antimicrobial activity was evaluated against *H. pylori* J99 (highly pathogenic strain) by incubating with the bacteria for 24h. Afterwards, plating was performed and the viable bacteria was determined by colony forming unit (CFU) counting. The quantification of the number of released NLC from these hydrogels was performed by nanoparticle tracking analysis.

**Results and Discussion**

LAGG 1% hydrogels did not have mechanical properties to allow its handling and undergo further testing. Results from compression tests showed that both LAGG 1.5% & LAGG 2% hydrogels had similar elastic behaviour. A slight decrease was observed in both storage modulus and loss modulus when the polymer concentration decreased. The Page 1760 of 2028
ratio between loss and storage moduli remained on the same range. The incorporation of NLC into the structure of the hydrogels (10% v/v) did not alter its mechanical properties. Degradability tests showed that both LAGG 1.5% & LAGG 2% hydrogels, either with or without NLC, had similar mass losses, except for pH 1.2, where less concentrated hydrogels had higher mass loss. Regarding the different pH tested, higher mass loss was achieved in pH 1.2 and pH 2.6, indicating different behaviour according to the pH, as expected. However, no significant variations were observed in the hydrogel’s diameter. NLC release study showed that, after 24h, around 4% of the nanoparticles were released from the cNLC-LAGG 2% hydrogels whereas in the cNLC-LAGG 1.5% only around 2% of NLC were released on all the pH’s tested. Confocal images showed that NLC were widely distributed throughout the structure of both cNLC-LAGG 1.5% & cNLC-LAGG 2% hydrogels. Antimicrobial studies showed that the amount of NLC released from the hydrogels after 72h of incubation was not enough to kill the bacteria since less than 2% of the nanoparticles were released from both NLC-LAGG 1.5% & NLC-LAGG 2% hydrogels. Therefore, further optimization of the NLC releasing profile needs to be done by tuning the acylation degree of the gellan gum.

**Conclusion**

These results highlight LAGG hydrogels as a good strategy to further pursue in order to deliver NLC on gastric settings and boost their efficiency for *H. pylori* eradication.

Design and development of bio-hybrid hydrogels containing the system of pH/thermosensitive nanocarrier - salicylic acid

Katarzyna Bialik-Wąs¹, Dagmara Malina², Klaudia Pluta²

¹ Cracow University of Technology, Faculty of Chemical Engineering and Technology, Department of Organic Chemistry and Technology, Kraków, PL; ² Cracow University of Technology, Faculty of Chemical Engineering and Technology, Department of Chemical Technology and Environmental Analytics, Kraków, PL

Introduction
Nowadays, hybrid biomaterials become more and more popular, because they can combine the features of inorganic, organic as well as polymeric components. Then the final product can be characterized by multitasking properties, which are interesting from the point of view of medical and biomedical applications [1-3]. Moreover, hydrogel materials can be used as modern wound dressings, especially in the treatment of long-healing skin disorders, such as bedsores, venous and diabetic ulcers [4,5].

Experimental Methods
Here, studies were focused on the design and development of bio-hybrid hydrogels based on sodium alginate (SA), poly(vinyl alcohol) (PVA), glycerin, and Aloe vera solution (AV). Additionally, salicylic acid - pH/thermosensitive nanocarrier were incorporated into SA/PVA/AV hydrogel matrix. This combination of active ingredients of natural and synthetic origin can improve the therapeutic efficacy of the product. The main goal of our research is the preparation of innovative dressings for the treatment of Psoriasis. Bio-hybrid hydrogels were obtained through the chemical crosslinking method using poly(ethylene glycol) diacrylate (PEGDA, Mₙ = 700 g/mol) as a crosslinking agent. First, the gel fractions of bio-hybrid hydrogels containing the system of pH/thermosensitive nanocarrier - salicylic acid were determined and their swelling behavior in distilled water and simulated body fluids was tested. Additionally, the degradation tests were carried out. Subsequently, the following properties of the modified materials were studied: structural (FT-IR spectra analysis), morphological (SEM analysis), and mechanical (tensile strength, elongation at break, and hardness). Finally, the cytotoxicity tests using in vitro method were conducted.

To identify the chemical structure of the bio-hybrid hydrogels as well as perform an analysis of the materials after degradation, infrared spectroscopy was done with a Thermo Scientific Nicolet iS5 FT-IR spectrometer equipped with an iD7 ATR accessory in the range of 4000 cm⁻¹ - 400 cm⁻¹. The hydrogel morphology was observed by a means of an SEM (Scanning Electron Microscope) using a Tescan Mira 3 instrument equipped with a FEG Schottky electron emission source at an acceleration voltage of 3.0 kV. The samples were sputter-coated with a thin film of gold for 90 sec. The maximum tensile strength and the elongation degree to break tests were conducted on the hydrogels using an MTS Bionix machine with a tensile loading rate of 0.2 mm/s. All specimens were cut into a specific dumbbell shape (75 mm long, 4 mm at the middle, and 25 mm of measuring segment).

Results and Discussion
The content of the gel fraction of bio-hybrid hydrogels reaches the value of about 70% and it turned out that the type of nanocarriers does not influence this parameter. Moreover, the basic SA/PVA/AV hydrogel matrix has a slightly lower result, which means that the addition of drug-carrier improved the degree of cross-linking. For all samples, the swelling abilities in PBS are at the same level about 200-250%. In the case of water, these values are more varied and they are about 200-340%. SEM images exhibited that the surface of hydrogels is crosslinked densely whereas the cross-section presented that the internal structure is more irregular and porous. The chemical structure of bio-hybrid hydrogels before and after degradation was confirmed based on the FT-IR analysis. In the range of 3500-
3000 cm$^{-1}$, it was observed some changes in the case of samples after degradation tests, which suggests that salicylic acid was released. Additionally, positive results from mechanical research were obtained.

**Conclusion**

On the basis of results, we can conclude that the presence of the system of pH/thermosensitive nanocarrier - salicylic acid does not significantly influence on different properties of the SA/PVA/AV hydrogel matrix. This is very important information because it confirms that it was developed a proper preparation method of bio-hybrid hydrogels is a new class of wound dressings. Moreover, the introduction of salicylic acid in the form of a pH/thermosensitive nanocarrier into the hydrogel matrix allows obtaining a double system of the active substance release. Due to the time release of drug is prolonged significantly.

Introduction

Adult cardiovascular tissue exhibits an inability to repair itself after injury, due to the limited regenerative capacity of mature cardiomyocytes (CMs)¹. Previous in vitro tests have shown a higher rate of cardiomyocytes proliferation in the presence of lactate. Elastin-like recombinamers, ELRs, are a class of recombinant polymeric material whose composition is bioinspired in natural elastin and characterized by their biocompatibility and stimuli responsive. Our objective is to prepare an injectable “click” chemical hydrogel based on ELRs² with polylactic acid (PLA) encapsulated, able to modulate the release of lactate to the medium. Lactate from both partially hydrolyzed PLA, after oxygen plasma treatment, and once PLA hydrolyzed at physiological conditions, will be released in a sustained manner as an energy source for cardiomyocytes. ELRs can include in their structure bioactive sequences such as cell adhesion and protease-sensitive domains³ so that biocompatible, bioactive and biodegradable ELRs hydrogels could prove to be very useful scaffolds for the regeneration of infarcted tissue and the consequent recovery of cardiac function.

Experimental Methods

Two different ELRs have been bioproduced and subsequently functionalized to bear azide and ciclooctine groups, respectively, by NHS-ester methodology. L-PLA (MW 10000, PDI < 1.1) has been subjected to oxygen plasma treatment and some ester bonds have been hydrolyzed, giving rise to lactic acid and low molecular weight (PLA)s as determined by ¹H-NMR and FTIR-ATR⁴. The covalent crosslinking of both modified-ELRs, in the presence of treated PLA, allowed the formation of the hydrogel with embedded PLA. An in vitro kinetic release study was performed to explore the delivery of lactic acid and the release profile was obtained by measurement of lactic acid by “Enzymatic UV method”.

Results and Discussion

We have obtained “click” ELRs hydrogels with embedded PLA as a sustained lactic acid drug delivery device. The hydrogel is formed by interchain crosslinking based on click chemistry methodology from two tailored designed ELRs, one of which bearing RGD adhesion domain and the other one bearing arginine enriched domain, to retain lactic acetate by ionic interactions between negatively charged carboxylic group and the positively charged arginine. PLA oxygen plasma treatment provides partially hydrolyzed PLA as well as lactic acid and lactic acid oligomers, as could be observed by FTIR-ATR and ¹H-NMR in which the corresponding new signals of smaller molecules appeared. Release tests carried out with PLA-embedded gels will show a continuous and sustained release of lactic acid. Previous studies have shown that gels embedded with lactate released all of it in less than 10 hours. Therefore, different release kinetics will be produced and, in a first stage, the lactic acid generated by PLA plasma treatment will be released and, in a sustained manner, lactate will be released as the PLA is hydrolyzed at physiological conditions.
These injectable biomaterials based on ELRs will help cardiac regeneration acting as lactate molecules releasing devices which favors the survival and integration of the cells.

**Conclusion**

In the face of classic treatments for heart disease, such as myocardial infarctions, by means of drugs or transplantation, tissue engineering is committed to repairing the affected tissues. In this regard, lactate-bearing cardiac scaffolds, such as injectable chemical hydrogels of ELRs, will be used to stimulate the regeneration of cardiac tissue.

Development of drug-loaded, 3D printed PLLA/PLCL bioresorbable stents: characterization and influence of sterilization

Victor Chausse\textsuperscript{1,2}, Clàudia Iglesias\textsuperscript{1}, Cristina Canal\textsuperscript{1,2}, Marta Pegueroles\textsuperscript{1,2}

\textsuperscript{1} Technical University of Catalonia (UPC), Biomaterials, Biomechanics and Tissue Engineering Group, Department of Materials Science and Metallurgical Engineering, Barcelona, ES; \textsuperscript{2} Technical University of Catalonia (UPC), Barcelona Research Center in Multiscale Science and Engineering, Barcelona, ES

Introduction
Bioresorbable stents (BRS) are designed to overcome the limitations of drug-eluting stents (DES) by providing temporary support to the vessel wall while simultaneously allowing for the release of an anti-proliferative drug to avoid neointimal hyperplasia. Since the stent resorbs, the cause of potential inflammation that can lead to late stent thrombosis (LST) may be avoided [1,2]. Besides, drug release from drug-loaded stents may also be driven by polymer degradation obtaining a sustainable delivery for longer periods of time. Nevertheless, BRS present a few limitations, such as the need for large strut thickness in order to achieve enough radial support to prevent vessel recoil, which in turn increases resorption time and the probability of late undesirable events [3].

The main aim of this work is the fabrication of 3D-printed polymeric BRS by solvent-cast direct-write (SC-DW) technique to characterize their degradation behavior and to study the effects of sterilization on stents’ physicochemical properties. To confer higher added value, modification of the inks with everolimus to prevent restenosis is further intended in order to manufacture drug-eluting bioresorbable stents and monitor its release.

Experimental Methods
Poly-L-lactic acid (PLLA) and poly(lactic-co-caprolactone) (PLCL) 3D-printed stents were obtained by using a modified commercial 3D printer (BCN 3D+, BCN 3D technologies) with a rotating mandrel, in order to print cylindrical structures. The ink consisted in a solution of high molecular weight PLLA (PL 65, Purac) or PLCL copolymer (PLC 9538, Purac) in chloroform at 10\% w/v and 12.5\% w/v, respectively. Stents were printed by SC-DW on mandrels with 3 mm in diameter using a 250 μm tip (Nordson). After fabrication, stents underwent a thermal treatment during 12 h at 80\°C.

An accelerated degradation assay was performed on printed stents by immersing them in 10 mL of media (0.1M NaOH solution) in sealed glass vials and maintained at 37\°C for 10 days [4]. At different time points, stents were taken from the media, dried and weighed to calculate mass loss. Stents were further characterized by SEM, DSC, GPC and compression tests.

Two sterilization methods were evaluated: ethylene oxide or γ-irradiation (8 kGy). Sterilization effects on stents' crystallinity, molecular weight and mechanical properties were analyzed with DSC, GPC and compression tests. Inks were further modified with the addition of antiproliferative drug everolimus (Sigma Aldrich) at 2 wt.\% and 4 wt.\% with respect to polymer content. Everolimus-loaded stents were printed by SC-DW (Figure 1) and characterized with SEM and compression tests. Everolimus release was evaluated by incubation of stents in 5 mL of release medium (0.7\% Triton X-405 in 0.01M potassium phosphate buffer pH 6 at 37\°C in 7\% ACN), which was replaced by fresh medium at selected time points [5]. The release of everolimus was quantified with High Performance Liquid Chromatography (HPLC, Prominence XR, Shimadzu). Statistical analysis was performed by non-parametric Mann-Whitney U-test using Minitab software.

Results and Discussion
PLLA and PLCL stents with 3 mm in diameter were obtained by means of SC-DW, with strut thickness in the range 130 to 150 µm. Chloroform residues were eliminated after thermal treatment and the crystallinity of the stents increased with respect to non-treated stents (i.e. PLLA: from 21% up to 30%).

Stents immersed in 0.1M NaOH solution showed significant degradation after 10 days, with mass loss over 60%. DSC results showed alterations in crystallinity over time and GPC confirmed a sustained decrease in molecular weight.

Stents were successfully sterilized by means of ethylene oxide or γ-irradiation (8 kGy) and changes were detected in terms of crystallinity, molecular weight and mechanical properties.

The addition of everolimus in the polymeric ink resulted in the manufacture of everolimus-loaded stents showing drug entrapment within stents’ struts. Everolimus release assays showed initial fast release due to surface-available drug followed by a highly desirable sustained release over 1 month (Figure 2). Release was higher for PLCL stents than for PLLA stents, although drug release was subjected to the polymer degradation time frame.

Conclusion

3D-printed polymeric PLLA and PLCL stents were successfully fabricated by SC-DW. Printed stents were fully characterized in terms of thermal and mechanical properties. The accelerated degradation assay in NaOH solution showed the degradation behavior for PLLA and PLCL, with changes regarding crystallinity degree and a marked reduction in molecular weight. Sterilization modified crystallinity, molecular weight and mechanical properties of printed stents. Ink modification with the addition of antiproliferative drug rendered everolimus-eluting stents. Everolimus release was found to be faster for PLCL stents than for PLLA stents.

Encapsulation of macrophages and umbilical cord-derived cells in a liquefied and compartmentalized environment aiming bone regeneration

Sara Nadine, Clara R. Correia, João F. Mano

CICECO - Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, Aveiro, PT

Introduction

The immune system plays an indispensable regulatory role in the progress of bone regeneration, with special focuses on macrophage activity.[1] Inspired on the native dynamics between immune and skeletal systems, we propose an in vitro bioengineering system of a biomimetic bone niche that comprises liquefied and multilayered microcapsules co-encapsulating macrophages, mesenchymal stromal cells (MSCs), and endothelial cells (ECs). This encapsulation system, already tested in vivo [2], is composed by (i) a multilayered membrane obtained through the layer-by-layer assembly of three polyelectrolytes (ii) a liquefied alginate core, (iii) surface functionalized poly(ε-caprolactone) microparticles (µPCL), and (iv) cells. While the multilayered membrane wraps all the cargo contents and ensures permeability to essential molecules for cell survival, the liquefied core maximizes their diffusion through the entire 3D construct. Additionally, µPCL are loaded into the liquefied core to provide cell adhesion sites. Taking advantage of the liquefied core, microcapsules are dynamically cultured using spinner flasks, which enhance MSCs osteogenesis while better mimicking the environment of native tissues.[3] Microcapsules encapsulating only MSCs and ECs (CO microcapsules) or a tri-culture with macrophages (TRI microcapsules) were cultured up to 21 days in culture medium with (OSTEO medium) or without osteogenic differentiation factors (BASAL medium). The main goal is to promote a well-orchestrated cell-to-cell interaction enabling the evaluation of the bioperformance of macrophages toward bone tissue repair.

Experimental Methods

Alginate microgels are generated by electrohydrodynamic atomization (EHDA) technique (Figure 1-I). For that, under influence of electrical forces (10 kV), a liquid jet of alginate containing a dispersion of cells (5x10^6 cells/mL) and µPCL (30 mg/mL) breaks up into droplets. MSCs, ECs, and macrophages are isolated from the umbilical cord tissue and blood, respectively. After crosslinking in calcium chloride, microgels encapsulating cells and µPCL are obtained. Then, layer-by-layer is performed using poly(L-lysine), alginate, and chitosan as polyelectrolytes to produce the multilayered membrane surrounding the obtained microgels (Figure 1-II). The process is repeated until a 10-layered membrane is created. Ultimately, the core is liquefied by chelation with EDTA (Figure 1-III). Afterwards, liquefied microcapsules are cultured up to 21 days in basal or osteogenic differentiation media. Microcapsules without macrophages are used as control. The proposed capsules were tested under dynamic culture conditions, using a rotary cell culture system.

Results and Discussion

Microtissues were successfully obtained inside the compartmentalized and controlled environment of capsules with an appropriate diffusion of essential molecules for the long survival of the encapsulated cells (Figure 2-A). The metabolic activity was increased in all microcapsules during time. Notably, the osteogenic osteocalcin marker was only found in microcapsules encapsulating macrophages (Figure 2-B). Nodules-like structures were observed by scanning electron microscope (SEM) in CO and TRI microcapsules cultured in OSTEO medium. The correspondent energy dispersive spectroscopy (EDS) mapping evidenced a phosphorus and calcium enriched extracellular matrix (Figure 2-D). Additionally, microcapsules encapsulating macrophages released significantly more osteoprotegerin...
(OPG), osteopontin (OPN), and vascular endothelial growth factor (VEGF), comparing with the CO microcapsules condition (Figure 2-C and 2-E).

**Conclusion**

Overall, the study demonstrated that the presence of macrophages promoted a well-orchestrated cell-to-cell interaction inside the microcapsules, allowing to recreate the bone repair process within a controlled and self-regulated “microengineered niche”. Accordingly, we intend to use the proposed system as hybrid devices implantable by minimally invasive procedures for bone tissue engineering applications.

High-throughput Screening to Mimic Tunica Media Smooth Muscle Cells Alignment in Porous Blood Vessel Scaffold

Klaudia M. Jurczak1, Ruichen Zhang1, Richte Schuurmann2, Henri G. Leuvenink3, Jan L. Hillebrands4, Ruud Bank4, Jean-Paul P. de Vries5, Patrick van Rijn1

1 University of Groningen, Department of Biomedical Engineering, Groningen, NL; 2 University of Groningen, Faculty of Medical Sciences, Groningen, NL; 3 University of Groningen, Department of Cardiology / Thoracic Surgery, Groningen, NL; 4 University of Groningen, Department of Pathology and Medical Biology, Groningen, NL; 5 University of Groningen, Department of Surgery, Groningen, NL

Introduction
The development of functional blood vessel engineering has become an urgent need for the treatment of cardiovascular disease and blood vessel disorders, such as aortic aneurysm. The ideal vascular scaffold should resemble the 3D geometry of native blood vessel and reconstitute its three layers including tunica intima, tunica media and tunica adventitia (1). The secondary medial layer consists of circumferentially oriented smooth muscle cells (SMCs) which are particularly important for the contractile function of blood vessel. Reproducing the adequate cellular orientation and facilitating SMCs colonization to enable standardized studies in CVD research still remains a challenge. We are fabricating vascular scaffolds from poly(trimethylene carbonate) (PTMC), the material that is flexible, biodegradable and biocompatible (2). For directing smooth muscle orientation, we are investigating the biophysical factors such as anisotropic topography using in house high throughput screening platform (HTS). The technology enables to identify optimum material parameters in a single cell experiment at the same time evading adverse effects of cell-material interactions (3).

Experimental Methods
Porous structures should facilitate cell proliferation and nutrient flow, therefore the porosity in PTMC is prepared by the means of salt leaching. To promote continuously varying surface parameter, PTMC is imprinted from stretched and plasma oxidized molds as described previously (4). The response of SMCs from porcine origin is further investigated.

Results and Discussion
Porosity of PTMC is evaluated by micro computed tomography (micro-CT). As previously published the pore size in range of 50-100 um should facilitate vascular permeability and support flow of oxygen and nutrients (5). PTMC anisotropic topography gradients are characterized via atomic force microscopy (AFM). Measurements of created wrinkles are taken along the surface area covered by the prism mask during plasma oxidation process. The wrinkle size increases from the least exposed side (close side of the mask) to the most exposed side (open side of the mask).

Conclusion
Combination of porous PTMC material with highly efficient screening technology of topography gradients can be a crucial tool for organized cell alignment and controlled phenotype of SMCs in tunica media. Development of such tissue engineered vascular scaffolds can provide a real benefit in pre-clinical testing of aortic aneurysm and other cardiovascular diseases.

Introduction
The aim of this study was to increase the effectiveness of heart failure treatment, in particular to overcome the material and technological limitations of cardiac assist devices. The main medical problem of state-of-the-art cardiac assist devices is device-induced thrombus formation, resulting from insufficient blood flow dynamics in the blood pump rotor, due to the high limitations of conventional pump manufacturing processes: milling or casting.

Experimental Methods
Based on research and simulations, the stereolithography (SLA) method was selected as an incremental manufacturing technology for blood pump rotors with increased affinity with flowing blood and reduced risk of thrombus formation. Currently, the SLA method, which does not meet the necessary requirements for the manufacture of safe devices for blood contact, requires R&D work to achieve the product goals of the project, for which an international consortium has been organised in the areas of: (i) Photo-polymerizing resins: a novel polymer with thiol groups, UV-polymerized, biocompatible and mechanically stiffened by carbon nanotubes in the SLA process; (ii) SLA technology: advanced light beam steering process in SLA technology for a highly smooth surface as a condition for minimising thrombogenicity; (iii) Surface: haemocompatible thin films resistant to corrosion in a biological environment, applied homogeneously over the entire surface of the device in contact with blood, using a low-temperature ALD (atomic layer deposition) process. All biomaterial tests were performed under the same experimental conditions, as described in detail elsewhere. Blood was collected from the same donor, i.e. a healthy man taking no medications.

The blood was brought from the Center for Blood Donation and Blood Treatment immediately before the test, which took ~60 min. A vacuum collection system was used (BD Vacutainer Systems), observing the rules for testing platelets: lack of a tourniquet, using a 12 G needle, and rejection of the first blood tube. In total, 3 tubes of 4.5 mL blood were used for the experiment, containing sodium citrate (0.5 mL, 0.105 M, BD Vacutainer systems). Blood morphology was investigated using an automatic cell counter (Sysmex K-1000 cell counter; Sysmex Co.), calibrated before each experiment. The discs were subjected to a sterilization process using gas ethylene sterilization. The measurement of each material was made using a control, unmodified polyurethane disc (3 discs). In addition to the dynamic test, two blood samples were stored under static conditions: non-activated and activated by the addition of adenosine-di-phosphate (ADP, Sigma- Aldrich, final concentration 20 μM). The analysis of each surface was repeated at least three times.

Results and Discussion
Page 1775 of 2028
A controlled cellular response was achieved by inventing new photopolymer and application 3D additive manufacturing method. As a result, it was possible to control cell attachment in the scale corresponding to biological processes. The newly elaborated material ensured optimal flow of oxygen and nutrients within a biomaterial what was of a key importance for processes of adhesion and proliferation of cells. As a result an antiadhesive surfaces to blood were elaborated. This solution has its premise in the construction of pumps.

**Conclusion**

The above technologies will enable the achievement of the project objective in the form of biomimetic, dynamic rotor designs developed on the basis of numerical simulation studies and experimental research for modification of the implantable centrifugal pump for long-term left ventricular assist.

Electrospun gelatin-lysozyme nanofibrils based patches for myocardial regeneration

Introduction

According to the World Health Organization, cardiovascular diseases, remarkably myocardial infarction, are the leading cause of death in the modern world. Currently, the only form of treatment is heart transplantation. Therefore, it is urgent to develop alternative and efficient therapies for the treatment of myocardial infarction. For instance, tissue engineering that combines cells with biomaterials, has the therapeutic purpose of regenerating damaged myocardial tissue, inducing cell growth and differentiation, while the implanted biomaterial is slowly bioabsorbed.

The results already obtained in this domain demonstrate the potentialities of this strategy in myocardial regeneration, however the development of biomaterials with adequate properties is still one of the main limitations.

Protein nanofibrils are self-assembled, highly organized, bio-based nanostructures, forming peculiar nanofibrillar structures. As a result of their biological nature and unique properties, arising from their remarkable mechanical performance, thermal stability, insolubility in aqueous media, and the ability to be formed in vitro from any protein or peptide, the protein nanofibrils are already being exploited in various applications, including in the design of scaffolds for regenerative medicine. However, the use of protein nanofibrils for the fabrication of biomaterials for the regeneration of an infarcted myocardium is an almost untouched field. In this context, this work aimed to study the effect of the addition of lysozyme nanofibrils (LNFs) to gelatin electrospun patches for application in myocardial regeneration.

Experimental Methods

The produced electrospun nanocomposite patches, with different contents of LNFs (0, 5 and 10% w/w), were produced, crosslinked, and characterized in terms of physicochemical and biological properties. Namely, the morphology, mechanical performance, and the antioxidant activity of the electrospun patches were evaluated, as well as their bioabsorbability, cytotoxicity and cell adhesion in vitro. Furthermore, a poorly water-soluble drug, curcumin, was incorporated into the electrospun patches to evaluate its release from the different produced materials.

Results and Discussion

The addition of the LNFs into the gelatin electrospun patches promoted an improvement of the mechanical properties of the scaffolds (Figure 1A), their bioabsorbability (Figure 1B), their antioxidant activity (Figure 1C), and the drug release ratio. All other properties of interest for the described application were maintained, namely the electrospun fibers morphology and thickness (ranging from 1.43 to 1.79 µm), non-cytotoxicity, cell adhesion and proliferation of both fibroblasts and cardiomyoblasts.

Conclusion

Considering the described results, LNFs revealed to be interesting functional nanostructures for the use on the development of innovative biomaterials for the regeneration of an infarcted myocardium.

Introduction
Cardiovascular diseases are the main cause of death worldwide. The substitution of diseased small diameter vessels (< 6 mm) is challenging due to the lack of applicable autologous grafts or eligible synthetic graft materials. The target of creating a small diameter vascular graft (SDVG) which has adequate mechanical properties and satisfying patency rates remains unmet so far. In this study, the cytokine expression of different graft materials during healing was observed to identify mechanisms which might help to improve vascular graft materials in future.

Experimental Methods
Autologous aortic grafts, biodegradable electrospun thermoplastic polyurethane (TPU) grafts and expanded polytetrafluorethylene (ePTFE) conduits were implanted in an infrarenal aorta replacement model in male Sprague Dawley rats. Grafts were retrieved after one week. Proteins from the anastomoses regions were isolated and analyzed with a Proteome Profiler Rat XL cytokine array. Furthermore, cells from the perivascular adipose tissue (PVAT) were isolated and characterized via immunofluorescence and 3D culture assays.

Results and Discussion
The comparison of different graft materials revealed that ePTFE grafts induce a higher expression of all cytokines. Significant differences were seen in the expression of pro-inflammatory CCL3, ICAM-1 and VCAM-1, anti-inflammatory IL-1RA and IL-13 as well as cytokines regulating tissue hemostasis. Autologous implants and TPU express higher levels of regulatory and proliferation inducing proteins IGF-1 and Galectin-3 whereas significant elevation of pro-inflammatory cytokines was absent. WISP-1, a molecule involved in smooth muscle cell proliferation and vascular calcification was significantly higher expressed in TPU graft condition compared to the native control. The isolation of cells from PVAT of anastomosis regions shows heterogenous cell populations consisting of adipocytes, endothelial cells, fibroblasts and mesenchymal stem cells.

Conclusion
Our findings give first insights into the graft healing mechanisms of different conduit materials and the possible influence of PVAT on the healing process. The selection of additional time-points for analyses and more detailed investigation of signaling pathways will follow. The observed expression profiles may help to identify potential reasons for graft failure and to select new therapeutic targets for improved graft healing.
Development and characterisation of a novel anti-inflammatory coronary stent coating

Daniel Longhorn¹, Susan Currie², Christopher McCormick¹

¹ University of Strathclyde, Department of Biomedical Engineering, Glasgow, GB; ² University of Strathclyde, Strathclyde Institute of Pharmacy and Biomedical Science, Glasgow, GB

Introduction
Coronary stenting triggers a cascade of inflammatory responses, leading to neointimal formation. The drugs used in current drug eluting stents (DES) inhibit smooth muscle cell proliferation, a key component in this cascade. However, these drugs also inhibit endothelial cell proliferation, thereby delaying recovery of a function endothelium [1]. Research activity is therefore focussed on the use of alternative drugs that inhibit neointimal formation without exerting deleterious effects on endothelial cells. Sodium salicylate is a drug with well characterised anti-inflammatory and anti-thrombotic effects [2], a profile of activity that makes it a particularly promising candidate for the next generation of DES.

The drug release profile is critical to success of a DES. A range of polymers have been used to provide sustained release of drugs from existing DES platforms, although their use has also been implicated in thrombosis and significant opportunities to use alternative coating technologies optimise drug release kinetics remain [3]. Electropolymerisation is used to generate polypyrrole (PPy) coatings and this may be utilised to develop a reliable and tuneable method of fabricating DES coatings. This study investigated the use of electropolymerisation for the production of PPy-Salicylate coatings. Characterisation of their drug-eluting kinetics and in-vitro biological compatibility with endothelial cells has allowed a series of optimised coatings to be identified for further evaluation.

Experimental Methods
PPy coatings were generated on 316L Stainless Steel wires (ø=200 µm) from a 0.1M pyrrole and 0.1M sodium salicylate solution by potentiostatic (+1.1 and 1.3 V vs. Ag/AgCl reference electrode) and galvanostatic (0.1, 0.5 and 1 mA) electropolymerisation for 10 minutes. The electropolymerisation reaction was initially characterised by monitoring the current and voltage during generation. PPy coatings were imaged using scanning electron microscopy (SEM) (15 kV, 400 and 2000x magnification) to assess surface topography, and further characterised using electrical impedance spectroscopy (EIS) in Phosphate Buffered Saline (PBS) (5 mV, 1Hz-100kHz). Separately, PPy coated samples were incubated in PBS for up to 7 days at 37°C and salicylate elution was determined using UV-spectroscopy (298 nm).

HUVECs were cultured on 316L SS strips (30 x 5 mm) coated by potentiostatic electropolymerisation. After 24 and 48h, the number of viable cells on each sample surface was assessed using MTT assays and a standard curve of known cell densities. Fluorescence microscopy (acridine orange) was also used to confirm cell attachment.

Results and Discussion
Current and voltage vs. time profiles identified potentiostatic (at both +1.1 and 1.3 V) and galvanostatic (at 0.5 mA) electropolymerisation as suitable methods for reliable generation of PPy coatings, which SEM imaging confirmed to have characteristic cauliflower topography. The impedance of 316L SS wires was significantly reduced by the presence of the PPy coating (1.3V, potentiostatic) at low frequencies (<50 Hz).

The total salicylate eluted from the coatings varied depending on the electropolymerisation conditions used, with potentiostatic (1.1V: 149±30, vs. 1.3V: 265±26 mg) and galvanostatic (0.1mA: 46±4, vs. 0.5mA: 257±32, vs. 1mA: 696±16 mg) methods generating coatings with significantly different salicylate elution characteristics (p<0.05, n=3,
one-way ANOVA and post-hoc Tukey. Salicylate eluted rapidly from all PPy coating, with >80% elution achieved at 24 h with all coatings except 0.5 mA galvanostatic, which exhibited slower release kinetics (>80% at 48 h).

After 24 h, the number of viable endothelial cells on PPy samples was comparable to 316L SS controls (316L: 9889±294, vs. 1.1V: 9556±676, vs. 1.3V: 8778±1528; p>0.05, n=3). After 48 h, there was however a significant increase in the number of viable cells on 316L (1433±2296) compared with the coated samples (1.3V: 8556±509; p<0.05, n=3, two-way ANOVA with post-hoc Fisher’s LSD). Imaging of stained cells confirmed the attachment of cells on all surfaces.

**Conclusion**

The data demonstrates the potential utility of electropolymerisation as a method for reliably generating PPy coatings with uniform surface characteristics. PPy coated samples exhibited lower impedance with Warburg characteristics suggesting the electrochemical behaviour of PPy is strongly influenced by its increased surface area. The difference in the mass of incorporated salicylate between conditions provides the means of generating tuneable elution characteristics. It is shown that endothelial cells attach to PPy surfaces and remain viable for 24 h, although further work is needed to understand reduced viability observed at 48 h before progression to in vivo evaluation is warranted.

Hybrid inorganic-organic borosilicate materials produced by non-hydrolytic sol-gel for tissue engineering applications.

Soraia Coelho, José Carlos Almeida, Isabel Margarida M. Salvado, Maria Helena V. Fernandes

Universidade de Aveiro, CICECO, Aveiro, PT

Introduction

Hybrid organic-inorganic materials based in the polydimethylsiloxane – silica (PDMS-SiO$_2$) system are known to be of great interest due to their wide range of possible applications, namely as biomaterials, anti-corrosion, anti-fouling, or anti-reflective coatings [1]. Recently, boron containing PDMS-SiO$_2$ hybrids were developed for biomedical applications in tissue engineering [2]. The incorporation of therapeutic ions such as boron has been recognized as an interesting way to stimulate bone regeneration and angiogenesis [3,4]. Angiogenesis is a process that consists in the growth of new blood vessels that allow the transport and exchange of oxygen, nutrients, growth factors and cells. An alternative to the use of vascular growth factors is the adoption of these inorganic angiogenic ions, due to its low cost, high stability and potentially greater safety [4].

Experimental Methods

The present work proposes a non-hydrolytic sol-gel protocol for the preparation of PDMS-borosilicate films incorporating therapeutic ions.

Results and Discussion

The structures of the hybrid materials were analyzed by FTIR, $^1$H MAS (magical angle spinning), $^{29}$Si MAS, $^{29}$Si-$^1$H CP-MAS (cross-polarization magical angle spinning) and $^{11}$B HAHN-ECHO NMR and are here discussed aiming to make a comprehensive relationship between structural features and rate of ions release from the fabricated films.

Conclusion

With the kind support of Biomaterials Science
Understanding and characterizing the drug sorption to Polyvinyl chloride and Polyethylene materials

Meriem Sahnoune, Nicolas Tokhadze, Philip Chennell, Julien Devémy, Alain Dequidt, Florent Goujon, Valérie Sautou, Patrice Malfreyt

Université Clermont Auvergne, CNRS, Sigma Clermont, ICCF, Clermont-Ferrand, FR

Introduction

Plastic materials such as polyvinylchloride (PVC) and polyethylene (PE) are widely used in various medical devices (MD)\(^1\). Two phenomena known as leaching and sorption lead to adverse effects for the patient. The leaching is defined by the migration of the plasticizer into the drug solution whereas the sorption relates to the adsorption into the polymer matrix\(^2\). Sorption can affect the efficacy of a drug product via loss of the active pharmaceutical ingredient (API) which makes difficult the control of the delivered drug concentration. Drug-polymer materials interactions represents a major issue for the pharmaceutical industry in the delivery of drugs. The understanding of the sorption requires experiments with concentration measurements, but also a microscopic description with an energetic view. This dual microscopic/energy approach can be carried out using molecular simulation methods. We investigate the adsorption of two drugs (paracetamol and diazepam) on PE and PVC materials. The diazepam is known to interact with medical tubings whereas the paracetamol did not show significant adsorption. We model the adsorption process of the drug on materials by calculating the potential of mean force (PMF) along the direction normal to the surface.

Experimental Methods

Experimental sorption studies were conducted to evaluate paracetamol and diazepam concentration variation after a static contact with pure PE or pure PVC (without additives) tubes. Paracetamol and diazepam were respectively diluted to 10 µg/ml and 20 µg/ml with sterile water. Initial API concentration was quantified just after tubes filling (T0), at day 1 (T1), 2 (T2), 4 (T4), 7 (T7) and 14 (T14). Quantification was performed by liquid chromatography with UV detection.

The molecular dynamics simulations were performed with the LAMMPS package on a system composed of a polymeric surface (PE or PVC), a drug (paracetamol or diazepam) and 4000 water molecules. In semi-crystalline PE, both crystalline and amorphous states coexist. In order to simplify the simulation, the amorphous and crystalline states have been considered independently. Thermodynamic properties were calculated over a period of 40ns. The potential of mean force (PMF) was calculated by using an extended version (eABF) of the Adaptative Biasing Force (ABF) method. In this study, the PMF profile corresponds to the Gibbs free energy profile \(G(z)\) along the \(z\)-coordinate between the \(z\)-positions of the center of mass of the polymer surface and drug molecule.

Results and Discussion

The evolution over time of the concentration of both drugs in contact with PVC and PE tubings is shown in Figure 1. For both materials, the paracetamol solution remained stable for 14 days. Diazepam concentration was also stable for 14 days in contact with PVC tubing, but when in contact with PE tubing, a drug loss was observed from day 1 and fell to 56% of the initial concentration at 14 days.

Figures 2 shows the profiles of the Gibbs free energy as a function of the \(z\)-separation distance between the centers of mass of the surface and the drug molecules. In any case, the adsorption is thermodynamically favored: all the PMF curves show a negative minimum of \(\Delta G\) close to the surface. The values of the free energy minimum fall into a range of -35 to -15 kJ/mol. The Gibbs free energy of adsorption is minimum for the system diazepam/PE (around -33
kJ/mol). When comparing experimental results to simulations, it appears that no drug loss by sorption was observed when Gibbs free energy was comprised between 0 and -25 kJ/mol, which corresponds to a weak adsorption.

**Conclusion**

We have reported a combined approach of experiments and molecular simulations to characterize the sorption of paracetamol and diazepam to pure PVC and PE materials. The simulated Gibbs free energy of adsorption that are within the range of -35 to -15 kJ/mol establish a physical adsorption through van der Waals interactions. The most favorable adsorption is predicted with diazepam that adsorbs on PE. The experiments establish a drug loss of 56% as diazepam is in contact with PE tubings whereas no drug loss has been measured on PVC tubings and with paracetamol. This coupling between experiments and molecular simulation is able here to provide a threshold value of about -30 kJ/mol above which we did not detect any drug loss. This is an essential result that should enable molecular simulations to be used for the prediction of adsorption properties and further for the design of new polymeric surface with specific properties.

In this study, experiments and simulations have considered PVC materials without plasticizers. Yet, plasticized PVC medical tubings are widely used for the infusion of medications and the presence of plasticizer is also expected to increase adsorption mechanisms\(^3\). Future work will be to develop more realistic model plasticized PVC materials.

Peptide-modified nano-bioglass for growth factor immobilization and delivery

Matthias Schumacher, Pamela Habibovic, Sabine van Rijt
Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL

Introduction
Systemic administration of signalling molecules (growth factors, GF) that promote tissue regeneration bears a risk for off-site effects and, by applying supraphysiological concentrations, cancer development. Hence, targeted GF administration with the help of suitable carriers is considered a superior approach to stimulate different stages of tissue regeneration (precursor cell recruitment, angiogenesis, differentiation etc.) [1]. In the context of bone regeneration, a lack of appropriate carriers that allow delivery of GF with unimpaired biological activity and that co-act as potent bone graft substitutes limits clinical implementation of this therapeutic approach. (Porous) bioactive glasses (BGs) are promising carriers for GFs because of their high bone regeneration potential, degradability and bioactivity [2]. In most reported cases, GF immobilization on BGs is based on electrostatic interactions, which are poorly controllable in terms of adsorption and release kinetics. Moreover, such immobilization may deteriorate GF protein conformation and activity. To overcome these problems, we propose nano-sized BG particles decorated with peptides that bind a target GF with high specificity while maintaining its native state as a novel GF delivery system. In this pilot study, a peptide sequence derived from the transmembrane glycoprotein prominin-1 [3] which binds pro-angiogenic vascular endothelial growth factor (VEGF, [4]) with high selectivity and affinity was coupled to amine reactive groups grafted on nano-sized BG particles. The degree of functionalization, binding efficiency and selectivity for VEGF as well as biological activity of the bound GF were studied.

Experimental Methods
Nano-sized bioactive glass particles (nBG) were synthesized via the sol-gel route using tetraethyl-orthosilicate (TEOS), triethyl phosphate (TEP) and calcium nitrate (CN) as precursors. nBG composition was chosen to achieve high bioactivity based on earlier findings [5]. 3-Aminopropyltriethoxysilane (APTES) was used to surface-graft the obtained nBG with reactive amine groups. Subsequently, VEGF-binding peptide was covalently attached to the particle surface using EDC coupling chemistry. The materials were characterized using FTIR, TEM and elemental analysis (ICP-MS), and surface modification and peptide coupling were monitored using fluorescent labelling. VEGF binding to peptide-functionalized nBG particles from single- as well as multi-protein solutions (competitive binding) were quantified.

Results and Discussion
Amorphous nBG particles with a diameter around 188.3 ± 21.2 μm were obtained (Fig. 1a). The density of reactive amine groups on nBG surface could be controlled and did not alter particle morphology (Fig. 1a, b). Alike, the amount of peptide covalently coupled to the surface of nBG-NH₂ could be controlled, enabling us to design particles with different VEGF binding capacity (Fig. 1c). Binding experiments (Fig. 1d) revealed efficient immobilization of VEGF on the peptide-modified nBG particles that was stable over several washing steps. In contrast, the amount of non-specifically bound GF was significantly lower and was further reduced during repeated washing of the control group.

Conclusion
Taken together, the proposed peptide-functionalized nBG particles are a promising new strategy to immobilize and deliver biologically active GFs as exemplified here using the pro-angiogenic factor VEGF. Employing a highly biocompatible and bioactive synthetic bone graft material as carrier, this system could aid bone regeneration.

Optimized terpene-loaded poly(\(\varepsilon\)-caprolactone) (PCL)-based nanoparticles with anti-bacterial properties

Leonard I. Atanase\(^1\), Oana M. Daraba\(^1\), Daniela L. Ichim\(^1\), Delia M. Rata\(^1\), Anca N. Cadinoiu\(^1\), Christelle Delaite\(^2\)

\(^1\) Apollonia University, Biomaterials, Iasi, RO; \(^2\) University of Haute Alsace, LPIM, Mulhouse, FR

Introduction
Terpenes have attracted a great interest in the recent years as these bioactive compounds can be used for topical applications on skin. Moreover, they can increase the skin permeation and have anti-inflammatory, anti-bacterial and anti-tumoral properties. In order to avoid their chemical degradation and volatilization, terpenes can be encapsulated in polymeric nanocarriers which must have several features: high encapsulation and loading efficiencies, controlled drug release kinetics, a simple, reproducible, and scalable preparation process as well as biocompatibility and biodegradability. Polymeric nanoparticles (NPs) obtained from preformed polymers are among the much easiest to obtain nanocarriers.

The aim of the present study was to prepare a series of optimized terpene-loaded NPs based on poly(\(\varepsilon\)-caprolactone) (PCL) homopolymers. These NPs were obtained by a nanoemulsion/evaporation method in the presence of poly(vinyl acetate-co-vinyl alcohol) (PVA) copolymers as emulsion stabilizers. The schematic representation is provided in Fig 1:

Experimental Methods
The obtained NPs were characterized by physicochemical techniques, such as: DLS, electrophoresis, SEM, TEM, FTIR, DSC, and TGA. Moreover, the cellular viability of the optimized terpene-loaded NPs was assessed using human fibroblast cell lines. Finally, their anti-bacterial activity was compared on both positive and negative Gram bacteria strain lines.

Results and Discussion
The effect of several parameters, such as: the nature of the organic solvent, the molecular weight of PCL homopolymers, the concentration of the PCL in the organic solution, the concentration, hydrolysis degree and molar mass of the PVA stabilizers, the drug/polymer ratio. Two terpenes, camphor and thymol, were loaded in these NPs in order to compare their anti-bacterial activity.

As expected, the size of the NPs decreased by increasing the concentration of the PVA solution and with decreasing the ratio between organic and aqueous phase. The optimal sizes of the NPs, under 150 nm with low PDI, and a ZP value around \(-6\) mV were obtained in the presence of a 1 wt% solution PVA sample with a hydrolysis degree of 80%.

Conclusion
These drug-loaded NPs, with low PDI and sizes, were obtained by a simple and reproductible method and can be applied to several biomedical applications.

Introduction
Bone infection or osteomyelitis remains a burden as a clinical complication of orthopaedic surgeries [1]. New approaches that hold great promise to treat and prevent these infections, are well acknowledged controlled antimicrobial release systems. These may consist in biomaterials based on porous scaffolds, granting the administration of large antimicrobial concentrations locally, without the systemic toxicity and for extended time. Targeting bone tissue engineering, synthesized scaffolds have combined bioresorbable polymers as poly(DL-lactic acid) (PDLLA) with bioactive bioglasses, presenting biodegradability, biosafety and can grant appropriate microenvironment, structure and surface chemistry to hold osteogenic differentiation and cell growth for bone regeneration [2]. Since co-encapsulation of drugs aimed at commonly associated diseases provides an advantageous means for administration [3], this research work presents a novel strategy directed to the co-delivery of two antimicrobials at the infection site (one antifungal agent and one antibacterial agent), regarding osteomyelitis treatment.

Experimental Methods
PDLLA scaffolds were prepared by solvent casting / particulate leaching techniques and then functionalized with bioglass. The manufactured scaffolds were adsorbed simultaneously with 0.1 mg/mL of minocycline (MH), a tetracycline analogue that exhibits important antibiotic properties, and 0.1 mg/mL of voriconazole (Vor), a potent second generation triazole, fungistatic against Candida species, leading to its decreased formation and growth restraining. Produced scaffolds were physicochemically characterized by attenuated total reflectance (FT-IR/ATR), scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS). Adsorption efficiency (AE, \%) and drug loading efficiency (DL, \%) were also determined. In vitro release studies in Hepes 10 mM solution at pH 7.4 (37°C, 7 days) have been completed. Finally, the antimicrobial activity (against S. aureus and C. albicans) was also evaluated using the agar diffusion method.

Results and Discussion
FT-IR analysis revealed that MH or Vor inclusion did not change the scaffold composition, as the obtained spectra can be considered analogous. SEM assays showed a rough and porous surface in all samples, where bioglass or salt particles cannot be noticed. In vitro release studies suggest that both antimicrobials were adsorbed to the polymer, maintaining an expected release profile. At the same time, results point to better AE and DL related to Vor, than the ones observed with MH. Lastly, microbiological appraisal suggests that the scaffold combining both antimicrobials has activity aginst C. albicans for 48 h and additionally, proposes a synergistic activity within their association.

Conclusion
The scaffolds presented physicochemical and pharmaceutical characteristics applicable for controlled antimicrobial release systems, administrated locally. Furthermore, the scaffolds displayed antimicrobial activity against S. aureus and C. albicans and a synergistic activity within the association is proposed. These scaffolds emerge as a promising drug co-delivery system for local antimicrobial therapy in osteomyelitis.

Effect of Calcium Interaction and Mineralization in the Transfection Efficiency of Polyplexes for Gene Therapy

Teo Atz Dick¹, Hasan Uludağ¹²

¹ University of Alberta, Department of Chemical and Materials Engineering, Edmonton, CA; ² University of Alberta, Faculty of Pharmacy and Pharmaceutical Sciences, Edmonton, CA; ³ University of Alberta, Department of Biomedical Engineering, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada, Edmonton, CA

Introduction
Mineralization is traditionally used to coat materials with calcium phosphate or calcium carbonate layers for cell delivery applications. Particulate systems can be mineralized to increased robustness and release of cargo triggered by endosomal pH intra-cellularly[1]. In nature, the mineralization process seems to give viruses the ability to survive harsh conditions outside the body and infect a host more efficiently through airways [2]. These properties seem to be translatable to therapeutic applications in gene therapy using viral particles [3]. In non-viral gene therapy using polyplexes, reports have been limited to the achievement of improved and sustained transfection levels by modification of polyplex physical properties [4]. However, emerging literature showing that a simple calcium incubation process can achieve similar improvements in transfection efficiency challenges the usefulness of mineralization [5]. Considering that calcium interaction with organic matrices is an essential step for mineralization, from the current status of the literature, it is difficult to ascertain if mineralization is needed for improvement of transfection efficiency or if calcium incubation by itself is enough. To answer this question, we developed negatively charged poly(aspartic acid) coated polyplexes capable of undergoing mineralization and performed an analysis of particle size, binding efficiency, and surface charge at the various steps of the particle fabrication and mineralization process as well as transfection and uptake studies in MC3T3-E1 mouse osteoblastic cells using calcium incubated polyplexes as positive controls to the mineralized polyplexes.

Experimental Methods
The polyplexes were fabricated by incubation of pDNA and a lipid-modified low molecular weight PEI (1.2 KDa) followed by coating by poly(aspartic acid) in pure water. Polyplexes were incubated with CaCl₂ or mineralized with Na₃PO₄ or Na₂CO₃ at various concentrations, and calcium incubated samples were used as positive controls to mineralized samples with the same Ca content. Particle characterization was done using gel electrophoresis of freshly prepared samples and samples submitted to heparin-induced dissociation, assessment of zeta potential and hydrodynamic size, transmission and scanning electron microscopy, and x-ray diffraction for phase identification. In vitro transfection and uptake efficiency of the calcium incubated and mineralized polyplexes in preosteoblastic MC3T3-E1 cells was assessed using a Flow Cytometer and fluorescence microscopy.

Results and Discussion
Calcium incubation and mineralization both increased polyplex robustness; however, only mineralization completely inhibited dissociation induced by heparin. Untreated polyplexes showed highly negative ζ-potential. Calcium interaction with polyplexes was identified by an increase in ζ-potential to close to neutral values, and mineralization was identified by a decrease in ζ-potential. Hydrodynamic size analysis by dynamic light scattering revealed that calcium incubation and mineralization were important factors in increasing the size of the polyplexes. TEM images revealed that untreated polyplexes were well dispersed, and calcium incubation triggered a noticeable increase in particle size and aggregation. Mineralization resulted in a heterogeneous morphology characteristic of mineralized
particles. Both uptake and transfection efficiency using MC3T3-E1 cells were improved by mineralization and calcium incubation.

**Conclusion**

Both calcium incubation and mineralization improved transfection efficiency and uptake of polyplexes through size increase, improved pDNA binding, and adjustment of zeta potential to less-negative values. We believe that in applications involving mineralization of polyplexes, the effect of calcium incubation should be assessed through the use of appropriate controls to avoid misinterpretation of the cause-effect mechanism. With calcium incubation being a more time-efficient process, we find that mineralization might not be necessary if improved transfection efficiency in vitro is the only effect desired. Other potential properties acquired through mineralization that are reported for other particle systems still need to be studied for the specific case of polyplexes, such as improved physical protection of cargo and superior efficiency when particles are administered through airways.

Protamine nanoparticles: a new attractive gene-delivery system for glioblastoma treatment

Sheila B. Esteban¹, Sonia R. Trotiño¹, Ruman Rahman², Cameron Alexander³, Marcos G. Fuentes¹, Noemi Csaba¹

¹ University of Santiago de Compostela-CIMUS, Pharmacology, pharmacy and pharmaceutical technology, Santiago de Compostela, ES; ² University of Nottingham, Biodiscovery Institute-School of Medicine, Nottingham, GB; ³ University of Nottingham, Boots Science Building-School of Pharmacy, Nottingham, GB

Introduction
Glioblastoma (GBM) is one of the most aggressive brain tumors and is classified as grade IV of malignancy by the WHO. Standard-of-care treatment combines surgical resection, radiotherapy, and chemotherapy, but such interventions result in severe side-effects and only offer a median survival of 15 months from diagnosis (1). Among the current treatments, gene therapy has become an attractive alternative due to its capacity to target specific pathways within glioblastoma cells by the introduction of exogenous tumor suppressor sequences that are rendered therapeutically effective by using delivery systems (2). Polymeric nanoparticles (NPs) have been explored as a gene-delivery system for the treatment of glioblastoma due to their intrinsic ability to encapsulate and protect DNA and RNA, high biocompatibility, and delivery efficacy (3).

Experimental Methods
Polymeric NPs were formulated by the ionic-complexation method using the ratio 4:1 of protamine:dextran (4:1 Pr:Dx NPs). The physicochemical and structural properties of the nanosystem were studied by Photon Correlation Spectroscopy, Laser Doppler Anemometry, and Transmission Electron Microscopy. The long and short-term stability was examined for one month under storage conditions and for 4 hours in biological media at 37°C, respectively. Moreover, the association of nucleic acids was studied by agarose gel electrophoresis using an excess of heparin as ionic competitor. Cell-viability studies were initially optimized in U87MG monolayers and spheroids, followed by assessment in three primary patient-derived glioblastoma cell lines (GIN-8, GIN-28 and GCE-28). The 2D and 3D cellular uptake of 4:1 Pr:Dx NPs was studied using fluorescently labelled NPs by confocal microscopy and quantified by flow cytometry. Finally, the transfection efficiency was studied using different concentrations of a model plasmid encoding the enhanced Green Fluorescent and Luciferase Proteins (pEGFP-Luc), by flow cytometry and a Luciferase Reporter Gene assay, respectively.

Results and Discussion
The formulation consisted of a population of spherical NPs composed by protamine, a cationic cell-penetrating peptide with high capacity to condense DNA, combined with dextran, a natural anionic polysaccharide. These polymeric NPs had a size below 150 nm, positive surface charge and allowed the efficient encapsulation of different nucleic acids. In addition, the formulation presented a satisfactory physical and biological stability. Viability studies indicated low/non-toxicity in U87MG cells and spheroids, as well as, in glioblastoma patient-derived cell lines. Microscopy studies revealed an efficient internalization of 99% of the NPs in 2D and 3D glioblastoma models. Finally, the transfection assay showed an efficient capacity of the polymeric NPs to transfect glioma cells and spheroids for doses above 1 µg/well.

Conclusion
We have developed a formulation based on polymeric NPs with physicochemical properties suitable for the association and protection of different genetic cargos. Their low cellular toxicity, high internalization, and their...
Capacity to transfect different 2D and 3D glioblastoma models indicated that this formulation could be considered a promising gene nanocarrier for glioblastoma treatment by gene therapy.

Introduction
Infections of the bone, whether acute or chronic, as a result of hematogenous spread or as a postoperative complication (e.g. implant-associated infections) are difficult to treat even according to the current state of medicine. Systemic and local antibiotic therapy using implantable PMMA (polymethyl methacrylate) chains are as much part of the standard therapy in today's guideline recommendations as radical surgical debridement (1). While systemic pharmacotherapy is easy to implement, the low degree of efficacy in situ is repeatedly demonstrated with nevertheless already very high dose applications. In contrast, PMMA cements which are provided with antibiotics release larger concentrations of pharmaceuticals on site, but must eventually be removed in a second operation. Biodegradable carrier systems such as calcium phosphates could therefore offer a suitable alternative, as they have already proven their biomechanical stability in dentistry and surgery. It has also been demonstrated in previous work that microporous b-tricalcium phosphate (b-TCP) ceramics impregnated with antibiotics (rifampicin, daptomycin) could ensure a high local release.

In this work, we now aim to demonstrate that antibiotic-impregnated hydrogels loaded into b-TCP scaffolds can release pharmaceuticals over a period of several weeks while maintaining high concentrations. In addition, Bone Morphogenetic Protein 2 (BMP2) was added to the gels showing positive effects on both bone and wound healing.

Experimental Methods
To prepare the hydrogels low viscosity plasma sterilized alginates were added to aqua bidest in solution along with BMP2 and antibiotics (either daptomycin, clindamycin or rifampicin) and homogenized for at least 12 hours. The gels were then loaded into microporous b-TCP ceramics using a patented flow-through chamber (EU patent PCT/EP2014/001935) and a directed vacuum, followed by crosslinking by a calcium chloride solution. Release experiments were then performed in aqua bidest after 1, 2, 3, 6, 9, 14, 21 and 28 days. Subsequently, quantitative analyses of the released antibiotics were performed by HPLC (high performance liquid chromatography) or of the growth factors by ELISA. For statistical analysis, mean values and standard deviations were determined via sampling time point and an analysis of variance was collected using ANOVA.

Finally, biocompatibility was investigated both qualitatively and quantitatively in several in vitro cell culture experiments (live/dead, LDH and WST) using the cell culture line MG63, and antimicrobial efficacy was demonstrated in microbiological fouling tests.

Results and Discussion
So far, parts of the HPLC analysis on the release of clindamycin are available as interim results (up to day 14). After only one day, over 80% of the antibiotic had been released. By the third day of collection (day 3), 89.5% of clindamycin had passed into the medium. Nevertheless, the released concentrations of pharmaceuticals remained above the minimum inhibitory concentration (MIC) of 5ng/mL (at 1.32µg/mL) up to day 14, while the detection limit was 0.76µg/mL.

During the production of the various hydrogels, different viscosities between the individual antibiotics were noticed, which may also be reflected in the releases.

Riboflavin-SPIONs for enhanced cellular internalization in breast cancer cells

Wid Mekseriwattana\textsuperscript{1,2}, Anna Roig\textsuperscript{2}, Kanlaya P. Katewongsa\textsuperscript{1,3}

\textsuperscript{1} Mahidol University, School of Materials Science and Innovation, Faculty of Science, Bangkok, TH; \textsuperscript{2} Universitat Autònoma de Barcelona, Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Bellaterra, ES; \textsuperscript{3} Mahidol University, Department of Biochemistry, Faculty of Science, Bangkok, TH

Introduction
Female breast cancer is the most prevalent type of cancer worldwide, according to a report in 2020 \cite{1}. Different types of riboflavin (Rf)-associated proteins were found to be overexpressed in breast cancer patients \cite{2, 3}; thus, several research efforts use Rf-vitamin and its derivatives as directing ligands to target drug delivery nanoparticles to the cancer cells. Although positive results have been reported in nanoparticle delivery, the uses of riboflavin are limited by its hydrophobicity, resulting in complex synthesis routes and unfavorable stabilizing properties which are crucial for nanoparticle formulation. Therefore, this work aims to develop a Rf-based ligand for superparamagnetic iron oxide nanoparticles (SPIONs) by a simple synthesis to provide stability to the Rf-SPIONs and demonstrate enhanced cellular uptake of SPIONs in breast cancer cells.

Experimental Methods
The ligand was made through conjugation of Rf with citric acid, followed by coating on the SPIONs through complexation of the citrate moieties and the Fe atoms. The stability of the Rf-SPIONs was evaluated in terms of aqueous hydrodynamic diameter and zeta-potential, in comparison with uncoated- and citrate-coated SPIONs. MCF-7 breast cancer cell line was used as an \textit{in vitro} model for cellular uptake assessments. Biocompatibility of Rf-SPIONs was ensured by performing MTT cell viability assays. Nanoparticle cellular uptake for the different systems were observed by Prussian blue staining and subsequently quantified by flow cytometry.

Results and Discussion
With the citrate-Rf ligand, Rf-SPIONs showed a sub-200 nm hydrodynamic size with a narrow polydispersity index, significantly lower than for the uncoated SPIONs. The Rf-SPIONs showed no toxicity toward the cells when treated with concentrations up to 200 µg mL\textsuperscript{-1}. Prussian blue staining and flow cytometry both showed a superior cellular internalization behavior of the Rf-SPIONs. At 4 °C, cellular uptake of the Rf-SPIONs drastically dropped as a consequence of the inhibition of cellular activity, suggesting an active transport cellular internalization pathway. The tests were also performed in MCF-10A normal breast cell line, and no significant differences in cellular uptake were observed among the three SPION systems studied.

Conclusion
The citrate-Rf has proven to be a potent ligand to functionalize SPIONs and activate their cellular internalization in breast cancer cells and in the future, could be applied to other nanoparticle platforms.

Lab-on-chip for studying Shwachman-Diamond syndrome mechanisms

Nora Selicato1, Eleonora De Vitis2,4, Francesca Gervaso2, Alessandro Polini2, Valentino Beizzeri3, Marco Cipolli1

1 Azienda Ospedaliera Universitaria Integrata, Cystic Fibrosis Center of Verona, Verona, IT; 2 CNR Nanotec, Institute of Nanotechnology, Lecce, IT; 3 Azienda Ospedaliero Universitaria Ospedali Riuniti di Ancona, Cystic Fibrosis Center, Ancona, IT; 4 Università del Salento, Dipartimento di Matematica e Fisica E. de Giorgi, Lecce, IT

Introduction

Shwachman-Diamond syndrome (SDS) is a rare inherited multisystemic syndrome (worldwide affects almost 1/75,000 live births) characterized by bone marrow failure, exocrine pancreatic insufficiency, skeletal dysplasia and failure to thrive. Similarly to other bone marrow failure syndromes, SDS is associated with juvenile myelodysplastic syndrome and high risk of leukemic transformation [1]. SDS is mainly caused by mutations in the Shwachman-Bodian-Diamond Syndrome (SBDS) gene (located on chromosome 7q11.22) encoding a protein involved in ribosomal biogenesis. Interestingly, three genes have recently been associated with an SDS-like phenotype: elongation factor-like 1 (EFL1), signal recognition particle 54 (SRP54) and eukaryotic elongation initiation factor 6 (eIF6). All these genes are involved in ribosome biogenesis, strengthening the postulate that SDS is a ribosomopathy [2].

Currently, there is no cure for SDS. The treatment is based on managing the symptoms. In order to prevent malignant transformation, hematopoietic stem cell transplantation is the unique available option. Promising new therapies aiming to correct the genetic defect have been supposed. Since most patients with SDS present nonsense mutations in the SBDS gene, recently it has been proposed the drug repositioning of the small nonsense suppressor molecule, namely ataluren [PTC124; 3-(5-(2-fluorophenyl)-(1,2,4)oxadiazol- 3-yl)-benzoic acid]. This drug has been already approved by the European Medicines Agency for the treatment of Duchenne muscular dystrophy. In previous studies, ataluren restored significantly SBDS protein expression in bone marrow progenitor cells from patients with SDS, promoting myelodysplastic syndrome and high risk of leukemic transformation [1].

Neutrophil chemotaxis plays a crucial role in human immune system. Unfortunately, neutrophil and monocyte chemotaxis is impaired in SDS [4]. The chemotaxis defects of SDS have been previously studied with traditional cell migration assays, which cannot provide the temporal and spatial control of the chemical gradients, neither study the single cell behaviour [5].

Experimental Methods

Lab-on-chips are a new research platform for studying chemotaxis and chemokinesis able to overcome the limitations of traditional chemotaxis assays due the advantage of visualization, precise control of the chemical gradient and small consumption of reagents. In this study, we developed a lab-on-chip platform and evaluated ataluren potential in restoring chemotaxis using a microfluidic device. We fabricated a flow-free microfluidic device with three different perfusable compartments with distinct inlets and outlets, interconnected through a series of parallel microchannels that can be used to control cell migration and cell differentiation on chip. The platform was fabricated by SU-8-based multi-level photolithography and PDMS replica molding. Gradient profiles were previously evaluated to ensure an adequate time to perform the chemotaxis experiments and a preliminary cell line was used to set up the device for the purpose of this study.

Results and Discussion

Firstly, we utilized the device to confirm the impaired SDS neutrophil chemotaxis. Primary neutrophils were obtained from patients carrying the c.183-184TA> CT nonsense mutation. A precise number of cells was seeded in the lowest...
compartment and the SDS neutrophil migration was evaluated in the presence and absence of a defined concentration of chemoattractants injected in the upper compartment of the device. Brightfield time-lapse images of cell migration were captured for maximum 1 hour and the cell trajectories analysed using Manual Tracking plugin ImageJ. Then, the data were further analysed to obtain the trajectory plots and the main output parameters for chemotaxis (Forward Migration Index, center of mass, velocities, Rayleigh test, distances, directness). Lastly, we tested ataluren potential in restoring the chemotaxis, treating primary mononuclear cells (MNCs) obtained from fresh peripheral blood or bone marrow specimens from SDS patients. At the seeding time, ataluren was added in the culturing medium at different concentrations and spontaneous growth of granulocyte-monocyte colony formation (CFU-GM) was determined at different time point of incubation. Then, the chemotaxis assay was performed and analysed as previously indicated.

**Clobetasol-loaded chitosan patches for the treatment of autoimmune diseases affecting the oral mucosa**

**Elena Maria Varoni**¹,², Lina Altomare²,³, Marcello Manfredi⁴, Andrea Cochis⁴, Lorenzo Bonetti²,³, Lia Rimondini⁴

¹ University of Milan, Dipartimento di Scienze Biomediche, Chirurgiche ed Odontoiatriche, Milano, IT; ² National Interuniversity Consortium of Materials Science and Technology (INSTM), Firenze, IT; ³ Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering “G. Natta”, Milano, IT; ⁴ Università del Piemonte Orientale UPO, Department of Translational Medicine, Center for Translational Research on Autoimmune and Allergic Diseases CAAD, Novara, IT

**Introduction**

The standard care for managing immune-mediated and autoimmune diseases affecting the oral mucosa includes the use of topical steroid therapy¹,². Clobetasol propionate (CP) is one of the most potent corticosteroids (Europe: class IV), used only for dermatological application due to its high lipophilicity¹. CP application in the oral cavity is challenging due to the salivary flow and the muscular activity, which easily displace the drug³. So far, no commercial CP formulation is available for the delivery of CP to oral mucosa³. Hence, we developed an innovative bilayer chitosan (CS)-based muco-adhesive patch, via electrophoretic deposition (EPD), loaded with CP, holding a porous architecture and showing an excellent swelling rate after re-hydration⁴. Here, we investigated the same patches for CP release under conditions similar to salivary environment, while an ex vivo porcine model of oral mucosa⁵ was used to evaluate CP absorption throughout the epithelial layers as well as mucoadhesion.

**Experimental Methods**

- **EPD of bilayer CS-CP patches**: CP (1g/L) has been mixed together with CS (1g/L) in a 30% water + 70% ethanol bath (pH = 4.8). Titanium plates (Ti, grade 2) were used in an electrophoretic deposition bath where conditions have been optimized to obtain CS-CP patches: square waves (100-75 V / Dc = 0.17 t = 5 min). Deposited patches were standardized as 2x2 cm² squares, freeze-dried and finally re-equilibrated at room temperature. CS bilayer patches were obtained by a double step deposition: a first deposition starting from a solution containing only CS and, after drying, a second layer was deposited starting from a CS solution with or without CP, namely CS-CP and CS respectively.

- **Morphological surface analysis**: Surface and cross-section morphology was visually investigated by SEM imaging.

- **CP in vitro release**: CP concentration within CS patches was determined by liquid chromatography mass spectrometry (LC-MS). CP release was performed in a dissolution medium (0.5M phosphate buffer saline and 0.5% sodium dodecyl sulphate, pH 6.8) at 37 °C. Specimens were incubated in 1 ml of solution, and fixed vertically in 2 ml tubes in agitation (100 rpm, 37°C) thus allowing CP release from both sides of the specimen. The solution was then collected and analyzed by LC-MS using a mass spectrometer coupled with an UHPLC.

- **Ex vivo CP release**: Porcine oral mucosa was surgically resected, standardized into 2 cm side-5mm thickness squares and maintained in DMEM/F12 medium at 37°C. Patches were adjusted onto mucosa samples at the air-liquid interface and allowed to spontaneously release CP for 0.5, 3 and 6 hours. At each time-point mucosa samples were separated from patches, mechanically homogenized and the CP amount determined by LC-MS.

- **Ex vivo mucoadhesion**: A tack –test was performed using Anton Paar MCR302 rheometer. Porcine oral mucosa 10 mm side-5mm thickness squares were deeply washed with PBS and frozen. After being re-equilibrated at RT, the mucosa was to a glass substrate and to the probe of the rheometer. Wet patches (CS or CS-CP) were similarly attached on the fixed side. Mucosa and patches were placed in contact; 1N force was applied for 10 sec. Mucosa
was moved in the opposite direction at 50mm/min until detachment. Release pressure (S=F/surface) and muco-
adhesion work (Wad=area under the curve) were calculated.

Results and Discussion
- **Morphological surface analysis**: SEM images (Figure 1 A-D) showed patches with a homogeneous and defined porous structure.
- **CP in vitro release**: CP was loaded in the patches at a concentration of 3458.8 ± 952.2 ng/mL. The amount of drug released was about 1245.7 ± 889.6 ng/mL/patch, as achieved after 40 min. Figure 2 A-B summarizes the release profile of CP from CS-CP patches.
- **CP ex vivo release**: After 6 hours ≈50% of the loaded CP was released in the tissue thus achieving an estimated drug amount of 1392.2 ± 708.3 ng/mL/patch. (Figure 2 C-D)
- **Ex vivo mucoadhesion**: No significant differences were observed between CS and CS-CP for both release pressure (557 ± 213 Pa and 448 ± 8 Pa, respectively) and Wad (745 ± 126 Pa*mm and 699 ± 128, respectively). The presence of the drug does not affect the mucoadhesive behavior of chitosan.

Conclusion
Bilayer CS-based patches can be successfully loaded using a highly lipophilic drug as CP, thus representing a promising drug delivery system for the oral mucosa. The CP drug release during time under in vitro condition similar to saliva is confirmed. The ex vivo porcine model of oral mucosa showed encouraging data about topical absorption and mucoadhesion.
Figure 2.
Clobetasol release and absorption in vitro (A-B) and in ex-vivo oral mucosa porcine model (C-D).

A Nanocomposite Coating for Implant-Associated Local Drug Delivery from Neuronal Electrodes: Nanoporous Silica Nanoparticles Embedded in Nanoporous Platinum

Mosaieb Habib1,3, Tim-Joshua Strauß1, Jennifer Harre2,3, Kim D. Kreisköther1, Saskia Zailskas1, Arne Schierz1,3, Hendrik A. Schulze1, Dawid P. Warwas1, Mandy Jahns1, Hans-Christoph Schwarz1, Thomas Lenarz2,3, Athanasia Warnecke2,3, Peter Behrens1,3

1 Leibniz University Hannover, Institute of Inorganic Chemistry, Hannover, DE; 2 Hannover Medical School, Department of Otorhinolaryngology, Hannover, DE; 3 Cluster of Excellence Hearing4all, Hannover, DE

Introduction
According to the WHO, 1 in 5 people worldwide live with hearing loss.[1] One type of hearing loss is sensorineural hearing loss, which is present in about 95% of deaf people. This condition results from damage to or loss of the actual sensory cells in the inner ear, the hair cells. The nerve cells, the spiral ganglia, are often still present but damaged. The cochlear implant, as an electronic stimulation prosthesis, can be used to restore hearing. Due to the previous disease as well as to the insertion trauma the biological balance in the inner ear is disturbed and the spiral ganglion neurons degenerate. With the help of neuroprotective substances, neuronal growth factors, anti-inflammatory drugs or antibiotics it is possible to restore the balance in the inner ear, to stabilize the spiral ganglion neurons and to furthermore induce the outgrowth of dendrites from these cells.[2] For optimal application, these drugs should be released locally, i.e. employing an implant-associated local drug delivery system. Due to the inertness of the materials from which the cochlea electrode is manufactured - platinum and silicone - the construction of such a system is not trivial.

Here, we present a novel nanocomposite material, composed of nanoporous platinum (NPPt) and nanoporous silica nanoparticles (NPSNPs) as a novel implant-associated local drug delivery system which is generated as a coating on the surface of the CI electrode.[3] NPPt exhibits high conductivity and favourable electrochemical properties. NPSNPs which are embodied in the pore system of the platinum offer a high specific surface area, large permanent porosity and a high versatility with regard to easily adjustable surface properties in order to accomplish a high drug loading.[4,5]

Experimental Methods
For the generation of the NPSNP@NPPt material on the surface of the electrode contacts, a hard template approach was used utilizing silica-polystyrene core-shell nanoparticles as template particles. Platinum was deposited electrolytically between the particles and the polystyrene was removed via extraction. The composite coating was characterized by means of scanning electron microscopy (SEM), krypton physisorption measurements, cyclic voltammetry and electrochemical impedance spectroscopy. Release experiments were performed with the dye methylene blue. Cell culture investigations with fibroblasts and spiral ganglion cells were conducted to investigate the biocompatibility of the novel material.

Results and Discussion
SEM investigations show the successful embedding of the NPSNPs in the pores of the NPPt (figure 1). The composite material exhibits good electrochemical properties and enhanced surface area due to the nanoporous silica nanoparticles. The release experiments indicate a higher loading and release of methylene blue. Cell culture experiments of the new material show good cytocompatibility.

Conclusion
The novel nanocomposite material combines the favourable properties of both nanoporous platinum and nanoporous silica nanoparticles, specifically the excellent electrochemical behaviour of NPPt and the high specific surface area, large pore volume and amenability to surface modifications of the NPSNPs. Cell culture experiments of the new material show high biocompatibility.

Introduction
In the past few decades synthetic polymers that degrade under physiological conditions (i.e., biodegradable polymers) have become increasingly common in medical and pharmaceutical applications. Especially, in the case of particulate drug formulations (such as nano- or micro-particles) an increasing number of polymeric materials, and especially polyesters, have been introduced and implemented for drug delivery. Among them, the preparation of long-acting injectable (LAI) formulations is probably the most intensively studied application for such polyester-based systems.

The present study evaluates the use of newly synthesized poly(l-lactic acid)-co-poly(butylene adipate) (PLA/PBAd) block copolymers as microcarriers for the preparation of drug-loaded long acting injectable (LAI) formulations. Aripiprazole (ARI), a second-generation antipsychotic drug, was used as a model drug.

Experimental Methods
PBAd and PLLA/PBAd, corresponding to a final copolymer weight ratio of 95/5, 90/10, 75/25 and 50/50 w/w PLA to PBAd, copolymers were prepared. PBAd was synthesized via a typical two-stage esterification and polycondensation of adipic acid and 1,4-butanediol in a 1/1.1 molar ratio, in the presence of catalyst tetrabutyl titanate. PLLA/PBAd copolymers were afterwards prepared via ring opening polymerization of L-lactide using Tin(II) 2-ethylhexanoate (TEH) catalyst. Aripiprazole (ARI) MPs were finally fabricated using PLA and PBAd polymers, as well as their copolymers via an emulsification/solvent evaporation method.

Results and Discussion
The prepared PLA/PBAd block copolymers were thoroughly characterized so as to evaluate their use as matrix/carriers for the preparation of ARI long-acting injectables depot delivery systems. FT-IR spectroscopy and XRD patterns were used to confirm their successful synthesis and their crystalline structure, respectively. FT-IR was also used to evaluate the molecular interactions among the copolymers. Their thermal properties were assessed by DSC, whereas monthly degradation tests exhibited slow polymer erosion, a key factor for slow drug-release (Fig.1). Cytotoxicity studies, both in vitro and in cell cultures, confirmed their good biocompatibility and low toxicity.

Regarding the fabricated microparticles, SEM images showed the formation of well-shaped spherical MPs, mostly in the range 15-60 μm, with smooth exterior surface and no particle’s agglomeration (Fig. 2), while DSC and pXRD data revealed that the presence of PBAd in the copolymers favors the amorphization of ARI. The effect of the newly synthesized block copolymers on the in vitro dissolution characteristics of ARI were finally evaluated. Results showed
that the prepared MPs followed a biphasic release profile in all cases, and highly tunable extended-release profiles for the API, which may be controlled for up to 30 days.

Conclusion

In the present study PLA/PBA-d-based ARI-loaded LAI MPs were successfully prepared for the first time. Results regarding the highly tunable enzymatic hydrolysis profile and the low cytotoxicity of the new copolymers, amplified the previously made suggestions that these new copolymers can be considered as a quite promising candidate for the preparation of drug sustained release formulations.

Determination of salicylic acid release profile from polymeric nanocarriers

Małgorzata Miastkowska, Katarzyna Bialik-Wąs

Cracow University of Technology, Department of Chemical Engineering and Technology, Kraków, PL

Introduction
In the preparation of controlled delivery system of active substance, the selection of an appropriate drug carrier is the most important. Currently, it can be used synthetic and natural biodegradable polymers, which occur in the nanometric scale. Moreover, polymeric materials which react to specific external factors, such as: temperature, pH, ionic strength, electric or magnetic field, light, and other chemical and biological stimuli, are particularly interesting. Due to they can be used in different area of medicine and pharmacy [1-4].

Experimental Methods
In this studies pH sensitive (poly(acrylic acid-co-methyl methacrylate)) and temperature sensitive (N-isopropylacrylamide) polymeric nanocarriers were obtained by radical polymerization and the initiator of the reaction was ammonium persulfate (APS), while poly(ethylene glycol) diacrylate (PEGDA, Mn = 575 g/mol) or N, N'-methylenebisacrylamide were used as the crosslinking agent, respectively. After that, the encapsulation of the model active substance – salicylic acid, was carried out. The salicylic acid belongs to nonsteroidal anti-inflammatory drugs with antiseptic and analgesic properties. After, the encapsulation efficiency was assessed and the average particle size of the carrier – drug system was determined. In addition, various studies were carried out using the following research techniques: SEM, DLS and FT-IR, which allowed to analyze both the carrier and the carrier-drug system. Finally, the release of drug (salicylic acid) was conducted using USP4 method (DZF II Flow-Through System, Erweka GmbH, Langen, Germany). The equipment incorporated seven in-line flow-through diffusion cells. The release study of salicylic acid was carried out using a regenerated cellulose membrane. The assays were performed in buffer solution at pH 7.4, at 37°C. The released concentration of salicylic acid in the receptor solution was analyzed by means of UV-Vis spectroscopy (Perkin Elmer Company), at the wavelength of 300 nm.

Results and Discussion
On the basis of obtained DLS histograms, the average size of the thermosensitive carriers was about 118 nm and for pH – sensitive was below 500 nm. The encapsulation was in the range of 70-80%. The chemical structure both carriers and carrier-drug systems was confirmed based on FT-IR spectra and it exhibited the hydrogen interaction between components. Additionally, SEM analysis showed that the polymeric carriers are in the spherical form as well as cylindrical and after the encapsulation the surface is more irregular.

The release profile of salicylic acid form pH and T-sensitive polymeric nanocarriers is shown at figure 1 and 2. In the case of salicylic acid, we observe pulsatile release from both carriers (Fig. 1 and 2). The significant difference is that in the case of a pH-sensitive carrier, the release takes place after a lag time of 5 h, while in the case of a thermally-sensitive carrier, we still observe the effect of rapid release, i.e. quick release caused by a weak carrier-drug bond [5].

Conclusion
This part of research constitutes the basic system of drug – thermo/pH-sensitive carrier for further research on the bio-hybrid hydrogel materials for the treatment of Psoriasis. In the next stage of studies, it is necessary to introduce a nanocarrier to hydrogel matrix, which will reduce the "burst effect" and result in prolonged drug release.

**Implementing RNAi Therapy Targeting FLT3-ITD Mutation in Acute Myeloid Leukemia (AML)**

**Aysha Ansari, Remant Kc, Hasan Uludag**

*University of Alberta, Edmonton, CA*

**Introduction**

Acute myeloid leukemia (AML) is a highly heterogeneous disease with considerable diversity in molecular pathogenesis and clinical outcomes. Crosstalk between different genetic pathways adds to the complexity of AML pathogenesis as well as treatment [1]. Almost 25% of newly diagnosed AML patients display an internal tandem duplication (ITD) in the *fms-like tyrosine kinase 3* (*FLT3*) gene. The FLT3-ITD mutation is an early driver of leukemogenesis and its presence is accompanied by a high leukemic burden and poor prognosis [2]. Although both multi-targeted and FLT3 specific tyrosine kinase inhibitors (TKIs) are being utilized for clinical therapy, drug resistance and high relapse rates are challenges that still need to be tackled [3]. RNA interference (RNAi), mediated by short interfering RNA (siRNA) presents a novel therapeutic modality with the potential of personalization due to its sequence-driven mechanism of action. The success of RNAi therapy to a great extent is dictated by the siRNA delivery vehicle employed. This study explored the use of lipid-substituted low molecular weight polyethyleneimine (lipopolymer) for delivering FLT3 siRNA in FLT3-ITD positive AML cells.

**Experimental Methods**

MV4;11 cells were utilized as an in vitro FLT3-ITD positive AML model for all studies. Low molecular weight (1.2 and 2 kDa) polyethyleneimine (PEI) polymers were modified with aliphatic lipids to yield lipopolymers which self-assembled into nanocomplexes with siRNA. Three siRNAs targeting different regions of the *FLT3* gene (FLT3 siRNA1, FLT3 siRNA2, and FLT3 siRNA3) and scrambled negative control siRNA (NC siRNA) were employed. Cell viability was assessed by the MTT assay. Cell proliferation studies were executed by performing cell counts (with trypan blue) daily over four days after treatment to generate the cell growth curves. RT-qPCR was conducted to quantify relative mRNA transcript levels and FLT3 protein levels were determined by flow cytometry through immunostaining. The percentage of cells undergoing apoptosis were evaluated by FITC-Annexin V/propidium iodide (PI) staining. The colony forming cell (CFC) assay was performed to determine effectiveness of FLT3 silencing in eliminating leukemia cells. Results are reported as mean ± standard deviation of three independent experiments and analyzed for statistical significance by Student’s two-tailed t-test (assuming unequal variance).

**Results and Discussion**

Treatment with lipopolymer/FLT3 siRNA nanocomplexes resulted in significant reduction in cell viability. Quantitative analysis revealed downregulation of *FLT3* gene transcript and FLT3 protein levels after treatment. This decrease in FLT3 mRNA and protein levels was manifested as a marked decline in cell proliferation rates (Figure 1) as well as induction of apoptosis, with a significant increase in percentage of cells in the late apoptosis stage. Furthermore, a notable drop in the ability to form colonies in methylcellulose post FLT3 silencing was observed. Combining the lipopolymer/FLT3 siRNA nanocomplexes treatment with current chemotherapy, specifically daunorubicin and midostaurin, showed enhancement of apoptosis as well as further depletion in AML stem cell burden through reduced colony formation ability.

**Conclusion**

The biological response to the decrease in *FLT3* gene and protein levels was seen in the significantly reduced cell numbers after treatment as well as increase in percentage of cells undergoing apoptosis. The decrease in the ability to form colonies post FLT3 silencing demonstrates the potential of RNAi by FLT3 siRNA to curtail the self-renewal ability.
capacity of AML progenitor cells. Furthermore, combining the RNAi approach with current chemotherapy showed potentiation of anti-leukemic activity. RNAi implemented with lipopolymer nanocomplexes, thus, bears promising potential for AML molecular therapy as well as prospectively serve as an addition to the treatment modalities available to target the heterogeneity prevalent in AML.

Pyridinium-decorated PVC surfaces for the prevention of ventilator-associated pneumonia

Matthew P. Wylie, Nicola J. Irwin, Louise Carson, David S. Jones, Colin P. McCoy

Queen's University Belfast, School of Pharmacy, Belfast, GB

Introduction
Ventilator-associated pneumonia (VAP) is the most common hospital-acquired infection in intensive care units and is associated with a significant risk of patient mortality \(^1\). Endotracheal tubes (ETT) are crucial in facilitating mechanical ventilation, but a significant drawback of these devices is their role in the development of VAP with bacteria capable of developing biofilms on ETT surfaces which can be displaced into the deep lung by air turbulence allowing the development of pneumonia. The use of antimicrobial-eluting surfaces to prevent VAP are often unsuccessful and encourage the development of antibiotic resistance as well as the risk of downstream toxicity \(^2\).

Non-leaching, durable antimicrobial surfaces are an attractive solution to medical device-related infection as they can avoid bacterial exposure to sub-lethal concentrations of antimicrobials. Quaternary ammonium compounds (QACs) are well described broad-spectrum antimicrobials which can be chemically modified without detriment to their activity. Modification of QACs with a thiol group can facilitate their permanent attachment to PVC via nucleophilic substitution to produce a long-lasting antibacterial surface which can be directly applied to PVC endotracheal tubes.

Experimental Methods
PVC was modified with 4-mercaptopyridine in a DMSO:H\(_2\)O cosolvent system and subsequently quaternised with haloalkanes to produce QAC-decorated surfaces. FTIR-ATR was used to confirm and quantify the attachment of 4-mercaptopyridine to PVC. QAC-surfaces were characterised using water contact angle analysis, thermal analysis, tensile strength and QAC leaching studies. The ability to prevent protein adherence was assessed using bovine serum albumin. Antimicrobial performance against methicillin-resistant Staphylococcus aureus (ATCC 33593), Pseudomonas aeruginosa (LMG679) was evaluated using anti-adherence assays, disk diffusion assays and fluorescent staining of biofilms.

Results and Discussion
FTIR-ATR analysis confirmed the covalent attachment of 4-mercaptopyridine to PVC with an average graft density of \(\sim 18\) µg cm\(^{-2}\). Attachment of a pyridine ring was confirmed by the appearance of a strong peak at 1574 cm\(^{-1}\). Subsequent quaternisation of PVC-pyridine surfaces with bromoalkanes was confirmed with FTIR-analysis by the loss of the peak at 1575 cm\(^{-1}\) and the emergence of a new peak at 1626 cm\(^{-1}\) as shown in Figure 1. Covalent bonding of QAC structures led to increased hydrophobicity of PVC surfaces from 75° for unmodified PVC to 85-89° for modified surfaces. A decrease in thermal stability of modified PVC films was observed but all QAC-films were thermally stable to at least 160°C confirming their compatibility with standard heat sterilisation techniques. Leaching studies over 14 days detected no release of pyridinium salts demonstrating the stability of their covalent attachment to PVC.

Reductions in bacterial adherence to PVC modified with QACs compared to control were observed as shown in Figure 2. Surfaces displayed significant inhibition of S. aureus adherence compared to P. aeruginosa with maximum reductions of 99.4% and 75.5%, respectively after exposure to \(10^6\) CFU/mL for 24 h. These initial results demonstrate the potential of covalent attachment of cationic moieties to PVC as a preventative method against VAP development. The reduced efficacy against Gram negative bacteria is likely caused by differences in the ability of tethered pyridinium structures to effectively disrupt the bacterial cell membranes of Gram positive and Gram negative bacteria.
Further studies will aim to optimise the performance against Gram negative bacterial biofilms through introduction of more complex cationic structures on the PVC surface.

**Conclusion**

QAC-tethered PVC surfaces display broad-spectrum resistance to biofilm formation. The surface modification technique can be directly applied to PVC device surfaces without adversely affecting bulk thermomechanical properties and could be useful for the prevention of medical device-releated infections, such as VAP. Further studies on biocompatibility will be performed to fully determine their applicability to VAP prevention.

Nanofibers functionalized with lignocellulosic-based nanoparticles to fight prevalent pathogens colonizing diabetic foot ulcers

Joana Domingues1,2, Maria O. Pereira2, Helena P. Felgueiras1, Joana C. Antunes1

1 University of Minho, Centre for Textile Science and Technology (2C2T), University of Minho, Campus de Azurém 4800-058 Guimarães, Portugal, Guimarães, PT; 2 University of Minho, Centre of Biological Engineering (CEB), University of Minho, Campus de Gualtar, 4710-057 Braga, Portugal., Braga, PT

Introduction
Non-healing diabetic foot ulcers (DFUs) are a common and costly complication of diabetes, leading to high limb amputation prevalence worldwide. Infection hinders wound healing initiation, particularly in severe and refractory cases, therefore effective solutions are greatly needed. Persistent pathogens such as Staphylococcus aureus and Pseudomonas aeruginosa are the main microbial inhabitants of infected DFUs, often gaining antimicrobial resistance to treatment [1]. Nanoparticle (NP)-mediated therapies may overcome this problem, as they are able to carry and protect loads from biodegradation, be internalized by the cell, and release the load(s) in a controlled manner [2,3]. As payloads, plant-derived essential oils (EOs) exert quick and strong bactericidal action. To achieve a more localized and sustained delivery of EOs, NPs can also be incorporated onto nanofibrous structures to act as wound dressings, topically controlling infections and accelerating wound healing. Hence, this work proposes EO-encapsulation into versatile and easily scaled-up polyelectrolyte complexed (PEC) NPs, produced from natural, renewable, and bactericidal polymers [quaternized cellulose (QC) and carboxymethyl lignin (CML)] and their incorporation onto electrospun nanofibrous mats, for effective treatment of infected chronic wounds such as DFUs.

Experimental Methods
The antimicrobial activity of laurel, oregano and dill EOs was screened for the first time against reference strains of S. aureus and P. aeruginosa, by minimum inhibitory concentration (MIC), following the broth microdilution method, and time-kill kinetics [1,4]. Glycidyltrimethylammonium chloride was added to microcrystalline cellulose to obtain QC. CML was obtained through reaction with monochloroacetic acid to softwood kraft lignin and served as anionic counterpart. EOs were added to the anionic polymer before complexation, then added to polycation and ultrasonicated to form EO-loaded QC/CML PEC NPs. Dialysis and condensation purified NP dispersions, and the release profile of loaded EOs was monitored by UV-Visible spectroscopy (UV-Vis). NPs were characterized through dynamic and electrophoretic light scattering (DLS and ELS), and transmission electron microscopy (TEM). Antimicrobial activity of loaded PEC NPs was confirmed through the determination of agar diffusion and time-kill kinetics assays, against S. aureus (ATCC 6538) and P. aeruginosa (ATCC 25853) [1,5]. Free EOs, polymer derivatives and unloaded PECs were also examined (controls). Polyvinyl alcohol (PVA) and polycaprolactone (PCL) solutions were prepared individually in acetic acid/chloroform and dimethylformamide (DMF), respectively, and blended at 3:1 ratio. These polymeric solutions were then processed by electrospinning at 21 cm distance of collector, using 18G needles, at potential 15-30 kV, and 0.4-3.0 mL/h of feeding rate. PVA/PCL electrospun mats were characterized by scanning electron microscopy (SEM), and Fourier-transform infrared spectroscopy (FTIR). Mats were loaded with EO-PEC NPs at 2x and 5xMIC for 72h, and the presence of the NPs was confirmed along the mats trough UV-Vis and SEM/TEM. EOs release profile in simulated body fluid was also monitored via UV-Vis, up to 24h. Thermal behavior of loaded mats was analyzed through thermogravimetry (TGA) and differential scanning calorimetry (DSC) [1,4]. The antimicrobial activity of EO-PEC NPs-loaded mats was tested by agar-well diffusion assay (halo formations) and time-kill kinetics studies up to 24 h of culture [4].

Results and Discussion
Page 1817 of 2028
PEC NPs nano-scaled size, narrow polydispersity index and positive zeta potential were verified by DLS and ELS, with round shaped morphology confirmed through TEM. EO encapsulation efficiency and loading content, NP stability (after freeze-drying), and load release were monitored by UV-Vis, DLS and ELS. The antimicrobial activity of EO-loaded PEC NPs was confirmed through time-kill kinetics and agar-well diffusion assays against *S. aureus* and *P. aeruginosa*. Electrospinning conditions and solvent concentrations were optimized to obtain uniform, continuous, bead-free nanofibers, with a flexible structure. The presence of the polymers in the produced electrospun mats was confirmed by FTIR [1,4]. Also, bright field and SEM were used to attest the uniformity of a nanofibrous polymeric structure. The presence of PEC NPs was verified along the mats through SEM/TEM. The sustained and controlled release of the entrapped EOs was also established in physiological media. TGA and DSC data attested the thermal stability of the loaded mats [1,4]. EO-loaded PEC NPs nanofibers showed promising antimicrobial activity against the aforementioned bacterial strains, but with less impact as expected since access to the wound is limited by nanofibers.

**Conclusion**

Preliminary data pointed out the potential of EO-loaded PEC NP-containing nanofibers to work as an alternative wound dressing to fight some of the pathogens colonizing DFUs.

Use of piezoelectric Poly-L-lactic acid (PLLA) film to fight bacteria growth

Lea Gazvoda (Udovč)¹², Matjaž Spreitzer¹, Marija Vukomanović¹

¹ Jožef Stefan Institute, Advanced materials Department, Ljubljana, SI; ² Jožef Stefan International Postgraduate School, Ljubljana, SI; ³ Jožef Stefan International Postgraduate School/ Jožef Stefan Institute, Advanced materials department, Ljubljana, SI

Introduction

Bacteria developing resistance to antibiotics motivate the research into finding new approaches to fight against it. One alternative method is to exploit piezoelectric property of soft polymer film, which is generally directed towards the wound healing process and cell stimulation growth. The need for electrostimulation of the wounded tissue also brings the possibility of infection when implants are inserted. It is important to access the issue of bacteria present, therefore determining the effect that electrostimulation can provide on present bacteria.

Our group is preparing biodegradable piezoelectric PLLA film, which could enhance the healing of the wound and at the same time prevent bacteria growth. A simple method like “template wetting” can be used to prepare nano-texture polymer films with stretched and crystalline nanotubes [1], which is a requirement for a polymer to exhibit piezoelectricity [2], with improved cell adhesion when compared to smooth films.

Experimental Methods

Anodised aluminium oxide plate (AAO) with well-determined nano-sized pores is used as a template, in which polymer is imprinted from the melt state. Collected nano-texture film is amorphous (no-piezoelectric) and is afterward annealed to crystalize and express piezoelectric properties.

Antibacterial test was performed in saline solution with bacteria and nano-texture film (crystalline and amorphous) in contact for 24h. Dilutions were transferred on agar plate for colony counting to compare bacterial survival with or without US stimulation (30 min at start).

Results and Discussion

Cellular weight can activate piezoelectric properties on nano-texture film [3], however to increase electric stimulation, US was used to enhance piezoelectricity of the film. Different behaviours were observed, depending on the bacteria strain used. We observed a high antibacterial effect (6 log reduction) with E. coli bacteria when in contact with piezoelectric nano-texture films when piezoelectricity was activated using US. Smaller but significant effect was observed for S. epidermidis, where 3 log reduction was confirmed. However, with one important difference, only when no US was used on piezoelectric nano-texture films, the drop in bacteria count was evident. This also suggests increased bacteria growth for S. epidermidis when US is used (higher electric stimulation), therefore some undamaged bacteria were observed with SEM. When bacteria were put into the growth medium after the test, a delay in bacteria growth was evident, which is in agreement with CFU count results.

Conclusion

By exploiting the piezoelectric properties, a charge on the surface is generated, which plays a key role in the healing process of injured tissues and also influences the bacteria growth. Therefore, we expect that prepared nano-textured PLLA films are piezoelectric and can stimulate human cell growth while providing protection against bacteria.

**Introduction**

Surface modification of Ti6Al4V (ASTM grade 5), through the fabrication of vertically oriented TiO$_2$ nanotubes, has received an increasing attention in the field of medical implants. Ti gr.5 has been widely used in both orthopedic and dental implants for over 5 decades, mostly due to its mechanical properties, corrosion resistance and overall biocompatibility. Nevertheless, it is a bioinert material and thus, even though it does not trigger an immediate immune rejection or any remarkable toxic effect in the body, it is also not able to actively drive osteointegration or prevent bacterial colonization by its own. On the other hand, vertically oriented, hollow nanotubular structures of TiO$_2$ render the surface of Ti grade 5 more attractive to cell attachment and tissue growth while simultaneously, can act as reservoirs that allow a controlled local release of antimicrobial agents. In this regard, the electrochemical anodization of Ti6Al4V is a simple and effective surface treatment that has the potential to improve both osteointegration and antimicrobial activity.

The purpose of this work is to develop an antibacterial surface modification on Ti gr.5, through the fabrication of TiO$_2$ nanotubes followed by incorporation of Zn or Cu into the nanotubular structures. These inorganic compounds are highly regarded due to their broad-spectrum antimicrobial action and osteogenic properties, therefore, being of interest for orthopedic applications.

**Experimental Methods**

TiO$_2$ nanotube arrays were grown on the surface of Ti6Al4V alloy through an electrochemical anodization in a non-aqueous, ethylene glycol-based electrolyte containing 0.5 wt.% of NH$_4$F and 2.5% V H$_2$O. In a first step, the anodization process has been optimized in order to obtain well-defined nanotubular structures with specific morphological features. A post-anodizing heat treatment was then performed so that a crystalline anatase oxide layer was achieved, with a higher mechanical stability. Following these treatments, Zn or Cu were incorporated into the nanotubular structures through an electrodeposition process. The morphology of the obtained surfaces was analysed through FESEM and the composition through EDXS.

The antimicrobial performance of the obtained surfaces was assessed against *Staphylococcus Epidermidis*, a gram-negative bacteria common in implant-related infections. Bacterial viability and adhesion were determined in phosphate-buffered saline through the determination of colony forming units.

**Results and Discussion**

Zn-incorporated nanotubes led to a significant reduction of both bacterial viability in the surrounding media and bacterial adhesion to the sample surface while Cu-incorporated nanotubes led to 100% loss of both bacteria viability and adhesion.

**Conclusion**

TiO$_2$ nanotubes have the potential to act as vectors for local drug release. Zn or Cu-incorporated nanotubes are effective active antibacterial surface modification towards *S. Epidermidis*.

Development of novel peptides and methods for the functionalisation of polymer, metal and ceramic medical surfaces

Klaudia O. Sobczak1, Pietro Riccio2, Diana Gomes2, Mohadeseh Zare2, Laura Colomina3, Edwige Meurice1, Anne Leriche1, Artemis Stamboulis2, Antonella Bandiera3, On behalf of Horizon 2020 Marie Sklodowska Curie ITN - Antimicrobial Integrated Methodologies for Orthopaedic Applications under the grant agreement 861138

1 Université Polytechnique Hauts-de-France, LMCPA, Cambrai, FR; 2 University of Birmingham, School of Metallurgy and Materials, Birmingham, GB; 3 University of Trieste, Life Sciences Department, Trieste, IT

Introduction
The post-operative complications related to orthopaedic surgeries are constantly increasing due to implant-associated infections, especially those associated with antibiotic resistance. This has resulted in the need for revision surgeries, causing an increase in health care costs and higher morbidity and mortality rates. Moreover, the ageing population leads to an increase in orthopaedic procedures, raising the probability of post-operative complications. Hence, there is an urgent need to develop antibacterial agents incorporated directly into the implants and maintain antibiotic resistance. The Horizon 2020 Marie Sklodowska Curie ITN Antimicrobial Integrated Methodologies for orthopaedic applications (AIMed) project brings together a network of 12 universities and six industrial and academic partners, the aim of which is to develop novel biomaterials for use as orthopaedic implants to target the problems mentioned above and train 15 Early Stage Researchers in antimicrobial methodologies.

Experimental Methods
The project will focus on developing novel peptide sequences based on human defensin domains, which are part of the human innate immune system. They exhibit a broad antibacterial activity and are less prone to induce resistance behaviour. One of the main aspects of AIMed is a cost-effective large-scale production of new biomaterials to be used by the healthcare sector and readily available to the end-users. For this purpose, the human defensin-like peptides will be designed based on computational models to optimise their biological activities. They will be produced via chemical synthesis and molecular biology procedures to establish the most efficient method that results in the highest purity end product.

The new defensin-like peptides will be fused with the human elastin-like polypeptide and bacterial collagen to form new biopolymers, which will mimic the natural extracellular matrix. These novel molecules will be grafted on implant materials to increase their biocompatibility and bioactivity. The resulting peptides will also be immobilised on the metallic, ceramic and polymeric implants using plasma surface functionalisation with primary amines. These amine groups act as anchor points to covalently graft biomolecules.

Results and Discussion
The resulting biomaterials will allow for the optimised and localised release of the antimicrobial agent, delivered directly to the infection site, without affecting the systemic microbiota. Different functionalisation methods will allow for implant integration with natural bone, enhancing bone tissue regeneration and antibacterial behaviour. The developed techniques will also take into consideration additive manufacturing applications.

Conclusion
This project intends to deliver novel materials suitable for future implant interventions, reducing the burden of post-operative infections and taking the pressure off the healthcare systems.

Development of novel copolymers to resist bacterial attachment to medical devices and surfaces.

Nicola McClelland¹, Colin McCoy¹, Louise Carson¹, Jessica Moore¹

¹ Queen’s University Belfast, School of Pharmacy, Belfast, GB; ² Engineering and Physical Sciences Research Council, EPSRC, Swindon, GB

Introduction
Polymeric biomaterials can be introduced into the body as part of an implanted medical device or used to replace an organ or bodily function and are increasingly ubiquitous in healthcare (1). The introduction of biomaterials into the body, however, brings with it a risk of infection from microorganisms (2). This infection represents a major risk to patients and financial burden to healthcare systems. With infection rates approaching 100% in some devices, there is an urgent need to develop ways to prevent bacterial biofilms forming on the surface of medical devices (3). Typically, infection involves initial attachment of bacteria to the surface of the biomaterial, followed by colonisation of the surface and development of a biofilm (2). This biofilm is highly resistant to treatment by antibiotics, and acts as a reservoir for further spread of infection in the body (4). This can lead to sepsis and death.

Using synthetic chemistry this research will develop polymers using new ‘building blocks’ that will provide a novel coating to current medical device materials. By selectively tuning the chemistry of these units, polymers can be engineered to inherently resist bacterial attachment (5). Herein, we report the anti-adherent properties of copolymers ethylene glycol di-cyclopentenyl ether acrylate-co-diethylene glycol methyl ether methacrylate (p(EGdPEA-co-DEGMA)) and ethylene glycol di-cyclopentenyl ether acrylate-co-2-hydroxyethyl methacrylate (p(EGdPEA-co-HEMA)). The ability of these materials to resist bacterial adherence, compared to a unplasticised polyvinyl chloride (UPVC) control, will be assessed.

Experimental Methods
Copolymer films were synthesized by mixing p(EGdPEA), p(DEGMA) and p(HEMA) to the appropriate ratio. The resulting solutions were injected into moulds and polymerised for 2 h at 90°C. Then, 1 cm diameter p(EGdPEA-co-DEGMA), p(EGdPEA-co-HEMA) and UPVC samples were cut and inoculated with 10⁶ CFU/mL Escherichia coli and Staphylococcus aureus suspensions, which were prepared in a 0.5% v/v tryptic soy broth-supplemented phosphate buffered saline solution. The inoculated samples were incubated at 37°C in an orbital incubator (100 rpm) for 4 and 24 h. Microbial adherence was quantified after 4 and 24 h.

Results and Discussion
S. aureus was more susceptible to the anti-adherent properties of the copolymers compared to E. coli with both p(EGdPEA-co-DEGMA) and p(EGdPEA-co-HEMA) reducing the number of adherent bacteria to below the detectable limit by 24 hours. In comparison, the p(EGdPEA-co-DEGMA) copolymer produced a 47% reduction; the p(EGdPEA-co-HEMA) copolymer produced an 88% reduction in adherent E. coli compared to UPVC at 24 hours.

Conclusion
Overall, the results confirm the strong capacity of novel copolymers to resist bacterial adherence over 24 h relative to control. These novel copolymers, with their inherent anti-adherent properties, have the potential to be further developed to potentiate their anti-infective properties.

Antimicrobial coatings for the prevention of catheter-associated urinary tract infections

Jane Burns, Colin McCoy, Nicola Irwin

Queens University Belfast, School of Pharmacy, Belfast, GB

Introduction
Catheter-associated urinary tract infections (CAUTIs) attribute to almost 80% of nosocomial infections worldwide. One of the main difficulties associated with CAUTIs that make them problematic to treat is device encrustation. Encrustation occurs due to colonisation of the catheter surface by urease-producing bacteria, mainly Proteus mirabilis, and leads to catheter lumen blockage (1). Up to 50% of all long-term catheterised patients experience recurrent infections and blockages, resulting in urine retention, septicaemia and pyelonephritis (2). Furthermore, many uropathogens have shown resistance to common antibiotics (3). Weak organic acids (WOAs) have been used as naturally occurring preservatives for centuries and are reported to exert their antimicrobial activity by the flow of unionised molecules through bacterial cell membranes. The reduction in intracellular pH due to accumulation of acidic anions and hydrogen ions causes damage to enzymes, increase in turgor pressure and oxidative stress, thereby inhibiting metabolic processes (4). Previously, the WOAs (citric acid, mandelic acid, malic acid, propionic acid, lactic acid, hippuric acid, benzoic acid and pyruvic acid), antibacterial activity, effect on P. mirabilis ATCC 51286 crystalline biofilm formation and efficacy against catheter blockages was determined (2). Herein, the efficacy of HEMA:PMMA hydrogel coatings, loaded with citric acid, in resisting bacterial adherence and urinary catheter encrustation is investigated.

Experimental Methods
The antibacterial activity of WOA-loaded hydrogel coatings against common uropathogens, (P. mirabilis ATCC51286, Staphylococcus aureus ATCC 29213, Escherichia coli NSM59 and Pseudomonas aeruginosa679), was investigated through determination of zones of inhibition and adherence assays. In vitro bladder model assays and scanning electron microscopy were performed for determination of bacterial viability, urinary pH, time to catheter blockage and the extent of catheter encrustation.

Results and Discussion
Significant reductions in P. aeruginosa adherence of ~ 99% was observed on citric acid-loaded hydrogel coated silicone samples relative to uncoated silicone controls (Figure 1). Preliminary results show the rate of calcium and magnesium phosphate encrustation around the catheter eyeholes was reduced in all of the catheters coated with WOA-loaded hydrogels, resulting in ~ 1.5-fold increase of catheter time to blockage relative to control (Figure 2, 57.11 h and 41.22 h respectively).

Conclusion
The multi-mechanistic, infection-resistant hydrogel coatings identified present a new strategy for the prevention of P. mirabilis crystallisation and are anticipated to play an important role in the prevention of CAUTIs.

Exploring the effect of pH on the antimicrobial activity of weak organic acids against common uropathogens.

May A. Tayyem, Nicola Irwin, Colin McCoy, Louise Carson

Queen's University Belfast, School of Pharmacy, Belfast, GB

Introduction
Urinary catheters are the most commonly used medical devices around the world. Although these devices are deployed to treat several conditions, their use is often complicated by infection where the formation of biofilms on catheter surfaces is a key element. Therefore catheter-associated urinary tract infections (CAUTIs) are among the most common nosocomial infections [1]. Colonization with urease producing species such as Proteus mirabilis induces an increase in urine pH, precipitating struvite crystals and the formation of crystalline biofilms resulting in catheter encrustation. Several approaches have been developed to prevent CAUTIs including the modification of catheter surfaces to offset the formation of crystalline biofilms or modulating urinary pH [2]. Weak organic acids (WOAs) have been employed as preservatives in food manufacturing for centuries as antimicrobial and antifungal agents. WOAs are reported to exert their antimicrobial activity by the flow of unionized molecules by simple diffusion through bacterial cellular membranes [3]. The accumulation of acid into the cytosol results in reduced intracellular pH, due to the accumulation of ionised anions and protons causing inhibition of bacterial growth through the inhibition of bacterial enzymes and glycolysis, and metabolic processes. Moreover, oxidative stress causes disruption of the integrity of cellular membrane [4]. Since extensive dissociation of WOAs are affected by the pH, the aim of this study was to investigate the effect of pH on the activity of WOA to inform potential employment of these agents as novel alternatives to antibiotics for the prevention and treatment of CAUTIs.

Experimental Methods
The antimicrobial activity of WOAs (citric acid, lactic acid, pyruvic acid, hippuric acid, benzoic acid, mandelic acid, propionic acid and malic acid), against common uropathogens (Proteus mirabilis ATCC51286, Pseudomonas aeruginosa 679, Escherichia coli NSM59 and Staphylococcus aureus ATCC29213) was investigated through the determination of minimum inhibitory concentration (MIC) values and minimum bactericidal concentration (MBC) values at normal (pH 6) and infected (pH 9) urine pH levels in Mueller Hinton Broth (MHB). Time-kill assays were conducted to evaluate the antimicrobial properties of pyruvic and citric acids against P. mirabilis in in vivo relevant conditions, in MHB at pH 6 and 9 and in artificial urine media.

Results and Discussion
Reduced bactericidal activity was demonstrated for WOAs at elevated pH levels due to dissociation of the acid molecules. Nevertheless, pyruvic and citric acids exhibited rapid killing in MHB at pH 6, with approximately three-log reductions after 1 h and 3 h incubation, respectively. In artificial urine media pyruvic acid achieved three-log reductions of the viable count after 1 h in comparison to citric acid which demonstrated bacteriostatic activity against P. mirabilis over the 24 h incubation period. On the other hand, pyruvic acid needed more than 12 h to exert its bactericidal activity when added to previously infected artificial urine media with P. mirabilis. This can be explained by the relation between the antibacterial activity of WOAs and pH, as WOAs cross the cell-membrane in their undisassociated form, ionise in the cytoplasm, exerting oxidative stress and affecting bacterial growth [4, 5].

Conclusion
Based on the promising antibacterial activity of WOAs in artificial urine, these agents are anticipated to play an important role in the prevention and treatment of catheter-associated urinary tract infections, as an alternative to conventional antibiotics thus preventing the emergence of resistant bacteria. Future work will focus on the effect of
these agents against urinary pathogens under in vivo representative conditions in multispecies communities. This includes the determination of multispecies interaction under static and dynamic conditions and the susceptibility of multispecies communities to WOAs.

Biobased polymeric network designed for lavender oil encapsulation

Aurica P. Chiriac, Loredana E. Nita, Alina G. Rusu

Petru Poni Institute of Macromolecular Chemistry, Department of Natural Polymers, Bioactive and Biocompatible Materials, IASI, RO

Introduction
The present study is devoted to the preparation of an amphiphil polymeric network for the entrapment of an essential oil. Poly(ethylene brassylate-co-squaric acid) (PEBSA), a biobased compound, was synthesized through a reaction of ethylene brassylate macrolactone ring-opening and copolymerization with squaric acid. The copolymer was evaluated for hydrophilicity and confirmed a balance between hydrophilic and hydrophobic character. In this context, lavender essential oil was encapsulated in the polymer matrix.

Experimental Methods
The encapsulation of lavender bioactive compound into the PEBSA polymeric matrix was realized by a co-precipitation technique, realized by an inclusion complexation performed in DMSO by entrapping the essential oil into the amphiphilic PEBSA network. The encapsulation yield as well as the antimicrobial character was evaluated by specific methods.

Results and Discussion
The complex formation between PEBSA and lavender oil was confirmed by physicochemical characterization. Thus, spectroscopic analyses confirmed the chemical structure of the copolymer and of the new compound, and the microscopy analyses illustrated the homogeneous aspect of the copolymer network and as well of the bioactive structure. The antimicrobial activity of the complex was also investigated.

Conclusion
The study confirmed the preparation of PEBSA/lavender oil bioactive complex. The antimicrobial activity of the complex investigated against eight different reference strains, namely bacterial strains - *Staphylococcus aureus* ATCC25923, *Escherichia coli* ATCC25922, *Enterococcus faecalis* ATCC 29212, *Klebsiella pneumoniae* ATCC 10031 and *Salmonella typhimurium* ATCC 14028, yeast strains represented by *Candida albicans* ATCC10231 and *Candida glabrata* ATCC 2001, and the fungal strain *Aspergillus brasiliensis* ATCC9642, proved an increased efficiency of the PEBSA/lavender oil complex against the bacterial strains represented by *S. aureus, E. coli, E. faecalis, K. pneumoniae*, and against the fungal strain represented by *A. brasiliensis*, and confirmed the advantage brought by using PEBSA matrix for coupling the essential oil.

Introduction

Post-operative infections can lead to compromised bone healing and non-union if not managed properly. The treatment of infection is complex often involving parenteral or systemic antibiotic drug administration, and in extreme cases, bone and tissue debridement is required due to the compromised blood circulation [1]. Although the systemic delivery of antibiotics is common practice for treating bone-related infections, the broad overuse of antibiotics has led to multidrug-resistant bacterial strains [2, 3], which now require higher and prolonged doses of multiple antibiotics. To tackle this problem, we aim to design and fabricate scaffolds for localised delivery of antibacterial agents which will prevent the occurrence of infections and potentially accelerate the healing and remodelling of hard tissue. Due to the growing urgency to minimise the dependency on antibiotic drugs, alternative treatment strategies, including the use of nanoparticles, have attracted significant attention. Nanoparticles (NPs) are emerging as novel antibacterial agents which have proven their effectiveness for treating infectious diseases [4] as due to their large surface area to volume ratio they can exhibit special properties which their bulk counterparts do not. In the present work, cerium oxide nanoparticles (Ce⁴⁺ and Ce³⁺) have been selected due to their reported antibacterial potential and the potential to enhance vascularisation [5].

Experimental Methods

Cerium oxide nanoparticles were formed using a hydroxide mediated approach. A 0.3M aqueous solution of sodium hydroxide was added dropwise to 0.1M aqueous cerium nitrate hexahydrate solution at 25°C. The mixture was left under continuous stirring for 24 hrs. The nanoparticles were collected by filtration and washed several times with distilled water and ethanol. Type-A NPs were subsequently frozen at -80°C for 24 hrs and then placed into a freeze dryer for 24 hrs. Type-B NPs followed the same procedure, however, after the nanoparticles were filtered and washed they were placed into a furnace at 80°C for 24 hours to dry. The nanoparticles were calcined at/above the phase change temperatures 280°C, 385°C, and 815°C identified by the Simultaneous Thermal Analysis technique.

Results and Discussion

Synthesis of cerium oxide nanoparticles (4 nm to 53 nm) was confirmed by the XRD, BET surface area, and TEM analysis. Interestingly, the drying method (i.e., freeze-drying or furnace drying) and calcination temperature significantly affected the physicochemical properties, i.e. size, shape, agglomeration, and the oxidation ratio Ce⁴⁺:Ce³⁺. The increased calcination temperatures from 280°C to 815°C caused the size of the synthesised nanoparticles to increase; the average particle size grew by eight times 280°C to 815°C (C815) when compared with FRNP nanoparticles. The FRNP, C385 and C815 nanoparticles exhibited antibacterial properties against Escherichia coli, Pseudomonas aeruginosa and Staphylococcus epidermis. The FRNP nanoparticles presented significant antibacterial efficacy as compared to the larger size C385 and C815 nanoparticles.

Conclusion

The antibacterial potential of cerium oxide nanoparticles is dependent on the particle size distribution and processing routes controlling the overall available oxygen vacancies in the fluorite crystal structure. The synthesised nanoparticles present a promising alternative to current treatments for bone-related infections.
nanoparticles consisted of particle sizes ranging from 4-53nm. The calcination temperature affected the agglomeration tendency, particle size distribution and the ratio of Ce$^{3+}$:Ce$^{4+}$ oxidation states. The antibacterial efficacy was characterised in the concentration range of 50-200µg/ml and tested against *Escherichia coli*, *Staphylococcus epidermis*, and *Pseudomonas aeruginosa* by determining the half-maximal inhibitory concentration (IC50). The freeze-dried nanoparticles exhibited 18.5±1.2%, 10.5±4.4%, and 13.8±5.8% increased antibacterial efficacy at concentrations of 200µg/ml compared to nanoparticles consisting solely of Ce$^{4+}$ ions.

Phosphatase Like Fullerene Nanostructures for Bone Regeneration

Gülcihan Gülseren

Konya Food and Agriculture University, Molecular Biology and Genetics, Konya, TR

Introduction
The phosphatase enzyme is a crucial marker for bone formation process and frequently used in bone regeneration studies because of its important role through process of osteogenesis. The model structures in our new design will form the basis for biomineralization as well as catalytic activity. The mineral induction capacity of the enzyme-like structure will be tested with the new design, since the alkaline phosphatase enzyme regulates biomineralization process beside its catalytic activity, and another function -biomineralization- will be provided by a single structure. In this context, osteoinductive and osteoconductive capability of the designed artificial mimic will be tested with in vitro studies following the kinetic demonstration of its biocatalytic activity. At present, artificial catalysis studies are only at the catalytic activity phase and the biological activities of these artificial catalysts were not tested in model cell applications. Our ultimate goal in this work is to develop a biomimetic enzyme structure that can be applied to living cells, mimicking not only the chemical function but also the biological functions of the enzyme. Thus, developed artificial model will be used as a potential alternative to natural enzymes for bone regeneration studies.

Experimental Methods
Fullerene synthesis was performed by conjugation of multiple bioactive sites. The Nuclear Magnetic Resonance, Thermogravimetry, Atomic Force Microscopy and nano Fourier Transform Spectroscopy analysis was used to chemical characterization of synthesized materials. Single molecule size and molecular assembly were shown by the Dynamic Light Scattering method. After particle characterization, the antimicrobial activity of synthesized nanoparticles was tested with enzyme kinetics study. Michaelis-Menten fittings were used for the calculation of kinetic parameters. Synthesis, characterization and kinetics experiments are followed by cell culture experiments for testing osteoregenerative potential of nanoparticles. Osteoprogenitor SaOS-2 cell line was used as a model for osteoregeneration. Biocompatibility of the fullerene-based biomaterial was checked with Alamar Blue viability tests. Alizarin Red Staining was applied for testing the biomineralization capability of the nanomaterial applied cell model. Lastly, osteoinduction was shown by RT-PCR, expression levels of Runx-2 and Col-1 were investigated to show osteogenic differentiation at the gene level.

Results and Discussion

Alizarin Red Staining was applied for testing the biomineralization capability of the nanomaterial applied cell model. Lastly, osteoinduction was shown by RT-PCR, expression levels of Runx-2 and Col-1 were investigated to show osteogenic differentiation at the gene level. The catalytic activity of phosphatase-like nanoparticles have been shown with the kinetics experiment. Fullerene based biocatalyst have exhibited significant activity in the presence of p-nitrophenyl phosphate which is a model substrate resembling the actual substrate of phosphatase. Biocompatibility

Page 1836 of 2028
was also shown with SaOS-2 cells, synthesized particles have found biocompatible. Fullerene biocatalyst also induced biomineralization of SaOS-2 cells, induced calcium deposition have shown with Alizarin Red Staining, osteoblast-like clusters were obtained by microscopy imaging. Osteoblast differentiation-specific gene expressions were also studied with RT-PCR.

**Conclusion**

In this study, a multi functionalized fullerene nanostructures have been used for bioregenerative application. This phosphatase inspired nanostructure can be employed for both catalytic purposes and osteoinductive/conductive purposes similar to its native counterpart. Carbon nanomaterials are more stable structures compared to biological macromolecules, hence the presented study will be inspirational for future biocatalyst studies with practical applications.

Detection of mesenchymal stromal cells osteogenic differentiation by SERS

Adrianna Milewska\textsuperscript{1,2}, Olafur E. Sigurjonsson\textsuperscript{3,4}, Kristjan Leosson\textsuperscript{1}

\textsuperscript{1} Innovation Center Iceland, Reykjavik, IS; \textsuperscript{2} University of Iceland, Reykjavik, IS; \textsuperscript{3} The Blood Bank, Landspitali University Hospit, Reykjavik, IS; \textsuperscript{4} Reykjavik University, Reykjavik, IS

Introduction
Mesenchymal stromal cells have been at the epicentre of regenerative medicine and therapeutic applications since their identification, due to their ability to differentiate into various cell types, such as osteoblasts. In vitro, osteogenic differentiation is induced by a cocktail of dexamethasone, ascorbic acid and β-glycerophosphate, however, it strongly depends on the donor-specific osteogenic differentiation potential. Since native MSCs demonstrate such variability, it is possible that their response to experimental manipulation may also vary, so it is of high importance to study cells with minimally invasive methods. The most commonly used procedures for following cell differentiation include e.g. immunofluorescence staining, qPCR, colorimetric assays. However, a label-free method that does not require the termination of the cell culture prior the analysis, is still lacking.

Experimental Methods
Here, we show the direct and label-free approach for studying the extracellular matrix and membrane changes during differentiation in mesenchymal stromal cells with surface enhanced Raman scattering (SERS). We have used SERS as a sensitive tool to study the structure of cellular compounds, providing comprehensive information on the molecules in the nm-scale proximity of gold nanoisland substrates. We fabricated the substrates by repeated gold deposition and thermal annealing, providing sufficient enhancement and a homogenous distribution of “hot spots” [1, 2]. In order to demonstrate their applicability as in-vitro sensing platforms for long-term cell proliferation, we cultured MSCs and recorded spectra of the cellular membrane at different timepoints during differentiation.

Results and Discussion
The results of biological assays indicate that the SERS platforms are biocompatible, suitable for long term cultivation of the cells and in principle do not induce cell death. Moreover, osteogenic differentiation on such substrates is not compromised, which was confirmed with Alizarin Red staining and Alkaline Phosphatase activity assays (Fig. 1). The SERS cell data generated with the use of our SERS-active platforms allowed to identify multiple characteristic molecular compounds of the cells in the close proximity of the gold nanoisland substrates and follow changes of extracellular matrix and calcium phosphate deposition during osteogenic differentiation (Fig. 2).

Conclusion
We have employed simple approach of SERS substrate fabrication. The substrates provide uniform and sufficiently high enhancement to enable molecular characterization at the single-cell level. In conclusion, the possibilities of SERS to follow biochemical and physiological changes in the cell membrane can be used to monitor the differentiation of the mesenchymal stromal cells into osteocytes.

Introduction
Heart disease is the leading cause of death globally. Myocardial infarction (MI) causes a decrease or interruption of blood supply to the cardiac district, leading to a significant loss of contractile cardiomyocytes and tissue remodelling with the formation of a fibrotic scar. Currently, microRNAs (miRNAs) have arisen considerable interest as a therapeutic approach to induce cardiomyocyte proliferation or transdifferentiation of cardiac fibroblasts (CFs) into induced cardiomyocytes (iCMs) in the perspective of cardiac regeneration (1,2). In a recent work, Paoletti et al. reported direct reprogramming of human CFs into iCMs by transfection of CFs with a combination of four microRNAs (miR-1, 133, 208, 499) called miR-Combo using a commercial lipidic transfectant. However, tailored designed nanocarriers are required for safe and efficient administration of reprogramming agents in order to increase direct reprogramming efficiency.

In this work, new lipoplexes composed of a cationic and a helper lipid mixture were designed for efficient encapsulation and delivery of microRNAs to human CFs respect to a commercial agent, aimed at enhancing direct reprogramming efficiency.

Experimental Methods
New lipoplexes based on a mixture of a cationic and a helper lipid and loaded with negmiR, miR-1 or miRcombo were prepared at different N/P ratios changing the amino to phosphate groups ratio (N/P 3; 1.75; 0.7; 0.35) (Figure 1). Lipoplexes were characterized in terms of size, zeta potential and encapsulation efficiency. Physical stability in different media and miRNA release were also evaluated. Biocompatibility, cellular uptake and transfection efficiency were assessed using adult human CFs (AHCFs). Furthermore, miRcombo-loaded lipoplexes were characterized for their physicochemical properties and their influence in miRcombo-mediated trans-differentiation of AHCFs into iCMs based on the expression of cardiac markers, such as cardiac troponin T (cTnT). Lipoplex properties and their biological effects were compared to those of a commercially available transfection agent.

Results and Discussion
Designed lipoplexes displayed an average hydrodynamic diameter increasing from 372 nm to 876 nm and a Z-potential decreasing from + 40 mV to -26 mV with decreasing N/P ratios (3.0-0.35). Lipoplexes encapsulated a high amount of miRNA (99%) and allowed faster miRNAs release than the tested commercial agent. Moreover, they showed long-term stability under storage conditions. Based on stability experiments at different temperatures (4°C and 37°C), lipoplexes with N/P ratio of 3 were selected for further biological characterisations with AHCFs. They showed biocompatibility and significantly enhanced miR-1 expression compared to the tested commercial agent. Lipoplexes loaded with miRcombo significantly enhanced the expression of cardiac markers such as cTnT, compared to the commercial agent.

Conclusion
Page 1840 of 2028
Our results indicate that the new designed lipoplexes are promising for *in vitro* miRNA delivery, showing biocompatibility and efficient miR-1 release to human CFs. Furthermore they improved miRcombo-mediated direct reprogramming of AHCFs into iCMs compared to the control commercial agent suggesting their potential as efficient vectors for direct cardiac reprogramming.

The Importance of Protein Corona when determining Nanoparticle-Biological Interactions: How the nanoparticle physicochemical properties change biological interactions in different biological environments

**Medina Guliyeva**, Oran Maguire, Charlie Brown, Amita Gupta, Saeed S. Motevallian, Joel Turner, Gavin Jell

**UCL, Department of Surgical Biotechnology, London, GB**

**Introduction**

Upon exposure to biological fluids a protein corona form around NPs. The formation of protein corona is dependent on the interplay between the physiochemical characteristics of NPs and the characteristics of biological environment (e.g. pH, temperature and the proteinous environment). The composition of the NP protein corona may be an important factor that determines cellular response, for example the concentration of proteins in serum has been shown to influence NP internalisation and active targeting success. In the last 5 years, 97% of in vitro tests concerning nanoparticle-cell interaction studies are performed using foetal bovine serum (FBS). Considering the known differences in the serum protein composition between foetal serum and adult bovine serum (BS) and human serum (HS), little is known about how this affects the cellular interactions or the accuracy of using NP-cellular interaction in vitro models. If the species of the serum influences NP-cellular interactions or the “biological identity”, this will help our understanding of the importance of the NP corona in determining biological interactions and improve the translation of nanomedicine by creating more accurate in vitro models.

**Experimental Methods**

**Size and composition analysis of protein corona.** Samples collected were then used for SDS-PAGE, DLS, LC-MS analysis. For SDS-PAGE analysis protocol used by Walkey et al was applied to investigate the NP protein corona composition. For DLS analysis samples were loaded into the chamber of disposable folded capillary cells (Malvern Instruments) and a Zetasizer Nano-ZS from Malvern Instruments (Zetasizer Nano ZSP, Malvern, England) was used to determine the particle sizes and zeta potentials. LC-MS analysis were performed using the protocol previously described in Lombardi et al. Analysis of cell uptake of nanoparticles. Qualitative analysis of NP uptake was performed using TEM. Human dermal fibroblasts (HDF; P10) and Bovine Dermal Fibroblasts (BDFs P10) were seeded at a cell density of 10^5 million cells/cm². HDFs were left to rest for 24hrs prior to washing with PBS and addition of DMEM (Gibco, high glucose), supplemented with 10% FBS, HS or BS. 1ml of AuNP (10^3 AuNPs/cell) were added to the media and plates were left overnight to allow uptake. Finally, the cells were washed thrice with PBS, fixed, and sectioned. Each section was placed onto a copper grid and imaged by TEM. Quantitative analysis of NP uptake was measured by ICP. HDFs BDFs were seeded at 10^5 million cells/cm². Cell growth medium was supplemented with 10% FBS, HS or BS and left to rest for 24hr. Cells were then treated with AuNPs (10^3 AuNPs/cell). Cell suspension were transferred to 25 ml glass bottles for Aqua Regia (1ml) digestion in the oven for 30 mins and left overnight in the fume cabinet for complete digestion. The final digests were then filtered and quantified using ICP.

**Results and Discussion**

Identification of proteins isolated from AuNP-protein corona formed in different sera. LC-MS analysis revealed that the top 10 abundant proteins isolated from protein corona complexes formed in HS, FBS and BS are...
dissimilar (Figure 2a). Serotransferrin and albumin are only proteins found in all sera (Figure 2a, 2b). Proteins isolated from corona formed in HS, FBS and BS contains 8, 4, and 4 distinct proteins respectively (Figure 2b).

**The uptake of AuNPs in different sera.** TEM and ICP revealed that the cell uptake of AuNPs (1000 NPs/cell) incubated in 10% HS by HDFs was increased by 3 folds compared to the uptake by HDFs which were incubated in 10% FBS (figure 3e). The uptake of AuNPs was also significantly decreased for HDFs incubated in 10% BS.

**The uptake of PEG-AuNPs in different sera.** Despite this lower uptake of NPs, species on sera still effected the biological indent and uptake. PEGylated NPs exposed to FBS had a significantly lower uptake compared to HS or BS (Figure. 4e). The different uptake of AuNPs in different serum conditions was also present in PEGylated NPs, emphasising the importance of selecting a suitable condition for nanoparticle-cell interaction assessments.

**Matching the species of serum to species of cells.** TEM images shows that the number of AuNPs in cells incubated in HS is higher than those incubated in FBS and BS (figure 5b-d). AuNPs internalised by cells in media supplemented by FBS appears ICP analysis revealed that the uptake of AuNPs by BDFs (figure 5e) incubated in HS is significantly higher than cells incubated in FBS (P<0.05). HDFs incubated in HS showed no significant change compared to those in BS (figure 5e). These results confirm the importance of selecting proper biological milieu and cell type for in vitro cellular interaction studies of nanoparticles.

**Conclusion**

Human serum better mimics the composition of the in vivo environment. Successful translation of NP targeting systems is reliant upon accurate modelling NP – cell interactions.

Hazelnut Extract-Loaded Nanostructured Lipid Carriers and Evaluation of Their Antioxidant Properties

Melis Emanet1,2, Ozlem Şen2, Gianni Ciofani2

1 Sabanci University Nanotechnology Research and Application Center (SUNUM), Istanbul, TR; 2 Istituto Italiano di Tecnologia, Smart Biointerfaces, Pontedera, IT

Introduction
In healthy physiological conditions, living organisms possess a variety of antioxidant mechanisms in order to scavenge over-produced reactive oxygen species (ROS). However, under pathological conditions, endogenous antioxidants may not be adequate to eliminate the excessive rate of oxidants [1]. In this case, a continuous exogenous antioxidant income is required, mainly from nutraceutical products, in particular derived from fruits, nuts, spices, vegetables, and mushrooms [2]. In this regard, extensive investigations on hazelnut extracts indicated as their high content in antioxidant compounds make them suitable as excellent nutraceutical agents, especially in neurodegenerative disorders [3].

Experimental Methods
NE-NLCs were prepared by hot homogenization technique using glyceryl dibehenate as solid lipid and oleic acid as liquid lipid, jointly to colloidal stabilizers (DSPE-PEG), surfactants (pooloxamer 188) and NE, as indicated in Figure 1B. The morphology of NE-NLCs has been assessed by transmission electron microscopy (TEM) imaging, while colloidal stability was analysed by dynamic light scattering and ζ-potential measurements. The antioxidant ability of NE-NLCs was investigated using a Total Antioxidant Capacity Assay Kit (Sigma-Aldrich).

Results and Discussion
TEM imaging of NE-NLCs indicates the uniformity of the structures, as shown in Figure 1A. The hydrodynamic size distribution of NE-NLCs resulted to be 210 ± 8 nm, while the ζ-potential -31.7 ± 0.6 mV. The antioxidant ability of NE-NLCs was found concentration-dependent, in the range of 12.1 – 149.4 μM of Trolox equivalent for concentrations in the range of 31 - 1000 μg/mL (Figure 1C).

Conclusion
All considered, the uniformity and the high stability of NE-NLCs in an aqueous environment indicate their suitability for biomedical applications. Besides the physical properties, an excellent concentration-dependent antioxidant ability of NE-NLCs suggests their exploitation in ROS scavenging treatments.
Representative TEM image (a) and schema (b) of NE-NLCs. Characterization of NE-NLCs antioxidant activity expressed as Trolox equivalent (c).

**Enhanced Magnetic Hyperthermia by Tunable Exchange Coupled Magnetic Nanoparticles**

**Valentin Nica, Andrea Desii, Alessio Carmignani, Gianni Ciofani**

*Istituto Italiano di Tecnologia, Center for Materials Interfaces, Pontedera, IT*

**Introduction**

Exchange coupled bi-magnetic nanoparticles have proved very interesting properties for inductive hyperthermia applications due to the quantum synergism between the magnetic core and a magnetically thin shell [1]. The heating ability of the particles is quantified by the specific absorption rate (SAR), an extrinsic parameter related to physio-chemical properties of particles such as composition, shape, size or magnetic shell thickness [2].

**Experimental Methods**

Shaped-anisotropic bi-magnetic nanoparticles have been synthesized by solvothermal route and their structural and magnetic properties have been studied. In the first step, we synthesized several types of nanoparticles as seed component. Secondly, magnetically core-shell nanoparticles were obtained by the seed-mediated route where a shell was over-grown by thermal decomposition onto the surface of the core nanoparticle. The nanoparticle shape, size and shell thickness has been controlled through their compositions, surfactant molar ratio of precursors, heating rate and reaction time. The structure and morphology of the core-shell nanostructures have been demonstrated by Raman spectroscopy, X-ray photoelectron spectroscopy (XPS) selected area electron diffraction (SAED), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Magnetic inductive measurements were performed to assay the heating capacity (i.e. SAR) of colloidal nanoparticles under an alternating magnetic field (AMF) (f=100 kHz, B=20 mT).

**Results and Discussion**

In this study various magnetic core-shell nanoparticles with shape anisotropy have been studied: Co$_{0.6}$Zn$_{0.4}$Fe$_2$O$_4$@CoFe$_2$O$_4$ (CZF), MnFe$_2$O$_4$@CoFe$_2$O$_4$ (MF), Fe$_3$O$_4$@CoFe$_2$O$_4$ (IO) and Fe$_3$O$_4$@Mn$_{0.5}$Zn$_{0.5}$Fe$_2$O$_4$ (MZF). The Raman peaks related to A$_{1g}$ and T$_{2g}$ vibrational modes matched the spinel structure of all studied systems. TEM images showed hexagonal (CZF), octahedron/polyhedral (IO), truncated-octahedron (MF) or cubic-type (MZF) morphology with mean size of particles between 8-15 nm. Dark field-TEM (DF-TEM) and X-ray photoelectron spectroscopy (XPS) results confirmed the formation of bi-magnetic core-shell nanoparticles. The shell thickness has been evaluated between 1-5 nm. For inductive heating measurements, the surface of magnetic nanoparticle was modified to provide water-based colloidal stability with a concentration of 5 mg/ml for all aliquots. The SAR results of core-shell nanoparticles demonstrated the superior heating properties compared to the core ones. This effect is attributed to the exchange-coupled interactions at the core-shell magnetic interface [3]. The SAR values of bi-magnetic samples (63 W/g to 176 W/g) with hexagonal and polyhedral morphologies did not show a strong variation compared with their seeds. Instead, the cubic-shaped system revealed approximately twofold value than the core counterpart. The thickness of the core-shell magnetic nanoparticles on SAR has been controlled by varying the precursor concentration. We observed a non-linear dependence of SAR on the shell thickness increase with the highest heating capacity corresponding at around 2 nm of the layer.

**Conclusion**

We synthesized four type of bi-magnetic nanoparticles with different morphology. The structural analysis demonstrated a spinel-type crystalline structure of all the samples. In the same experimental conditions, the inductive measurements of water-based colloids have shown greater heating rate of magnetically core-shell nanoparticles compared with the magnetic cores due to exchange-coupled spin mechanism occurred at physical interface between...
layers. With respect of nanoparticle mean size, the cubic-shaped nanoparticles (MZF) have proven the highest heating capability ($\text{SAR}=176 \text{ W/g, } f=100 \text{ kHz, } B=20 \text{ mT}$). Thus, the control of SAR can be performed by tailoring the material characteristics in terms of shape, size, composition and core-shell design with different chemical and physical structures. The designed anisotropic bi-magnetic nanoparticles could be used in a variety of systems as heat induction applications like magnetic hyperthermia, drug delivery vehicles or self-healing materials.

Introduction
In recent years, Superparamagnetic Iron Oxide Nanoparticles (SPIONs) coated with dimercaptosuccinic acid (DMSA) have been widely described as good candidates for biomedical applications such as targeted drug delivery, magnetic separation, biomedical imaging or hyperthermia due to their low toxicity and excellent magnetic properties [1]. Among the different existing methods to synthesize SPIONs, Flame Spray Pyrolysis (FSP) technology allows large-scale production and control of the size and properties of the nanoparticles [2]. Since most nanoparticles designed for biomedical applications will encounter blood while being transported to the target tissue, it is important to assess their hemocompatibility to ensure their safety for clinical applications [3].

In this study, SPIONs were produced by a FSP process and surface-activated to allow their coating with DMSA. The resulting nanoparticles were characterized in terms of physico-chemical and magnetic properties and a bioanalytical evaluation, including a hemocompatibility study, was performed to explore their potential in biomedical applications.

Experimental Methods
SPIONs were synthesized and optimized employing FSP technology. Briefly, SPIONs were obtained passing an optimized iron-based organometallic precursor mixture in organic solvent through a flame constituted by oxygen and methane. The oxidative conditions of the flame, concentration of the organometallic precursor, ratio precursor/oxygen 0.5 approx., feeding flow and/or gas career were the controlled parameters of synthesis. The particles were further treated with 2 M HNO₃ under agitation for 15 minutes. The supernatant was then removed by magnetic separation and 1 M Fe(NO₃)₃ was added to the particles. The mixture was refluxed under stirring for 30 min and subsequently treated with 2 M HNO₃ and washed with water (3x). To perform the coating, a solution of 15 mg of DMSA in 10 mL of distilled water was added to a suspension of the nanoparticles in 20 mL of distilled water at pH 3 achieving a concentration in Fe of 3 mg/mL. The mixture was gently stirred manually, the pH adjusted to 11 and after 20 min of sonication, it was dialyzed against 5 L of water for 2 days. Finally, the pH was adjusted to 7 and the colloidal suspension filtered through a 0.22 mm filter. The nanoparticles were characterized by Transmission Electron Microscopy (TEM), X-ray diffraction (XRD), Dynamic Light Scattering (DLS) and Fourier Transform Infrared spectroscopy (FT-IR). Concentration in Fe₂O₃ was determined by Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES). Magnetic characterization was carried out in a vibrating sample magnetometer (VSM). To determine platelets activation, nanoparticles were incubated with platelet-rich plasma for 20 min at 37 °C in a platelet aggregometer TA-8V (Stago, France). Circulating monocytes activation was analyzed by fluorescence-activated cell sorter (FACS) with human anti-CD14, anti-CD16 and anti-CD11B after 2 h of exposure to the SPIONs. Stained cells were acquired in flow cytometry Canto-II equipped with FACSDIVA™ software (BD, Biosciences).

Results and Discussion
SPIONs between 10 and 18 nm in diameter have been successfully synthesized by FSP and subsequently coated with DMSA obtaining a time-stable colloidal water dispersion. The DLS result showed a great improvement in nanoparticle dispersion after acid treatment and DMSA coating. The infrared spectrum confirmed the DMSA coating. Finally, a biological assessment was performed confirming that our IONPs coated with DMSA failed to induce significant platelets clotting, reaching 0.52% and 4.33% of aggregation in IONPs and IONPs-DMSA respectively (control with platelets receptors agonists was 77.3%). Moreover, increasing in the expression of activating molecules on circulating monocytes such as CD11B was absent in presence of IONPs-DMSA after flow cytometry analysis. Thus, fold increase of CD11B in scaled dose of IONPs vs IONPs-DMSA was: 1.59±0.00014 vs 1.095±0.021 (50 μg/mL), P<0.001; 1.48±0.049 vs 0.88±0.042 (100 μg/mL), P<0.01 and 1.36±0.16 vs 0.99±0.16 (200 μg/mL).

**Conclusion**

Large-scale SPIONs produced by a FSP process have been coated with DMSA for the first time and their characterization and hemocompatibility results demonstrate their potential for biomedical applications.

Manganese Dioxide-based Nanoreactors for Reduction of Oxidative Stress and MRI Imaging

Soraia V. Lopes1,2, Piotr Walczak3, Miroslaw Janowski4, Rui L. Reis1,2, Joana Silva-Correia1,2, Joaquim M. Oliveira1,2

1 University of Minho, 3Bs Research Group, Guimarães, PT; 2 ICVS/3B’s - PT Government Associate Laboratory, Braga/Guimarães, PT; 3 University of Maryland, 3Department of Diagnostic Radiology and Nuclear Medicine, Baltimore, US; 4 Mossakowski Medical Research Centre, NeuroRepair Department, Warsaw, PL

Introduction
The use of nanoparticles in imaging techniques and therapies targeting inflammation has been increasing due to their small size and easy manipulation [1]. In particular, manganese (Mn2+) based nanoparticles have been greatly explored. This is due to the fact that manganese ions are naturally present in the brain, accumulate in the mitochondria of brain cells and can act as a contrast agent, therefore increasing signal intensity and specificity in magnetic resonance imaging (MRI) [2]. Additionally, manganese ions are able to decompose reactive oxygen species, commonly present in the inflammatory process of neurodegenerative diseases [3]. In this study, we present the development of nanoreactors with applications in cell delivery, Manganese-enhanced MRI (MEMRI), and reducing oxidation in degenerated tissues.

Experimental Methods
Different types of manganese dioxide nanoparticles and blends of methacrylated gellan gum and hyaluronic acid (HA) were investigated. Chemical and morphological analysis were performed by dynamic light scattering, scanning electron microscopy, in vitro degradation, and swelling ability. Round-shaped particles with overall average size of 70 nm were achieved. The addition of different concentrations of particles and different HA ratios do not seem to affect the hydrogels' stability. The in vitro cytotoxicity assessment of the materials was evaluated using immortalized rat lung fibroblast cell line (L929 cells) after 24 and 72 hours of culture.

Results and Discussion
Overall, differences could be seen with the addition of the different nanoparticle types and hyaluronic acid. The presence of the MnO2_S (synthesized MnO2) nanoparticles led to a lower cytocompatibility whereas, the MnO2_C1 (Manganese (IV) oxide ReagentPlus®, ≥99%) type presented the lowest toxicity to cells. Additionally, a lower percentage of hyaluronic acid in the formulations seems to be more favorable for cell proliferation and viability. Looking at the different nanoparticle concentration, for the MnO2_S and MnO2_C1, higher concentrations (75 and 100 ng/mL) do not seem to negatively affect cell viability. The opposite can be seen for the MnO2_C2 (Manganese(IV) oxide activated, ~85%, <10 μm) nanoparticle type.

Conclusion
This work evaluated different types of manganese nanoparticles and identified potential nanoreactor formulations suitable for combined use in MEMRI techniques and for reduction of oxidative stress in tissues.

The Guiding Effect of Self-assembling Hydroxyapatite Nanorods on Bone Regeneration

Jishizhan Chen, Wenhui Song

University College London, Centre for Biomaterials in Surgical Reconstruction and Regeneration, Division of Surgery and Interventional Sciences, London, GB

Introduction

Liquid crystal-like, low-dimensional and long-range ordered structures (LC) are found in human tissues including bones. The excellent mechanical and biological functions of natural bones entail the well-orchestrated nano-scale hydroxyapatite (HAp) crystals within collagen fibres matrix. However, the understanding of the self-assembling of HAp nanocrystals and formation of hierarchically ordered bone structure are still elusive. Our study aims to develop an in situ traceable anisotropic HAp nanorods doped with citrate and terbium (Cit/Tb-HAp NRs), investigate their self-assembling behaviour and illuminate their potential and pathway of guiding ordered osteogenesis at multi-scale in vitro.

Experimental Methods

The Cit/Tb-HAp NRs were synthesised utilising a hydrothermal method. The lyotropic LC behaviours and fluorescence was observed. The toxicity, influence on ALP activity, and traceability of free NRs were initially investigated on NIH 3T3 cells. The large-scale alignment of NRs was achieved by spin coating technic and characterised by optical and electron microscopy. The study on proliferation and osteogenesis differentiation of human bone marrow-derived stem cells (hBMSCs) in response to aligned Cit/Tb-HAp NRs are performed.

Results and Discussion

The Cit/Tb-HAp NRs can self-assemble into a liquid crystalline phase and are then trackable under both polarised light and fluorescence microscopy. It is found that the NR suspension with a concentration of 100 μg/mL or lower is a relatively safe dose for 3T3 cells compared to controls and may be beneficial to osteogenic differentiation. The entry of the NRs into 3T3 cells are visualised directly utilising a confocal microscope. The spin coating affiliates the alignment of NRs at a macroscale, which induces elongation of cells into spindle-like shape and large-scale orientation along the NRs.

Conclusion

This study demonstrates the self-assembly, biosafety, traceability, and large-scale guiding effect of Cit/Tb-HAp NRs. Further study of the large-scale ordered osteogenesis of hBMSCs will be conducted in the future.

Fluorination of G4 PAMAM dendrimers for gene delivery

Lydia N. Dos Orfaos¹, Helena M. Tomás¹, João M. Rodrigues¹,²

¹ CQM - Centro de Química da Madeira - Universidade da Madeira, Ciências Exatas e da Engenharia, Funchal, PT; ² School of Materials Science and Engineering/Center for Nano Energy Materials, Northwestern Polytechnical University, Xi’an, CN

Introduction
Dendrimers are polymers that are widely used as drug/gene delivery vehicles since they present interesting properties, such as a well defined 3D structure, internal void spaces, and the ability of functionalization of their terminal groups. Fluorine has been incorporated in several drugs since it improves their bioavailability, protein-ligand interaction, and metabolic stability. Moreover, the presence of this element in polymers has also been shown to increase their transfection efficiency both in vitro and in vivo.

This work aimed at the fluorination of generation 4 poly(amidoamine) dendrimers (PAMAMG₄-NH₂) with 2,3,5,6-tetrafluoro-4-hydroxybenzoic acid (TFHBA) to obtain a new gene delivery vector with high cytocompatibility, increased transfection efficiency, and the possibility of traceability by magnetic resonance imaging (MRI). For comparison purposes, a non-fluorinated compound, the 4-hydroxybenzoic acid (HBA), was also used due to its resemblance with TFHBA.

Experimental Methods
The functionalization of the dendrimer with the TFHBA or HBA compounds involved their dropwise addition, at different molar equivalents (compound/dendrimer ratios), under stirring, to commercial PAMAMG₄-NH₂ solutions. The reactions were left to occur for two days. Conjugates were prepared at 8.5, 16.5, 32.5, 48.5, and 64.5 compound/dendrimer ratios. After a purification step by dialysis, dendrimers with different functionalization degrees were obtained and characterized by NMR (e.g., ¹⁹F, ¹H, ¹³C), FTIR, UV/visible, photoluminescence, and elemental analysis. The ability of the dendrimers to condense pDNA was assessed by the PicoGreen® assay. Cytotoxicity of the dendrimers and dendriplexes was evaluated using HEK 293T cells and the resazurin metabolic activity assay. Transfection efficiency was studied using the green fluorescence protein (GFP) and luciferase reporter genes by fluorescence microscopy and enzyme activity determination, respectively.

Results and Discussion
The conjugation of TFHBA or HBA with PAMAMG₄-NH₂ dendrimers was confirmed based on the analysis of the obtained structural data. Reaction yields were good, ranging from 88% to 97%.

The biological studies showed that the cytotoxic behaviour of the conjugates varied with the degree of functionalization. In general, the dendrimers prepared at high compound/dendrimer ratios were noncytotoxic at concentrations up to 90μg/mL, being the TFHBA conjugates less cytotoxic than their HBA counterparts and the pristine dendrimers PAMAMG₄-NH₂. Furthermore, the fluorinated dendrimers were able to condense pDNA and transfect HEK 293T cells more than the PAMAMG₄-NH₂ dendrimer by itself.

Conclusion
The functionalization of PAMAMG₄-NH₂ with the selected compounds HBA and TFHBA, at different ratios, was successfully achieved. The biological assays showed that these fluorinated dendrimers present low cytotoxicity and good transfection efficiency, clearly pointing out their potential application as new gene delivery vectors. Work is underway to explore the antibacterial activity of the compounds and their possible use against HIV and/or cancer.

Ascorbic acid and hydrazine as reducing agents for the synthesis of Cu DENPs

Duarte Fernandes¹, Carla S. Alves¹, João Rodrigues¹², Pedro Pires¹

¹ Universidade da Madeira, CQM - Centro de Química da Madeira, Funchal, PT; ² Northwestern Polytechnical University, School of Materials Science and Engineering/Center for Nano Energy Materials, Xi’an, CN

Introduction
As opposed to more expensive and less earth-abundant metals like silver and gold, copper-based nanoparticles (Cu NPs) are expected to be a more sustainable material. Also, the good electronic, antimicrobial, optical, and other physicochemical properties displayed by copper materials make them attractive for industrial applications. However, the use of Cu NPs is limited due to their intrinsic instability under atmospheric conditions, making them prone to oxidation. To increase the stability of Cu NPs, various efforts have been made involving, for instance, the association of Cu NPs and organic compounds such as polymers.

Experimental Methods
The purpose of this work was the development of a synthesis procedure of long-term stable Cu-based dendrimer entrapped NPs (Cu DENPs) and their characterization. Fourth-generation hydroxyl-terminated polyamidoamine (G4-OH PAMAM) dendrimer was used as a template for the controlled growth of the Cu NPs. Three temperature conditions were tested, 0º, 25º and 50 ºC. The environmentally friendly ascorbic acid was used as a reducing agent and an antioxidant. Hydrazine was also tried as a reducing agent. Experiments were performed using various ratios of only one of the reducing agents or both at the same time. The final product was purified by dialysis.

Results and Discussion
In contrast to ascorbic acid, hydrazine by itself was not suitable for this synthesis method, since it led to the formation of particles of sizes in the order of hundred nanometers as observed by Scanning Electron Microscopy (SEM). Over time ultraviolet-visible (UV-Vis) measurements of the prepared Cu DENPs, at optimal conditions, suggested a considerable stability of the NPs. Analysis by nuclear magnetic resonance (NMR) Spectroscopy indicated that the signals from the dendrimer were highly dependent on the nature of the Cu DENPs, which is most likely related to the Cu oxidation state. The NPs presented some fluorescence under UV light, and thus were also characterized by Photoluminescence (PL) Spectroscopy.

Conclusion
Although the results indicate the successful realization of our goal, complementary characterization, namely Transmission Electron Microscopy (TEM), are underway to better elucidate the size, structure, and chemical nature of the final product. Thereafter, biological studies will be performed to evaluate the cytotoxicity and antimicrobial activity of the final product.

Functionalized lipid nanocapsules for brain delivery of retinoic acid towards a dual assault on multiple sclerosis

Rui P. Moura1,2,3, Ana P. Pêgo1,2,4, Anne des Rieux5, Bruno Sarmento1,2,3

1 i3s - Instituto de Investigação e Inovação em Saúde, Nanomedicines & Translational Drug Delivery Research Group, Porto, PT; 2 ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Porto, PT; 3 CESPU - iiNFACTS Instituto de Investigação e Formação Avançada em Ciências e Tecnologias da Saúde ), Gandra, PT; 4 FEUP - Faculdade de Engenharia da Universidade do Porto, Porto, PT; 5 UCL-LDRI - Université Catholique de Louvain, Louvain Drug Research Institute, Advanced Drug Delivery and Biomaterials, Brussels, BE

Introduction

Acquired demyelinating diseases, namely multiple sclerosis, have a plethora of detrimental consequences. Currently, treatments which involve substances that promote remyelination are hindered by failure of active molecules reaching therapeutic concentrations in the brain. Through the use of a safe, solvent free, and rapid to scale up process of development of lipid nanocapsules we propose to tackle this limitation [1]. This work aims to establish functionalized lipid nanocapsules containing retinoic acid, a drug with dual demonstrated effects in oligodendrocyte progenitor differentiation into mature oligodendrocytes [2, 3], responsible for production of myelin, and inflammation and microglia activation control. The rationale behind the encapsulation and targeting is ensuring retinoic acid reaches effective, active concentrations at the central nervous system (CNS), where it would otherwise be impaired by the blood-brain barrier.

Experimental Methods

Lipid nanocapsules (LNC) were developed using a standard phase-inversion protocol [4] using our adaptations to tailor the nanocapsules for our suiting. Retinoic acid was previously dissolved in dimethyl sulfoxide and added as such to the nanocapsules. Super paramagnetic iron oxide nanoparticles (SPIONs), stabilized by oleic acid, were encapsulated within LNC using the same protocol. Size, PdI and zeta-potential measurements were performed using a Malvern Zetasizer ZS and the encapsulation efficiency of retinoic acid was measured by HPLC [5]. Stability assays were performed at pre-established ICH conditions. Transmission electron microscopy imaging of retinoic acid LNC and retinoic acid-SPION-LNC was performed using a Joel JEM 1400 microscope. A release assay under simulated biological media (PBS, pH 7.4, 37°C) was performed, assuring sink conditions.

The LNC were surface-functionalized with a transferrin-binding peptide through a post-manufacture procedure wherein NH2-Peg-Maleimide was incorporated into the shell, and linked by thiol conjugation via a terminal cysteine. Cell viability and uptake assays were performed in hCMEC/d3 cell line (passages between 51-59 were used). The viability assays were performed using the MTT reduction assay at 4- and 24-hours incubation time. The uptake assay was performed using Imaging Flow Cytometry (ImageStream). Cell viability is also being assessed in microglia cell lines. Furthermore, activation of this cell line by LPS and the impact of RA-LNC in inflammation resolution is currently underway.

Results and Discussion

RA-LNC were developed with 70 nm, a small, nominal size ideal for central nervous system, with a monodisperse cell population with zeta-potential of -5 mV. The encapsulation efficiency of retinoic acid was approximately 88%, with an effective drug loading of 0.20%. The SPION encapsulation was confirmed by TEM. LNC demonstrated stability at 4°C for upwards of 9 months, maintaining their physico-chemical properties and preserving RA, an otherwise unstable molecule, within its shell. The LNC release in a 196-hour window less than 0.5% of its payload,
demonstrating the ability to preserve the payload adequately and only release it when in contact with a cell through membrane fusion.

The functionalization process was assessed by size alterations in the LNC and by elemental analysis for the presence of Sulphur.

Cell viability showed a concentration related toxicity, namely due to the high amount of lipids in the LNC but was safe and tolerable to hCMEC/d3 at 1-10µg/mL of retinoic acid, well above its active concentration.

The uptake assay demonstrated high uptake of the RA-LNC by the endothelial cells, with preserved cell morphology. It is foreseen that the results from microglia will show strong uptake, as well as the resolution of inflammation in an LPS-activation assay (ongoing).

Conclusion

To sum, size-tailored, monodisperse LNC encapsulation both RA and SPIONs were developed and optimized, and assessed for their in vitro potential, showing good potential for therapy in demyelinating disorders. As of yet, only a safety profile and interaction with endothelial cells was assessed for the LNC, but results in microglia are soon to follow and an effect on the control of the activation and the inflammation that is typical of neurodegenerations is an expected result of the LNC.

Introduction
Orthopaedic implants, in consequence of the aging population, are frequently needed medical devices. Periprosthetic joint implant-associated infections (PJIs) are currently one of the leading causes of failure in primary and revision total knee and total hip arthroplasty. In USA and UK only, these infections are forecasted to have an annual rate of 38K-270K by 2030 [1]. PJIs are very difficult to treat particularly in patients with immune depressed systems, or relevant co-morbidities (e.g. diabetes), as well as in cases of trauma (infection rates around 30%) or after second surgery (revision surgery, up to 40%) [2]. Current treatment relies on systemically-administered antibiotics. However, the poor peri-implant vascularization may contribute for a low local antibiotic concentration insufficient to control infection. Moreover, antibiotic use may promote further antibiotic-resistance bacteria, as already seen by the significant prevalence of resistant strains isolated from PJIs [3]. Consequently, there is a demand for antibiotic-free alternatives, such as the exploration of antimicrobial peptides (AMPs)-based solutions.

Experimental Methods
Chitosan (acetylation degree of 6% and Mw= 342-393 kDa) was used for nanogel production due to its biocompatibility, ease of functionalization, degradation potential, and also due to its antimicrobial and osteogenic activity [4]. Chitosan was purified and functionalized with norbornenes (Norchip), the “enes” with highest reactivity, through the reaction with carbic anhydride [5].

Norchip nanogels were produced by water-in-oil nanoemulsion through thiol-ene photo-crosslinking using 1,4-Dithiothreitol (DTT), a di-sulphydryl linker, and non-toxic photoinitiator (VA-086) under UV photoactivation. After production, crosslinked nanogels were recovered by centrifugation, and subsequently washed with ethanol and type II water gradients. The hydrodynamic diameter (dh) and ζ potential of the nanogels were both measured with a Malvern NanoZetasizer. Later, to optimize the nanogels conjugation with AMP, a surrogate was used (the aminoacid N-acetyl-cysteine (NAC)). Then, the same conjugation protocol was applied with an AMP and immobilization was confirmed by Fourier Transform Infrared Spectroscopy analysis (FTIR).

For the stability assays, nanogels were immersed in phosphate buffer solution (pH 5.8) at room temperature during 7, 14 and 1 month, and then characterized by Zetasizer.

Results and Discussion
The obtained nanoemulsions, revealed particles with homogenous size distribution (~120 nm, PDI 0.2) and with a neutral charge. The UV-crosslinking was successfully achieved allowing the formation of particles that were stable during 14 days at pH 5.8. In addition, the conjugation of nanogels with NAC proved feasibility of the conjugation protocol, allowing the effective immobilization of AMP as demonstrated by FTIR.

Conclusion
Norbornene functionalized chitosan is a dual benefit biomaterial as under UV photoactivation allowed the production of nanogels and biological molecule interest immobilization. The obtained homogeneous conjugated-nanogels are
currently under *in vitro* bacterial tests. Altogether, this strategy has the potential to create a new biomaterial with efficient antimicrobial activity, to mitigate PJI’s hurdle without promoting further antibiotic resistance.

Factors affecting bio-artificial liver prototype performance

Neda Heidari, Susan Sandeman, Richard Faragher
university of brighton, school of pharmacy and biomolecular sciences, Brighton, GB

Introduction

Acute liver failure (ALF) and acute chronic liver failure (ACLF) are life-threatening conditions with mortality rates of up to 85%. The only reliable treatment is orthotopic liver transplantation but there is a shortage of organ donors. In the UK ~29% of patients wait for a transplant for more than 6 months and 8% die before receiving one. This shortage of organ donors and the high mortality rate for patients with liver failure has led to the development of alternative liver replacement strategies to either bridge patients to transplantation or temporarily support native liver function for recovery to occur. Bioartificial livers (BALs) have been developed to overcome the limitations associated with non-biological devices and also to replace the metabolic activities of the liver (1). There are different designs incorporating hepatocytes within a biocompatible matrix. However, none have shown a significant survival benefit for patients in clinical trials to date. One potential limitation for these devices is the rapid reduction in hepatocyte function after exposure to patient plasma over time. Evidence from studies exposing hepatocytes to toxin containing ALF plasma suggests that there is a detrimental effect on hepatocyte function leading to the hypothesis that factors in liver toxin loaded plasma plays a role in altered hepatocyte physiology and reduced BAL function (2). The aim of this study was therefore to investigate the role and significance of liver toxin exposure on hepatocyte cell cycling and other phenotypic characteristics linked to function in a macroporous cryogel bioartificial liver prototype material.

Experimental Methods

In this study, HHL7 and HepG2 cells characterisation was established by immunocytochemistry assay for the presence of non-parenchymal and parenchymal phenotype marker in liver cells lines. Their characteristics were also compared with non-liver cell lines 3T3.

In order to establish a hepatocyte extracellular matrix model in the BAL prototype, HEMA-MBA cryogels were synthesised and modified with alginate to provide a 3-D environment for HepG2 and HHL-7 cell lines. HepG2 and HHL-7 cells viability was measured by MTT and live and dead assays on HEMA-MBA-Alginate cryogels for 7 days. Key metabolic functions such as albumin synthesis and urea production were measured in cryogels (3-D surface)seeded with hepatocytes and their functions were compared with hepatocytes on 2-dimensional surfaces. Also, an effective method was improved to measure hepatocytes cells proliferation and viability after exposure to different water and lipid-soluble liver toxins. Albumin and urea production was measured using standard assay kits in 3D cultures of HepG2 cells exposed to medium loaded toxins over clinically relevant periods of time (6 to 8 h).

Results and Discussion

The results of the ICC assay shows that parenchymal marker CK8 was present in all cell lines (HHL-7 and HepG2) with the exception of the non-liver cell (3T3 cell line). The non-parenchymal phenotype marker CK7 was found in HHL-7 but was absent from the HepG2 and 3T3. Therefore, HHL cell lines retained the expression of CK7 and CK8 and maintained primary hepatocyte phenotype.

The 3D porous scaffold from hydroxyethyl methacrylate -based cryogels provided a conducive microenvironment for HHL-7 and HepG2 cells to proliferate and improved their function compared to two-dimensional surfaces. The cell viability for both HepG2 and HHL-7 cell lines increased after 7 days of incubation. However, the difference is not statistically significant. The data obtained shows that this polymer could maintain cell viability over 7 days of incubation. Also, the function of liver cells including albumin production and urea synthesis grown on three-dimensional scaffolds was enhanced compared to the activity of cells grown on two-dimensional surfaces. The results

Page 1863 of 2028
suggest that HepG2 and HHL-7 liver cell function in three-dimensional environments more closely mimic physiological responses than existing two-dimensional culture systems. Further, the data in this study shows that exposing HepG2 cells to liver toxins treatment caused a significant alteration in cells phenotype and a disturbance in the cell cycle. Also, a subsequent decline in synthetic functions of HepG2 cells was observed after liver toxins treatment.

Conclusion
The 3-D culture system in this study was biocompatible and retrained the hallmarks of hepatocytes-specific functions by albumin and urea production. Also, liver toxins treatment had negatively affect hepatocytes proliferation and functions on both 2-D and 3-D surfaces. In future work, a vitro model of liver failure will be set up to assess the impact of liver toxins treatment on bioartificial liver prototype performance and develop methods to suppress these effects in the BAL prototype.

Investigating Cell ‘Visco-Transduction’ in Engineered Viscoelastic Hydrogels

Ludovica Cacopardo, Nicole Guzzelli, Simona Piaggi, Alessandro Corti, Arti Ahluwalia

University of Pisa, Pisa, IT

Introduction
Despite tissue intrinsic viscoelasticity, only recently mechanobiology studies started investigating cell response in the light of time dependent substrate properties. However, these studies are usually based on hydrogels where both viscous and elastic properties are altered at the same time [1-2]. For this reason, we engineered hydrogels with a constant equilibrium elastic modulus and different characteristic relaxation times that can be modulated varying the liquid phase viscosity without modifying the crosslinking of the solid network [2].

Here, we optimised agarose gel properties for the culture of adipose-derived mesenchymal stem cells (ADSCs) in order to understand if they are able to sense and respond to substrates with different viscous properties.

Experimental Methods
0.5% w/v agarose gel were fabricated using aqueous solutions with increasing dextran concentrations (0, 3, 4 % w/v), and hence viscosities. Mechanical properties were investigated using the epsilon-dot method [3]. ADSCs (50.000 cells/cm²) were cultured for 21 days on the gels with 0 (high τ) and 4% (low τ) w/v dextran coated with 5% w/v gelatin and in 96-well multiwell plates (τ → ∞) as controls. The experimental setup is schematized in Figure 1D. The Alamar blue assay was performed at different time points and cell viability was normalised for the cell number obtained via image analysis. In order to optimise culture times for cell differentiation, at day 7 and 21, controls cells were fixed with 4% paraformaldehyde and permeabilized with 0.01% w/v Triton-X. Samples were thus incubated overnight with Yes-associated protein (YAP) and CD45 (negative marker for cell stemness) primary antibodies and, then, for 2h with the respective secondary antibody. Finally, nuclei were stained with DAPI and actin with rhodamine-conjugated phalloidin (ThermoFisher, USA). Images were acquired with a confocal microscope (Nikon A1, Japan).

All reagents were purchased from Sigma-Aldrich (Milano, Italy), unless differently specified.

Results and Discussion
Results showed a significant decrease of the instantaneous elastic moduli (Einst) and of the relaxation time (τ), while the equilibrium elastic modulus (Eeq) did not vary significantly (Figure 1A-B). Moreover, Eeq resulted in the optimal range to mimic the mechanical properties of the stem cell niche (≅ 3 kPa [2]). In all culture conditions, cells showed an increasing viability with increasing culture time (Figure 1C). Finally, in Figure 1E-G, it is possible to observe that, in the controls, cells started to differentiate at 21 days as shown by YAP migration in the nucleus and CD45 expression in the nuclear membrane.

Further experiments are ongoing to better analyse cell differentiation in all the substrates by means of tissue specific stainings, morphological and gene expression analysis. After the investigation of cell ‘visco-transduction’, further studies will be performed to understand if cell behaviour is influenced from past viscous stimuli.

Conclusion
Hydrogels with tunable viscoelastic properties were adapted for the culture of ADSCs, thus allowing to study cell response to substrate with different τ. In particular, culture times were optimised observing cell differentiation in the controls after 21 days. The final goal is the definition of optimal substrates to preserve their undifferentiated status in
culture, in order to develop more physiologically relevant in-vitro models to study cell responses to mechanical alterations of their environment.

Tissue-mimicking Gelatin Microgels Implement 3D In Vitro Nanotoxicity Screening

Eunheui Gwag\textsuperscript{1,2}, Leon Abelmann\textsuperscript{1,3}, Andreas Manz\textsuperscript{1,4}, Baeckkyoung Sung\textsuperscript{1,2}

\textsuperscript{1} KIST-Europe, The Environmental Safety Group, Saarbrucken, DE; \textsuperscript{2} University of Science and Technology, The department of Energy & Environmental Engineering, Daejeon, KR; \textsuperscript{3} University of Twente, MESA+ Institute for Nanotechnology, Enschede, NL; \textsuperscript{4} Saarland University, Department of Systems Engineering, Saarbruecken, DE

Introduction

Although metallic nanoparticles (NPs) have been extensively studied in pharmaceutics applications, the potential adverse effects of the NPs on the human health and related biological mechanisms are not clear\textsuperscript{1,2}. Conventional \textit{in vitro} nanotoxicity assessments based on 2D cell culture methods are limited in their capability to provide mechanistic information on the NP-cell interactions that occur in the 3D microenvironments of biological tissues\textsuperscript{3}. The nanotoxicity can be demonstrated using human liver cell (HepG2 cell line) models as the nanoparticles can accumulated in the liver regardless of the administration method\textsuperscript{4}.

In this presentation, we show a 3D nanotoxicity screening platform in which HepG2 cells are encapsulated in covalently cross-linked gelatin microgels. Using this colloidal platform, we investigate the toxicity of silver NPs on 3D cultures of HepG2 cells, and compare the (sub-)cellular responses and effects of toxicity with the conventional 2D cell cultures.

Experimental Methods

HepG2 cell-laden gelatin droplets were generated using water-in-oil mini-emulsification. After physical gelation by cooling, a plant-derived cross-linker genipin was added for \textit{in situ} covalent cross-linking of gelatin chains to form stable microgel bead\textsuperscript{5}. The suspension of cell-embedded microgels was then exposed to Ag-NPs for 24-hour with varying dosage at 37 °C with 5% CO\textsubscript{2}. Liver cytotoxicity was quantified by measurement of the cell viability and lipid droplet formation using fluorescence microscopy. The extent of oxidative stress was measured by microplate spectrophotometer. For this, we used the assays of Live/Dead\textsuperscript{®} fluorescence, 2',7'-dichlorofluorescein diacetate (DCFDA), and boron-dipyrromethene (BODIPY 505/515) staining. The cells were indicated using 4',6-diamidino-2-phenylindole (DAPI) staining. The amount of Ag\textsuperscript{+} from dissolved Ag-NPs was quantified using inductively coupled plasma mass spectrometry (ICP-MS), and the cytotoxicity of Ag\textsuperscript{+} was investigated using Ag\textsubscript{2}NO\textsubscript{3}. The results of the microgel-based 3D cell cultures were compared to standard 2D culture. The Ag-NP suspensions in cell culture media were characterized using dynamic light scattering (DLS) and zeta potential measurements.

Results and Discussion

Spherical gelatin microgels had an average diameter of 343±7 μm and encapsulated 4-120 cells depending on the size. Cytotoxicity comparisons were made between the dose-response curves of 2D and 3D cultures of HepG2 cells. The cell viability results showed that the cells encapsulated in a gelatin microgel were less affected by Ag-NP. Furthermore, Ag\textsuperscript{+} had no significant differences in 2D and 3D cultures in terms of cytotoxicity. The dependence of cell viability on the strength of oxidative stress was quantified as a function of Ag-NP concentration. We observed an increase in oxidative stress that induced mitochondrial dysfunction and elevated lipid droplet accumulation. The differences in lipid metabolism and cell viability for 2D and 3D cultures indicated that the nanotoxicity mechanisms in different tissue microenvironments on a subcellular level.

Conclusion

We conclude that the HepG2 cells in 3D gelatin microgel are less sensitive to the adverse effects of Ag-NPs in the level of cell membrane integrity and mitochondrial activities.

Control of Nuclear Deformation of Polarized Macrophages on Micropatterned PMMA Surfaces

Ezgi Antmen1, Eric Mathieu4, Nihal E. Vrana3,4, Vasif Hasirci1,2

1 Middle East Technical University, Center of Excellence in Biomaterials and Tissue Engineering, Ankara, TR; 2 Acibadem University, Biomaterials R&A Center and Department of Medical Engineering, Istanbul, TR; 3 SPARTHA Medical, 14B Rue de la Canardiere, Strasbourg, FR; 4 INSERM Unité 1121, Biomaterials and Bioengineering, CRBS, 1 Rue Eugène Boeckel, Strasbourg, FR

Introduction
Chronic inflammation and foreign body response are crucial in the long term in vivo performance of implants. Macrophages are an important part of this response and their phenotype is a defining determinant of how an implant will integrate with the host. For proper implant integration, polarization of macrophage subpopulations should shift from an M1 phenotype (pro-inflammatory) to an M2 phenotype (anti-inflammatory). M1 macrophages are known as classically activated macrophages and show a pro-inflammatory phenotype during the early stages of the tissue repair process. On the other hand, M2 macrophages are known as alternatively activated macrophages and show an anti-inflammatory expression profile.1 Thus, to prevent excessive inflammation, macrophage polarization should be towards M2. We hypothesize that as highly plastic cells biomaterial surfaces can modulate the nuclear deformation of macrophages and hence their polarization since shape, migration and adhesion of cells are influenced by the surface topography of a substrate. Several studies, including ours, have shown that many cell types react strongly to microtopography.2 Control of the material surface topography gives the opportunity to change macrophage function, phenotype and polarization.3 Previously, the effect of nanogratings and microscale protein patch patterns on macrophage polarization have been shown.4,5 However, the effect of micropatterned substrates on polarization of the macrophage nuclei has never been tested. We hypothesize that this line of study would give important information about the mechanisms of polarization of the macrophages on biomaterials. Thus, in the proposed project, nuclear distortions of the macrophages on micropatterned surfaces were analyzed by using an image analysis software and a correlation of the nuclear deformation with the polarization of macrophage cells were correlated.

Experimental Methods
Micropatterned PMMA surfaces designed with square prism shaped pillars with 4x4 µm² area with 4 µm gap were used. Surfaces were produced by soft lithography and solvent casting method. RAW 246.7 monocytic cell lines were studied on these micropatterned surfaces. Cells were seeded on micropatterned surfaces first and then they were differentiated into M1 and M2 phenotypes with LPS and IL-4, respectively. After 24 h culture duration, nuclear morphology and cytokine secretions of the cells were analyzed with the help of confocal laser scanning microscopy (CLSM) and scanning electron microscopy (SEM).

Results and Discussion
RAW 246.7 macrophage cells were seeded on micropatterned surfaces and they were polarized into M1 (with LPS) and M2 (with IL-4) phenotypes. With CLSM and SEM, nuclear deformability and cell cluster formation were analyzed. The results show that there is a distinct difference between M1 and M2 macrophages in terms of their nuclear deformation, adhesion and cluster formation which has not been reported before in the literature. CSLM showed that nuclei of M1 cells deformed completely whereas M2 did not show any nuclear deformation (Figure 1). SEM showed that M2 macrophages formed more distinct clusters whereas M1 macrophages spread more on the surfaces (Figure 2). Both cells resulted in pillar bending but with M2 it was more distinct probably due to the crowded clusters of cells which applied much force on the pillars.
Conclusion
In this study, the effect of micropatterns on the polarization of the same starting cells is presented (same passage, same conditions, only stimulation is different. With the use of surface topography, immunomodulation of the incoming immune cells was achieved.

Nanophase surface roughness enhances neural cell functions

Didem Mimiroglu¹,², Tulin Yanik³,¹, Batur Ercan⁴,⁵,⁶

¹ Middle East Technical University, Biochemistry, Ankara, TR; ² Sivas Cumhuriyet University, Biochemistry, Sivas, TR; ³ Middle East Technical University, Department of Biological Sciences, Ankara, TR; ⁴ Middle East Technical University, Department of Metallurgical and Materials Engineering, Ankara, TR; ⁵ Middle East Technical University, BIOMATEN, Ankara, TR; ⁶ Middle East Technical University, Department of Biomedical Engineering, Ankara, TR

Introduction
There are various factors important in the design of nerve guidance conduits (NGCs) used in peripheral nerve injuries. These factors include biodegradability, conductivity, permeability and supporting neural cell adhesion, proliferation and migration. Since the structure of molecules and cell-ECM interactions occur within the nanoscale, the surface of NGCs implanted should mimic the nanophase topography of ECM. While there are many studies investigating the effects of nanophase topography on various cells types, i.e. endothelial cells, mesenchymal stem cells, fibroblasts, etc., studies focusing on the effects of nanophase (<100nm) topography on neural cell functions are limited. As a matter of fact, most studies in neural tissue engineering focus on submicron level (>100nm) surface topography. Therefore, the aim of the study was to investigate the effects of <100nm topographical structures on poly(lactic-co-glycolic) acid (PLGA) on neural cell functions.

Experimental Methods
Nanopit features possessing 30 and 80 nm diameters were formed on stainless steel by anodization, and these structures were transferred onto PLGA surfaces via replica molding method. To confirm whether nanophase topographies were correctly obtained, scanning electron microscopy (SEM) and atomic force microscopy (AFM) characterizations were conducted. Additionally, hydrophobicity of the surfaces were determined using sessile drop water contact angle measurements. For the neural cell viability (mouse neuroblastoma N2a cell line), MTT analysis was conducted. To understand neural cell spreading, cells were stained with DAPI, vinculin, and f-actin. Finally, neural cell activity was assessed with c-fos protein expression levels by Western-blotting.

Results and Discussion
It was confirmed that nanophase topographies were successfully transferred onto PLGA surfaces. Sessile drop water contact angle measurements showed that hydrophilicity increased on surfaces having nanophase topographical features. For the proliferation studies, cellular density was found to increase up to 2-folds for nanophase surfaces compared to control ones on the 3rd and 5th days of culture. As a result of the neural cell spreading, it was found that more neurite extensions were formed on nanophase topographical surfaces (A and B) than the control (C, Fig. 1). Additionally, c-fos protein expression levels increased up to 2-fold for nanophase topographical surfaces than the control.

Conclusion
As a conclusion, the nanophase topographies successfully transferred onto PLGA surfaces, and these topographies were correlated with the increase in hydrophilicity. Additionally, it was observed that nanophase surface topography had favorable effects for cellular proliferation, cell spreading and cellular activity on neural cells. All of these results showed that fabrication of <100nm sized topographical features is a promising approach for NGC applications.

Assessment of cell-biomaterial interactions in three dimensional hybrid spheroidal assemblies

Maria Gabriella Fois, Niloofar Z. Tahmasebi Birgani, Alexander P.M. Guttenplan, Clemens van Blitterswijk, Stefan Giselbrecht, Pamela Habibović, Roman Truckenmüller

Maastricht University, MERLN Institute for Technology-Inspired Regenerative Medicine, MAASTRICHT, NL

Introduction

Conventional 'two-dimensional' (2D) cell culture on (bio)material surfaces is still commonly employed for the early-stage assessment of interactions of cells or tissues with materials considered for biomedical applications. However, simplified 2D culture models often fail to mimic key aspects of the 'three-dimensional' (3D) microenvironment of cells in human tissues [1], and therefore, are increasingly complemented or replaced by 3D models. The spheroid model [2] presents a more close-to-native spatial configuration of cell-cell and cell-matrix contacts and more realistically recapitulates gradients of soluble factors such as signaling molecules existing in human tissues. Spheroids are more and more the culture model of choice for toxicity and efficacy testing of pharmaceutical or other soluble compounds [3]. Here, we present a novel in vitro platform based on spheroids from cells and microsized biomaterials, as a 3D model of the interaction between cells and biomaterials in human tissues. The presented cell-microbiomaterial spheroid model can be a valuable tool for assessing interactions of cells and either materials for classical biomedical devices or dedicated/designed microbiomaterials. The latter in turn can be applied for building hybrid microtissues for academic fundamental R&D, for industrial toxicity and efficacy testing, or for clinical (regenerative medicine) applications, for example, via bioprinting or bottom-up tissue engineering.

Experimental Methods

We showcase our approach by the example of MG63 osteoblast-like cells and human mesenchymal stromal cells (hMSCs), and a small library of shape- and size-harmonized model microbiomaterials. Practically, the microbiomaterials are three-dimensionally dispersed in the spheroids by co-aggregation. The cell behavior in response to the interaction with the micromaterials is then evaluated according to the considered target application.

Results and Discussion

The self-assembly of the microbiomaterials and the cells is supported by low-attachment geometrical confinements in the form of functionalized round-bottom microwells densely packed in arrays. Fabricated from thin and highly transparent polycarbonate films, these advanced microwell arrays are suitable for both high-throughput and -content imaging. We validated our approach by addressing cell-biomaterial interactions such as cell adhesion to the material, the hybrid spheroids' morphology, material-related cell death/cytotoxicity of the material, cell metabolic activity, cell proliferation and (osteogenic) differentiation. The cells in the hybrid spheroids were viable and metabolically active after 7 days of culture, presenting acceptable levels of cell death compliant to the selected (micro)biomaterials. To demonstrate the use of the hybrid spheroidal model for the evaluation microbiomaterials for bottom-up tissue engineering of bone, we investigated osteogenic differentiation in spheroids aggregated from cells and microparticles of bionert, e.g. smooth titanium, and bioactive, e.g. tricalcium phosphate (TCP), biomaterials. High levels of ALP activity, a well-known early osteogenic marker, were measured for hybrid spheroids containing TCP biomaterials, in the absence of stimulation through soluble osteogenic factors. The obtained results were benchmarked against a conventional 2D culture counterpart, by the evaluation of the aforementioned cell behaviors on flat surfaces presenting chemistries similar to that of the microparticles.

Conclusion
Overall, using bioassays with different readouts, we showed that the cell response to differences in the properties of the microbiomaterials, their amounts or dosage, and the duration of interaction with or times of exposure to them can be accurately measured in the hybrid spheroid model. Outlooks for this technology include normalization and standardization efforts, for example, in conjunction with developing consistent methods for microbiomaterial processing, increasing throughput via automated workflows, and further advancing miniaturization, for example, by integrating microfluidic-based technologies. Biologically, the aim is to branch out to the generation of more complex in vitro assemblies, thereby recapitulating native multicellularities and structural organization in the hybrid spheroids.

Directing Mesenchymal Stem Cells osteogenic differentiation by varying hydrogel stress relaxation

Emilie Prouvé1,2, Murielle Rémy2, Pascale Chevallier1, Drouin Bernard1, Marie-Christine Durrieu2, Gaétan Laroche1

1 Laval University, Laboratoire d’Ingénierie de Surface, Centre de Recherche sur les Matériaux Avancés, Département de Génie des Mines, de la Métallurgie et des Matériaux, Université Laval, Axe Médecine Régénératrice, Centre de Recherche du Centre Hospitalier Universitaire, Quebec, CA; 2 Bordeaux University, Univ. Bordeaux, CNRS, Bordeaux INP, Chimie et Biologie des Membranes et Nano-Objets UMR5248 CBMN, Pessac, FR

Introduction
Mesenchymal Stem Cells (MSCs) are adult stem cells which have gained high interest in regenerative medicine considering their self-renewal ability, multipotency, ease of access, and high proliferative rate. However, the use of MSCs in clinical applications still requires a better understanding of their biological behavior to provide the ability to control their in-vitro differentiation into a specific lineage needed for therapy1. While many studies have evaluated the impact of hydrogel stiffness on stem cells behavior, it is now acknowledged that hydrogels, as well as biological tissues, are intrinsically viscoelastic. In addition, some recent studies demonstrated that hydrogel stress relaxation can influence cell differentiation2. However, these studies sometimes led to contradictory results, and their number is still limited. Consequently, it is of particular interest to supply hydrogels with different controllable stress relaxation properties, to further assess their impact on MSCs differentiation.

Experimental Methods
Poly(acrylamide-co-acrylic acid) hydrogels were synthesized by varying the amount of crosslinker (bis-acrylamide) and the ratio between the two monomers to obtain hydrogels with controlled stiffness and relaxation profiles. The mechanical properties of the gels were measured by compressing the gel disks to 5 consecutive steps of 3% strain with a deformation rate of 1 mm.min⁻¹ and a relaxation time of 2 hours, using a Mach-1 V500CS (Biomomentum, Canada) apparatus. For cell culture experiments, the hydrogels were functionalized with a BMP-2 mimetic peptide via sulfo SANPAH under UV irradiation. After ethanol sterilization, human bone marrow MSCs were seeded on the gels at a density of 3 000 cells per cm² and cultured in Osteogenic Differentiation Medium (Promocell, Germany) at 37°C and 5% CO₂ for two weeks. The expression of Runx-2, osteopontin and E11 were assessed by incubating cells for 1 h at 37 °C with rabbit monoclonal anti-Runx2 (1:1600 dilution), or mouse monoclonal anti-osteopontin (1:200 dilution), or anti-podoplanin primary antibody (2 µg/mL), then with the secondary antibodies Alexa Fluor™ 647 goat anti-mouse IgG and Alexa Fluor™ 488 goat anti-rabbit IgG (1:400 dilution) for 1 h at 37 °C.

Results and Discussion
In this study, poly(acrylamide-co-acrylic acid) hydrogels were synthesized with an almost identical stiffness of around 55 kPa, as this value lies within the range of stiffnesses that have been found to promote MSCs osteogenic commitment. Then, it has been found that the stress relaxation increases with the amount of acrylic acid in the gel, with hydrogels containing 0%, 10%, or 18% of acrylic acid exhibiting an average relaxation of 15%, 30%, and 70%, respectively. Subsequently, the hydrogels were functionalized with a mimetic peptide of the BMP-2 protein, known to favor MSCs osteogenic differentiation3,4. Thereafter, human bone marrow MSCs were cultivated on the hydrogels with different stress relaxation for two weeks in osteogenic culture medium. The morphology of the cells was first considered by visualizing cell cytoskeleton. As shown in Figure 1, MSCs on glass in osteogenic culture medium (Fig. 1a) are large, highly spread, and exhibit a cuboidal morphology typical of osteoblasts, while the cells on the different...
hydrogels (Fig. 1b-c-d) present a smaller cell body and a dendritic morphology characteristic of osteocytes. Quantification of Runx-2 (Fig. 1e) expressed in osteoblasts, osteopontin (Fig. 1f), expressed in osteoblasts and osteocytes, and E11 (Fig. g), strongly expressed in early osteocytes, revealed a higher expression of the three markers on hydrogels with 30% and 70% relaxation, as compared to the hydrogel with 15% relaxation and to MSCs on glass.

**Conclusion**

This study shows the importance of considering the impact of hydrogels viscoelastic properties on MSCs differentiation, as hydrogels with higher stress relaxation (30% and 70%) promoted higher expression of Runx-2, osteopontin, and E11, which indicates a more advanced differentiation, as compared to pure polyacrylamide hydrogels presenting a low relaxation (15%). Furthermore, this study highlighted that the combination of the BMP-2 mimetic peptide with these hydrogels seems to promote a differentiation into osteocytes, which is unprecedented in vitro, and therefore constitutes a major step towards the study of hMSCs osteogenic differentiation. Future work will aim at evaluating the expression of other osteocyte markers, such as DMP-1 and sclerostin, in order to identify the best hydrogel mechanical properties for MSCs osteogenic differentiation, as well as assessing the impact of different biomolecules on MSCs differentiation.

Introduction
Orthopedic device-related infection (ODRI) represents a major threat to the success of orthopedic and trauma surgeries. With an incidence ranging from 1 or 2% in case of elective joint replacement up to 30% in complex open fractures, ODRI significantly affects patients’ recovery and compliance. Due to the inaccessibility of the infection site, current therapies rely on high dosage prolonged systemic antibiotic treatments, which can increase the risk of resistance development. Moreover, when antibiotics are not resolutive, surgical revision is required causing not neglectable burden on the healthcare system. ODRI is mainly associated with contamination happening during the surgery which cannot be avoided in toto. Nonetheless, hematogenous infections can jeopardize even first successful operations. Upon contamination, bacteria adhere to the surface of the implant and form a biofilm through the production of extracellular polymeric substances (EPS). These form a matrix that acts as a barrier hampering the action of immune response and antibiotic treatments.

Our group has recently reported the application of an in-house discovered antibiofilm compound, based on the 2-aminoimidazole core, for the prevention of Staphylococcus aureus biofilm formation on titanium surfaces1. The active compound LC0024-NH2 was covalently bonded ensuring activity retention in the long term.

In this work we present an optimized coating procedure that resulted in higher loading and enhanced activity in vitro. The coating was challenged with common sterilization procedures and co-administration with antibiotic was also performed. Finally, an in vivo biocompatibility experiment was carried out with coated implants on a rabbit osteotomy model.

Experimental Methods
LC0024-NH2 was covalently bonded onto the surface of titanium disks and orthopedic implants (i.e. locking compression plates (LCPs) and screws) by formation of ureidic bonds. To this mean the titanium surface was first functionalized by treatment with 3-aminopropyltriethoxy silane. Hexamethylene diisocyanate was employed as a linker between the aminated surface and LC0024-NH2. Loading of the active compound was assessed by fluorescence spectroscopy upon hydrolytic cleavage. The antibiofilm activity of the coating was tested against a clinical isolate of Staphylococcus aureus (JAR060131) by growing the biofilm on the surface of the titanium disks in static conditions for 24 h. The number of planktonic and biofilm cells was determined by plate counting. The effect on biofilm formation was also visualized by scanning electron microscopy (SEM) upon fixation with glutaraldehyde. The effect of antibiotic co-administration was assessed by treatment of 24h biofilms with cefuroxime. Stability of the coating against sterilization procedure (steam sterilization and exposure to ethylene oxide) was evaluated by means of both chemical analysis and in vitro assays. In vivo biocompatibility of the coated implants was assessed in a rabbit model.
osteotomy model using female New Zealand white rabbits. The effect on fracture healing was assessed 8 weeks after the surgery.

Results and Discussion
The optimized coating allowed for a 5-fold increase in loading while shortening the procedure with one step as compared to our previous report. The coating proved to be resilient to common sterilization procedures. The increased loading also resulted in a higher activity against biofilm formation, causing a 1 log reduction in biofilm cells without affecting planktonic cell viability. This biofilm-specific activity is a key feature of our approach since, by specifically interfering with the production of biofilm public goods, the chance of resistance development is reduced. As reported in our recent study on *Salmonella*, strains sensitive to the inhibitor are able to exploit the public goods produced by the resistant strains. This lets the sensitive population overcome the resistant one which is in turn counter-selected. When treated with antibiotic the biofilm grown on the coated surface experienced an additional reduction in biofilm cells as compared to the biofilm grown on the control uncoated titanium disks. Finally, the coating was successfully applied on locking compression plates (LCPs) and screws used in the *in vivo* study. The coating did not interfere with fracture healing nor enhanced the inflammatory response.

Conclusion
In this study we reported an optimized coating procedure to covalently bind the antibiofilm compound LC0024-NH₂ on titanium surfaces. This resulted in higher loading and enhanced activity *in vitro*. When applied to fracture fixation devices the coating did not negatively affect fracture healing in a rabbit osteotomy model. These positive results pave the way for future translational studies where we aim to confirm the effectiveness of the optimized coating against infection in vivo. Furthermore, they put our technology one step closer to clinical trials, confirming its potential in fighting ODRI without inducing local toxicity.

Figure 1. Coating structure and antibiofilm activity
Chemical structure of the antibiofilm compound LC0024-NH₂ and schematic representation of the coating sub-units are shown (top).
*In vitro* characterization of planktonic growth and biofilm formation of *S. aureus* JAR060131 on LC0024-Ti disks. The coating showed no effect on planktonic cells whilst the number of biofilm cells was significantly reduced compared to the control grown on uncoated disks (bottom).
Figure 2. SEM pictures and rabbit osteotomy model
SEM-BSE images of fixed biofilms grown on control-Ti (uncoated) and LC0024-Ti (coated) disks are shown (top). The surface of the coated disks showed mainly isolated cells whereas aggregates of biofilm cells are visible on the surface of the control uncoated disks. Intra-operative pictures of the surgical site after placement of uncoated and coated plates are shown. The radiographic pictures show complete bridging of the osteotomy gap and formation of periosteal callus (bottom).

Introduction
Proteins are the first biological component to arrive to the surface of any medical device inserted in the body, thus determining subsequent interactions with other biological systems (mammalian cells or bacteria), and ultimately the device’s biological fate. Graphene-based materials (GBMs), promising candidates for biomedical applications [1,2], have been shown to interact strongly with proteins [3]. The physicochemical features of GBMs-integrated surfaces, as surface roughness, chemistry and wettability, drive the mechanisms of interaction and the type of proteins that adsorb [3, 4], and so it is of paramount relevance to better understand this interaction. Studies focused on the potential and impact of this GBMs-protein interaction are however scarce, with proteins being often neglected in biological studies. Here, films produced with GBMs with different features were incubated with human plasma proteins and evaluated by proteomic analysis, in order to clarify the impact of surface features, as oxidation degree, roughness, or wettability, on protein adsorption.

Experimental Methods
GBMs with different layer thickness and oxidation degree, namely graphene oxide (GO) and reduced GO (rGO) (0.34 nm thick) and graphene nanoplatelets (FLG) and their oxidized form (FLGO) (6-8 nm thick), were used to produce films by vacuum filtration. GBMs films were characterized regarding elemental composition and functional groups (XPS), crystallinity and structural properties (XRD), surface topography (SEM, AFM), and wettability (contact angle measurements). Protein adsorption to films was conducted using a pool of four donors of human plasma, to reduce the impact of plasma donor variability. Plasma was added on top of GBMs films and incubated for 3 h at 37 °C under static conditions. Surfaces were then gently rinsed with dH\textsubscript{2}O to remove unbound proteins. Adsorbed proteins were solubilized, and each sample was processed for proteomics analysis, following the solid-phase-enhanced sample-preparation protocol [5]. Enzymatic digestion was performed, and peptide concentration determined using the quantitative fluorometric peptide assay. Peptides from each condition were the injected in the nanoscale liquid chromatography coupled with mass spectrometry (nanoLC-MS/MS) for protein identification and quantification. Raw data was processed using Proteome Discoverer 2.4.0.305 software and searched against the UniProt database for Homo sapiens Proteome 2019_09. At least two unique peptides were considered for protein analysis.

Results and Discussion
XPS shows high content of oxygen-containing groups in oxidized films (GO and FLGO, \sim32\%), with intermediate levels in rGO (13.5\%) and negligible amounts in FLG (3.5\%) films. XRD confirms that intrinsic crystallinity and structural properties of raw GBMs is kept in films. SEM shows sharp edges exposed in FLG films, while a wrinkled surface with fused platelets is observed on oxidized and rGO films. AFM, however, highlights some differences: GO and FLGO films have a smoother surface, nanotopography, and low height variation, while rGO and FLG present microtopography, high peak to valley height heterogeneity, and more flat areas. Oxidized surfaces are hydrophilic, while rGO and FLG get closer to hydrophobicity.
Plasma proteins incubation with films clearly shows that proteins adsorb in higher amounts to reduced or non-oxidized films (26.5% on rGO, 49.3% on FLG), contrary to oxidized surfaces (8.3% on GO, 7.6% on FLGO), highlighting the impact of GBMs oxidation degree on protein adsorption. The most abundant proteins in human plasma and adsorbed to GBMs films are similar: albumin (∼75%), immunoglobulins (∼8%), serotransferrin (∼4%), and fibrinogen (∼1−2%), with these percentages being proportional to the total amount of adsorbed proteins. Focusing on the most abundant proteins (higher than 1%), differences appear between GBMs films. Proteins such as complement C3 and α-2-macroglobulin adsorb more to oxidized surfaces, while proteins as α-1-antitrypsin and haptoglobin prefer reduced and nonoxidized films. Apolipoprotein A-I (major component of HDL) is identified only in oxidized surfaces without being within the 1% most abundant proteins in the plasma. In some cases, despite belonging to the 1% most abundant proteins in oxidized films (e.g. α-2-macroglobulin and complement C3), higher amounts can be found on rGO and FLG films.

Conclusion

Overall, human plasma proteins adsorb less to oxidized films than to rGO and FLG, highlighting the importance of fine-tuning surface features for a better control of the biological outcome. Proteins adsorbed in higher amounts are mainly related with complement activation (complement factor H, complement C3), coagulation (fibrinogen, antithrombin-III), lipid metabolism (apo A-I, apo B-100), and protease inhibitors (α-1-antitrypsin, α-2-macroglobulin). Such insights on the type and amount of adsorbed proteins to each surface are valuable to better tune and design surfaces according to an envisaged biomedical application.

Dependence of surface topography parameters on the strength of cell adhesion

Przemyslaw Kurtyka1,2,3, Roman Major3, Maciej Gawlikowski2, Marcin Kaczmarek2, Roman Kustosz1

1 Foundation of Cardiac Surgery Development, Artificial Heart Laboratory, Zabrze, PL; 2 Silesian University of Technology, Faculty of Biomedical Engineering, Zabrze, PL; 3 Polish Academy of Sciences, Institute of Metallurgy and Materials Science, Krakow, PL

Introduction
Modifications of the surface of biomaterials currently offer enormous opportunities to obtain a stable connection of the biomaterial-tissue system. The phenomenon of bone tissue accretion has already been well understood and described in the literature and has been used in clinical practice. There are no data on the phenomenon of connective tissue adhesion to the surface of the biomaterial and research describing the influence of the biomaterial surface topography features on this phenomenon. The project includes material tests to parameterize the obtained surfaces and biological tests determining the effect of shear stress on the number of residual cells as a result of rotational motion.

Experimental Methods
The paper presents vacuum sintering modification performed on titanium alloy Ti6Al7Nb in form of cylinders Ø14mm x H 3mm. The compliance of the base material with the standard was confirmed on the basis of the microstructure study, the chemical composition analysis and the study of mechanical properties. Before sintering, samples were subjected to tumbling to obtain a homogeneous surface topography. The roughness of the base material was measured with the use of contact profilometry and resulted Ra=1.5µm and Rz=12.5µm. The sintering was performed using CpTi powder differed in size and morphology. The modified surfaces were characterized by material examinations including scanning electron microscope [SEM], contact angle measurement, contact profilometry and digital microscope [DM]. Samples colonized with fibroblasts were incubated until full confluence. The strength of adhesion of the obtained cell layer to the material substrate was examined using the developed and validated device. Therefore it was possible to assess the impact of the analysed biomaterial surface on the flowing medium under conditions of high shear stress. The system forced the medium flow between the rotating disc made of titanium alloy with modified surface and the immobile polished surface made of surgical steel. The gap size was selected experimentally within the scope of 0.05-0.3mm, and the rotational speed in range od 500-3000RPM. The cell adhesion force was determined comparatively for all samples as the decrease in number of cells per area unit. The number of cells was estimated using the Confocal Scanning Microscope LSM EXCITER 5.

Results and Discussion
The results have shown that surface after PS is characterized by high roughness of about ≈ Ra=35µm, high porosity ≈64% and wettability ≈100°. The DM cross section images revealed its complex 3D morphology. On the basis of SEM photos, the presence of interconnected pores was observed with various degrees of tortuosity, which may positively influence cell adhesion and tissue formation. On the basis of the conducted research, it was possible to determine the correlation of the shape and size of the powders used for modification on topographic parameters and the strength of cell adhesion.

Conclusion
On the basis of the obtained results, the dependence of surface topographic parameters on cell adhesion was observed. The research confirmed the effectiveness of the presented rotational method in order to estimate the...
adhesive strength comparing different modifications. The method, on the other hand, is not free from errors, however the modernization of the construction may result in improved accuracy.

Characterization of adsorbed HSA protein layers on UV-C modified Ti6Al4V surfaces

Margarita Hierro-Oliva\textsuperscript{1,2,3}, Amparo M. Gallardo-Moreno\textsuperscript{1,2,3}, M. Luisa Gonzalez-Martin\textsuperscript{1,2,3}

\textsuperscript{1} University of Extremadura, Badajoz, ES; \textsuperscript{2} CIBER-BBN, Badajoz, ES; \textsuperscript{3} INUBE, Badajoz, ES

Introduction
Human serum albumin (HSA) is a very abundant protein in the blood plasma. Coatings in biomaterials with this protein are commonly used to decrease platelet adhesion and to reduce bacterial adherence [1]. The surface properties of biomaterials, such as chemical composition and hydrophobicity, are decisive for the adsorption of proteins to their surface [2]. It is possible to modify the hydrophobicity of titanium alloys by UV-C radiation without modifying its chemical composition [3]. In this context, the purpose of this work is to study how the change in Ti6Al4V hydrophobicity affects the properties of adsorbed HSA layers.

Experimental Methods
Experiments were carried out with commercially available Ti6Al4V disks (DKSH, Switzerland). Some of them were treated with an ultraviolet lamp during 15 hours. Protein adsorption experiments were performed at 37 °C for 2 hours of incubation, in PBS buffer, using 1 ml solution of 30 µg/ml of HSA (Sigma-Aldrich, Germany). After adsorption, the samples were rinsed three times in deionized water and dried in air. Contact angles on discs were measured using the sessile drop technique with a G20 goniometer (Krüss, Germany). Deionized water (DW), formamide (F, Fluka, Germany) and diiodomethane (D, Sigma-Aldrich, Germany) liquids were used to measure static contact angles at room temperature. X-ray photoelectron spectroscopy (XPS) measurements were performed in a K-Alpha (Thermo Scientific) with monochromatic AlKα (1486.68 eV) X-ray source with a spot size of 400 μm.

Results and Discussion
The results obtained by XPS confirm the existence of the adsorbed protein layer on the surface of the titanium alloy by increasing the intensity of the N1s peak. It is also possible to detect the amide group, existing in proteins, by deconvolution of the C1s peak. The modification of hydrophobicity of the titanium alloy surfaces does not present significant changes in the layer of adsorbed proteins that can be detected by XPS. Measurements made on the Ti6Al4V surfaces of contact angles show that surfaces that have not undergone UV-C treatment have a hydrophobic character and seem to have a tendency to decrease their average water contact angle with the presence of the protein surface layer. On the other hand, samples that have been subjected to UV-C radiation show a superhydrophilic character and the adsorption of the protein layer on these samples makes them hydrophobic.

Conclusion
After adsorption of HSA on Ti6Al4V surfaces, differences in the hydrophobicity of the substratum becomes shadowed by the protein layer, as the similar water contact angle value obtained after protein adsorption.

Exploring the antiamyloidogenic properties of dendrimers for an Alzheimer’s disease nanotherapy

Débora A. Moreira\textsuperscript{1,2}, Sofia D. Santos\textsuperscript{1}, Victoria Leiro\textsuperscript{1}, Ana P. Pêgo\textsuperscript{1,2,3}

\textsuperscript{1} University of Porto, i3S/INEB - Instituto de Inovação e Investigação em Saúde/Instituto de Engenharia Biomédica, Porto, PT; \textsuperscript{2} University of Porto, FEUP - Faculdade de Engenharia da Universidade do Porto, Porto, PT; \textsuperscript{3} University of Porto, ICBAS – Instituto de Ciências Biomédicas Abel Salazar, Porto, PT

Introduction

There are more than 50 million people worldwide living with dementia, and this number is expected to triple by 2050 \cite{1}. Alzheimer’s disease (AD) is the most prevalent form, corresponding to 60-70\% of all cases \cite{2}. The disease is characterized by extracellular aggregation of amyloid ß (Aß) peptide and intracellular aggregates of hyperphosphorylated tau protein, both leading to toxicity and neuronal death. The available therapies for AD act only on symptoms attenuation, hence cognitive impairment is not only irreversible but also inevitable \cite{3}. Therefore, there is an urgent need to develop disease-modifying therapies for AD.

Nanotechnology shows high potential for AD therapies, as the nanoscale size and controllable surface properties of nanoparticles make them able to cross the blood-brain barrier, reach the AD brain, deliver therapeutics in a specific and controlled way, and improve their pharmacokinetic and pharmacodynamics. Dendrimers are specially interesting as nanotherapeutics for AD treatment due to their unique structural characteristics. They are globular, have a well-defined and very branched structure, controllable nanosize (<15 nm) and multivalency. These intrinsic features allow them to act as efficient and multivalent carriers of different therapeutic molecules. In addition, these nanosystems have also been used as a drug \textit{per se} \cite{4}. With that in mind, a proprietary family of dendrimers was explored to hamper with Aß (1-42) peptide aggregation.

Experimental Methods

The structure of the dendrimers was characterized by nuclear magnetic resonance and Fourier-transform infrared spectroscopy, while its size and zeta potential by dynamic light scattering. Aß aggregation kinetics was studied by the fluorescence probe thioflavin T (ThT) when in the presence of different peptide/dendrimer ratios.

Results and Discussion

Results showed that the dendrimers were able to reduce Aß fibrillation when peptide/dendrimer ratios were equal or higher than 1. For ratios below 1, the dendrimers increased and altered Aß aggregation kinetics to different extents, as shown by a ThT destabilized signal. These preliminary results seem to indicate a dual effect of these dendrimers and their impact and potential in AD therapeutics: (i) at high peptide/dendrimer ratio they can inhibit Aß fibrillation, thus inhibiting the formation of toxic Aß species; (ii) at low peptide/dendrimer ratio they seem to promote the aggregation/fibrillation, altering the kinetics of aggregation.

Conclusion

Therefore, these dendrimers show relevant \textit{in vitro} antiamyloidogenic properties. Future studies will dissect the mechanism of interaction of the dendrimers and Aß and explore their impact in relevant cell lines.

Generation of a 3D artificial liver model using electrospun PCL scaffolds and footprint-free hiPSC-derived hepatocytes

Josefin Weber¹, Christiane Lörch¹, Carsten Linti², Michael Doser², Meltem Avci-Adali¹

¹ University Hospital Tuebingen, Department of Thoracic and Cardiovascular Surgery, Tübingen, DE; ² German Institutes of Textile and Fiber Research Denkendorf DITF, Biomedical Engineering, Denkendorf, DE

Introduction
Liver tissue engineering aims to provide close-to-nature 3D models to get further insights into the various functions, complex structures, and disease mechanisms of the liver and to establish future therapeutic approaches. The generation of human-induced pluripotent stem cells (hiPSCs) from patients' somatic cells and the subsequent differentiation into desired cell types, like hepatocytes, opens up numerous possibilities in regenerative medicine and tissue engineering. The use of hiPSCs represents an unlimited stem cell source for the generation of hepatocytes. In this study, using self-replicating mRNA footprint-free hiPSCs were generated from urine-derived epithelial cells. After a 2D pre-differentiation of these hiPSCs into hepatoblasts, the cells were seeded on poly-ε-caprolactone (PCL) scaffolds produced by an innovative combination of fused filament fabrication (FFF) 3D printing with melt electrospinning and differentiated into hepatocytes.

Experimental Methods
3D PCL scaffolds were produced by DITF Denkendorf. The scaffolds were coated with vitronectin to enable cell adhesion and proliferation. Afterwards, the scaffolds were populated with 5x10⁵ hiPSC-derived hepatoblasts and differentiated into mature hepatocytes using a cocktail of growth factors and small molecules. After two weeks of differentiation and maturation, the attachment, spreading, and proliferation of the cells, as well as the expression of hepatocyte-specific markers and the functionality, such as albumin secretion, were evaluated by performing fluorescence microscopy, qRT-PCR, flow cytometry, and ELISA. The 3D differentiation efficiency was compared with the hepatic differentiation under 2D conditions.

Results and Discussion
The seeding of hiPSC-derived hepatoblasts on vitronectin-coated scaffolds resulted in uniform attachment of the cells to the PCL fibers. In the course of the following two weeks of differentiation and maturation, the cells started to proliferate leading to build a 3D network across the fibers. The successful differentiation of the hepatoblasts into mature hepatocytes was confirmed by the expression of the hepatocyte-specific markers albumin, apolipoprotein A-II (APOA2), alpha-1-antitrypsin (A1AT), cytochrome P450 3A4 (CYP3A4), and alpha-1-fetoprotein (AFP). The differentiation efficiency of the 3D generated hepatocytes was compared to hepatocytes generated under 2D conditions, using fluorescence microscopy, qRT-PCR, flow cytometry, and ELISA.

Conclusion
The footprint-free hiPSCs generated by the application of self-replicating mRNA from urine-derived cells were successfully differentiated in combination with 3D PCL scaffolds into hepatocytes and created a simplified 3D liver-like model with specific hepatic functions. This model can be applied to study specific genetic diseases and novel treatment methods. Furthermore, the influence of drugs on patient-specific hepatocytes can be evaluated.
Miniaturized microenvironment as a versatile platform to study mechanosensing at single-cell resolution

Castro Johnbosco, Malin Becker, Kannan Govindaraj, Tom Kamperman, Jeroen Leijten

University Twente, Department of Bioengineering, Enschede, NL

Introduction
Cell-matrix interfaces govern cellular behavior and dictate virtually all levels of cellular function ranging from protein expression to cellular phenotype. The interplay between microenvironmental mechanics and cellular biology effectively guides cell function and fate. Although cellular heterogeneity in primary cell populations is widely accepted, single-cell resolution data on the heterogeneity in mechanobiology and mechanotransduction have remained scarce as current state of art systems are mostly geared towards multi-cellular cultures and population-level analyses.

Experimental Methods
Thereby, we propose a miniaturized microsystem to scrutinize the mechanistic activities of a single cell with its immediate pericellular environment. Droplet-based microfluidic emulsification was used to position individual single mesenchymal stem cells inside the center of a picoliter droplet of designer polymer solutions, in a high throughput manner. To this end, we used polysaccharides such as dextran that were functionalized with tyramine moieties to produce single-cell microdroplets which then were enzymatically crosslinked into single-cell microgels facilitating temporal tuning of biochemical, mechanical, and biophysical entities of these single-cell microgels. The microrheological properties of various single cell-laden micromaterials were determined using nanoindentation techniques.

Results and Discussion
We demonstrated that the encapsulated cells switched their phenotype depending on the microenvironmental stiffness and mapped this behavior at single-cell resolution. Immunostainings revealed that matrix protein production was strongly correlated with alterations in mechanical properties. Gene expression analysis corroborated that the dependency in stemness maintenance was affected by the mechanics of the cell’s mechanical surrounding.

Conclusion
Thus, we endorse a platform that bestows a highly tunable microenvironment to individual cells that reports the mechanobiological crosstalk at single-cell resolution.
The production of microgels via droplet microfluidics. The nanoindentation analysis of cell-laden microgels using a nanoindenter. Confocal microscopy of single cell-laden microgel stained for actin and nucleus.

Engineering the colorectal tumor on-a-chip

Mariana Carvalho\textsuperscript{1,2}, David Barata\textsuperscript{3}, Liliana Teixeira\textsuperscript{4}, Stefan Giselbrecht\textsuperscript{4}, Rui L. Reis\textsuperscript{1,2}, Joaquim Oliveira\textsuperscript{1,2}, Pamela Habibović\textsuperscript{4}, Roman Truckenmüller\textsuperscript{3}, J. Miguel Oliveira\textsuperscript{5}

\textsuperscript{1} 13B’s Research Group, I3Bs – Research Institute on Biomaterials, Biodegradables and Biomimetics, University of Minho, GMR, PT; \textsuperscript{2} ICVS/3B’s - PT Government Associate Laboratory, Braga/Guimarães, PT; \textsuperscript{3} MERLN, Maastricht University, Department of Instructive Biomaterials Engineering, Maastricht, NL; \textsuperscript{4} MERLN, Maastricht University, Department of Complex Tissue Regeneration, Maastricht, NL; \textsuperscript{5} University of Minho, 3Bs Research Group, Institute 3Bs, Guimarães, PT

Introduction

Colorectal cancer is the third most common cancer world wide and its incidence increases with ageing. Understanding the mechanisms of tumor growth rely in further advances to unveil cancer-causing agents, drug screening and in the development of personalized therapies. Standard 2D in vitro models and in vivo animal models have undoubtedly contributed to the development of anti-cancer drug candidates. Yet their translation into successful clinical trials is critically low, which reinforces the need of a deeper understanding of tumorigenesis [1]. Therefore, 3D models integrating tissue engineering (TE) strategies with microfluidic technology have sparked the expectation on physiologically relevant microfluidic in vitro models [2].

Experimental Methods

Human colon cancer HCT-116 cells (ATCC) and intestinal microvascular endothelial cells (Innoprot) were cultured with specific media according to supplier’s specifications, at 37°C in a humidified atmosphere containing 5% CO\textsubscript{2}. The model includes a core region defined by human colorectal cancer cells (HCoMECs) embedded in a soft 3D matrix (Matrigel\textsuperscript{®}) being laterally surrounded by perfused engineered endothelial microvessels (Figure 1d).

Results and Discussion

Herein, we describe an “on chip in vitro tumor disease model” (Figure 1 a-b) that works as a screening tool for the generation and maintenance of stable gradients of Gemcitabine-loaded dendrimer nanoparticles (Figure 1c). The model includes a core region defined by human colorectal cancer cells (HCoMECs) embedded in a soft 3D matrix (Matrigel\textsuperscript{®}) being laterally surrounded by perfused engineered endothelial microvessels (Figure 1d). We achieved an “on chip in vitro tumor disease model” (Figure 1a and b)) that works as a screening tool for the generation and maintenance of stable gradients of Gemcitabine-loaded dendrimer nanoparticles. Subsequent Viability studies based on automated field of view imaging of the microfluidic 3D model corroborate the fact that cells are exposed to a gradient of Gemcitabine.

Conclusion

The developed on-chip model allows a co-culture of colorectal cancer cells and colonic endothelial cells, comprising both cancer and vascular parts of tumor microenvironment. The design of the model allows for the obtention of molecule gradients, which is foreseen to play an important role in assessing the influence of chemoattractants and drugs. Moreover, the model offers the potential to include complex microenvironments by means of including other cell types, such as immune cells or patient-derived cells, which can be key to bringing us closer to an effective treatment for colon cancer.

Developing a coronary artery-on-chip model to study arterial calcification

Danielle Baptista¹², Armand Jaminon², Nilooftar Tahmasebi¹, Barend Mees², Leon Schurgers², Roman Truckenmüller¹

¹ University of Maastricht, MERLN, MAASTRICHT, NL; ² University of Maastricht, CARIM, MAASTRICHT, NL

Introduction
Vascular calcification is a well-known marker of subclinical atherosclerosis and, when present in coronary arteries, an independent predictor of coronary heart disease [1]. Although numerous studies have explored the link between vascular calcification and various biological and mechanical factors, a unifying mechanism that explains the initiation and development of this orchestrated condition has not yet been unraveled. Conventional research models are often based on in vivo animal models, ex vivo settings and in vitro static two-dimensional (2D) models [2]. Ex vivo models do not represent the complexity under which vascular calcification is initiated and progresses in blood vessels, and consequently fail to reproduce extensive calcification that is usually seen in pathological conditions in vivo. On the other hand, animal-based in vivo models fall short in providing clinically translatable outcome. Hence, there is still a large unmet demand for reliable and predictive human in vitro models to mimic pathological calcification of blood vessels. Recent advances in microfluidic and organ-on-chip technologies have resulted in the development of more complex human-based in vitro models to recapitulate the unique anatomical and biomechanical aspects of vessels combined with the biochemical and biological microenvironment that the corresponding cells experience [3]. However, to the best of our knowledge, current organ-on-chip models have not yet been applied for vascular calcification. Here, we present the development of a coronary artery-on-chip model that enables investigating the role of dynamic culture conditions on the onset of in vitro calcification. The model consists of a microfluidic chip with a channel representing the coronary artery. In the microchannel, vascular smooth muscle (VSMCs) and endothelial cells (ECs) will be co-cultured and emulates the arterial wall, which subsequently will be calcified. This co-culture will be subjected to stimuli, such as different shear stress regimes, mimicking both physiological and pathological conditions, with the aim to study effects on vascular calcification.

Experimental Methods
We have developed a microfluidic chip comprised of a straight channel that represents human adult coronaries. The first-generation chip was fabricated from polydimethylsiloxane (PDMS) via soft lithography and bonded to a polycarbonate (PC) film with PDMS mortar as described elsewhere [4]. As a first step of developing a co-culture on chip, we cultured human primary VSMCs, known to be key players in arterial calcification in vitro [5], inside the channels to obtain a VSMC monolayer. For this, VSMCs were seeded inside the channels that were pre-coated with either laminin or fibronectin. In addition, varying seeding densities were tested in order to maximize cell coverage and to ensure the formation of a confluent monolayer. Current experiments include the characterization of VSMCs with respect to their phenotypes. Within these conditions, we analyzed expression of common biomarkers including alpha smooth muscle actin (αSMA), calponin (CNN1), phosphorylated myosin light chain (pMLC) and F-actin.

Results and Discussion
We successfully fabricated a microfluidic chip consisting of a PDMS layer, featuring three identical straight channels, bonded to a 50 µm transparent PC film that is comparable to commonly used cell culture plastics, is optically transparent and renders a device easy to handle. Additionally, since the PC film can be peeled off the PDMS housing...
and easily cut, one device enables multiple analysis. The bonding between both parts resulted in stable constructs with no leakage (Fig. 1 a).

To efficiently obtain VSMC monolayers prior to perfusion on-chip, we optimized seeding density and surface coating (Fig. 1 b). A density of 10000 cells/µl in conjunction with fibronectin-coated channels showed superior cell adhesion and the resulting VSMC monolayer exhibited a contractile-like phenotype within 24 hours after seeding. To further characterize VSMCs, expression of contractile markers was assessed through immunocytochemical analysis. The cells cultured with fibronectin and laminin (Fig. 2 a-b) displayed similar expression of F-actin. CNN1 expression appeared stronger for cells on fibronectin while αSMA expression appeared stronger for cells cultured with laminin.

pMLC, despite being a very specific marker for contractile VSMCs, was not detected for any condition, possibly due to the late passage of VSMCs that were used. Next steps will include perfusion and calcifying conditions on-chip, as well as incorporation of ECs into the model.

**Conclusion**

In this study, we successfully took the first steps towards developing a physiological and clinically relevant coronary artery model that combines organ-on-chip technology with primary human cells. The results, despite preliminary, highlight the potential of the model that will be used to study vascular calcification under dynamic conditions.

Quantifying the minimal metabolic requirements to support stem cell survival using a gradient generating dynamic microfluidic cell culture platform

Melvin Gurian, Yvonne W. Schreurs, Liliana S. Moreira Teixeira, Iris E. Allijn, Jeroen Leijten

University of Twente, Developmental BioEngineering, Enschede, NL

Introduction
Metabolites are essential for cell survival, function, and fate of cells [1, 2]. Indeed, nutrient deprivation contributes to the rapid loss of implanted cells and engineered tissues. Knowledge on the minimal levels of nutrients that are required to maintain cell viability could aid predictable survival of living implants. Current knowledge is typically based on static culture systems in which cells are exposed to a culture medium that is initially chemically defined. However, the nutrient content of media in static systems decreases rapidly over time [3]. As starvation-induced cell death occurs in a delayed manner, it has remained unknown what the critical level of metabolite concentrations is to ensure the survival and function of implanted cells and tissues. Here, we report on the development and use of a dynamic microfluidic-based cell culture platform for the determination of minimal metabolic requirements for mesenchymal stem cell (MSC) survival and function at physiologically relevant oxygen concentrations.

Experimental Methods
Soft lithography and replica molding was used to create microfluidic devices that were composed of a gradient generator that was followed by an array of parallelly placed cell culture chambers. Approximately 3500 MSCs were seeded per culture chamber and exposed to a range of metabolite concentrations. All platforms were used inside a XVivo hypoxia chamber to effectively control the oxygen concentration. Fluorescent microscopy was used to visualize cell morphology and survival over time.

Results and Discussion
Perfusing the microfluidic device with fluorescein dyes validated that the gradient generator offered long-term stable and linear control over the media in each individual cell culture chamber. Subsequently, chemically defined media with quantified nutrient content was flown through the microfluidic device at 8ul/min, which offered neglectable amount of nutrient loss e.g. due to absorption to the microfluidic channels. Furthermore, we confirmed with cell laden chambers the dynamic flow to be sufficiently fast to maintain constant metabolite concentrations, while keeping the hydrodynamic shear sufficiently low (<0.3dyn/cm2 [4]) to avoid causing adverse effects on cell behavior. Cells were then cultured over a maximal period of seven days to quantitatively determine the minimal concentrations to sustain cell survival, as well as function for a panel of relevant metabolites in a time resolved manner.

Conclusion
This approach allowed the determination of the relative importance of individual metabolites on the survival of MSCs, which offers novel fundamental insights into what is required to avoid starvation-induced cell loss of implanted cells and prevascular tissues.

Introduction
Plastic surfaces as in vitro cell culture supports have greatly facilitated the study of cell behavior. However, flat surfaces only allow the development of two-dimensional (2D) cell culture, where cells grow by forming a monolayer. Cells adopt a flattened morphology that affects gene and protein expression [1]. Therefore, cell behavior on monolayer culture differs from the in vivo pattern, where cells are embedded in the extracellular matrix (ECM), a three-dimensional (3D) network composed by fibrous proteins and array of molecules. Some studies have demonstrated that this key difference in cellular surroundings may influence cell metabolism and the differentiation state of the cells [2]. In fact, there is small subpopulation within the tumor that exhibits an undifferentiated state and other characteristics similar to the mammary stem cells. They are so-called cancer stem cells (CSCs) and have the ability to initiate tumors, are resistance to many current anticancer therapies, and are thought to be partially responsible for tumor recurrence. Targeting CSC population could represent an effective approach for oncologic treatments. CSCs can be identified by increased activity of the aldehyde dehydrogenase (ALDH) enzyme and, in breast cancer, they can be isolated based on their expression pattern of CD44+/CD24−/low and high expression of CD49f and ESA surface proteins [3]. Additionally, the induction of epithelial-to-mesenchymal transition (EMT), through decreased E-cadherin expression and upregulation of vimentin, results in stem properties.

All things considered, it is important to maintain the differentiation state of the cells to properly study CSC niche. For this reason, 3D structures have emerged as innovative cell culture supports that aim to emulate the in vivo cell environment. Scaffolds, which are composed by a network of filaments mostly made by synthetic materials, mimic aspects of the physiological surrounding of cells [4]. Therefore, estrogen receptor positive (ER+) breast cancer cells are proposed in the present work in order to study the impact of 3D scaffolds culture on the stem-like population. Knowing how cell surroundings modulate stemness state could favor CSC experimentation and, consequently, the development of targeted therapies.

Experimental Methods
Polycaprolactone (PCL) and electrospinning were chosen as biopolymer and technology to manufacture 15% w/v PCL scaffolds. Two ER+ breast cancer cell models were used, luminal A HER2- T47D and luminal B HER2+ BT474 cells. Both cell lines were cultured on scaffolds, and cell proliferation was analyzed by MTT assay. Cell cycle was also evaluated on cells cultured on 2D and 3D scaffolds. For T47D cell model, the T47D Fluorescent Ubiquitination-based Cell Cycle Indicator (FUCCI) cells were used, where cell cycle activity can be visualized by monitoring the oscillation dynamics of fluorescently tagged cell cycle fusion proteins. For BT474 cells, an EdU (5-ethyl-2'-deoxyuridine) assay was performed to analyze cell cycle status. In order to discern a possible impact of 3D culture on the cancer stem-like cell population, several stemness features were analyzed. ALDH activity was quantified with an ALDEFLUORä kit, as well as the protein expression pattern of CD44, CD24, CD49f, and ESA by flow cytometry.
The expression of EMT-related genes was evaluated such as SNAIL, SLUG, TWIST, ZEB1, ZEB2, ECADH and VIM, along with the expression of OCT4 and NANOG stemness-related genes. Finally, cells derived from ER+HER2- and ER+HER2+ primary tissue samples were cultured on the PCL meshes and a MTT assay was performed.

Results and Discussion
Impact of 3D culture with PCL scaffolds are summarized in Table 1. T47D cells acquired a more quiescent and mesenchymal phenotype during scaffolds culture, based on analyses of cell proliferation kinetics and ECADH/VIM expression, which led to an overactivation of the ALDH enzyme, a cancer stem cell marker. However, a -lower percentage of CD44+/CD24-low and CD49f cells and lower EMT transcription factors expression was also found in T47D cells cultured in scaffolds relative to monolayer culture. On the other hand, BT474 cells showed a similar cell proliferation rate in scaffolds relative to monolayer culture, as well as ALDH activity. 3D-cultured BT474 cells displayed less CD24 and CD49f levels, accompanied by an epithelial phenotype with lower EMT transcription factors expression. Importantly, ES 15% PCL scaffolds proved to be suitable for the culture of primary ER+ breast cancer cells, which adopted a similar cell growth behavior to that of tested model cell lines.

Conclusion
In summary, presented results provide evidence of the suitability of electrospun PCL nanofibers to accommodate 3D ER+ breast cancer cells culture, either established cell lines or primary samples. A modulation of the differentiation and stemness state of the cells was observed to occur within 3D surroundings. However, more efforts are needed to fully understand the mechanisms underlying these alterations.

Introduction
Organ-on-a-chip technology promises to revolutionize how pre-clinical human trials are conducted. Engineering an in-vitro environment that mimics the functionality and architecture of human physiology is essential towards building better platforms for drug development and personalized medicine. However, the complex nature of these devices requires specialized, time-consuming and expensive fabrication methodologies. Alternatives that reduce design-to-prototype time are needed, in order to fulfill the potential of these devices. Here, a streamlined approach is proposed for the fabrication of organ-on-a-chip devices with incorporated microactuators, by using an adaptation of xurography. This method can generate multi-layered, membrane-integrated biochips in a matter of hours, using low-cost benchtop equipment.

Results and Discussion
Devices produced with the proposed technology are capable of withstanding considerable pressure without delamination. Furthermore, this method is suitable for the integration of flexible membranes, required for organ-on-a-chip applications, such as mechanical actuation or the establishment of biological barrier function. The devices are compatible with cell culture applications and present no cytotoxic effects or observable alterations on cellular homeostasis. A proof of principle stomach-on-a-chip device was designed to emulate the outer strata of the gastric epithelium. The engineered stomach-on-a-chip was shown to display enhanced phenotypical and functional traits characteristic of the normal gastric mucosa.

Conclusion
The proposed fabrication method can rapidly generate organ-on-a-chip prototypes for a fraction of cost and time, in comparison to conventional soft lithography, constituting an interesting alternative to the current fabrication methods.

Tunable magnetic hydrogel for cardiomyocytes training

Baptiste Le Roi\textsuperscript{1,3}, Ben M. Maoz\textsuperscript{1,2,3}

\textsuperscript{1} Tel Aviv University, Biomedical Engineering, Tel Aviv, IL; \textsuperscript{2} Tel Aviv University, Sagol School of Neuroscience, Tel Aviv, IL; \textsuperscript{3} Tel Aviv University, Center for Nanoscience and Nanotechnology, Tel Aviv, IL

Introduction
Heart failure is a major cause of death in Europe as 2\% of the European population die from it every year. Heart failure naturally comes with the age but also with the regular consumption of toxics such as tobacco or alcohol. The main cause of heart failure is called cardiomyopathy and corresponds to a permanent loss of contraction strength of cardiac cells. Current treatment are palliative and do not target cardiac cells but arteries which become more compliant.

The contractile force generated by cardiomyocytes (CMs), a key indication of heart functionality, is dependent in part on the levels of external pressure to which the CMs are exposed before and during contraction (preload and afterload, respectively). Yet, current in vitro methods are unable to mimic the conditions that create such pressure. Consequently, these methods cannot provide sufficient information regarding CM functionality and drug response.

The proposed work aims to create an in vitro platform that overcomes this limitation, thereby revolutionizing current cardiac in vitro paradigms. The presented platform, involves the use of magnetic fields to apply dynamic forces to CM tissue, thereby mimicking in vivo conditions.

Experimental Methods
In the presented work, we aim to overcome limitations of current in vitro cardiac models by creating a human-relevant in vitro model of the cardiovascular system that mimics the dynamic environmental pressures to which CMs are subjected in vivo. In this work, we were able to:

• Develop a magnetically controllable soft substrate that uses magnetic fields to mimic preload and afterload pressures.
• Integrate CM into the magnetic substrate and identify their response to the substrate.
• Assess CM functionality under various preload/afterload conditions, and compare it to known PV loops

Results and Discussion
We have achieved a proof of concept for some of the key elements of the proposed platform (Fig. 2). Specifically, we have successfully synthesized MNPs and embedded them in biocompatible gels (gelatin) \cite{1}. In addition, a permanent magnet was used to demonstrate the gels’ response to a magnetic field \cite{2}. Then we applied an Ogden model of second order on uniaxial compression test led on gels, we determined that gels present a stiffness of 3.7 kPa which is coherent with values found in literature \cite{3} and that MNP do not act as stiffener. Finally we demonstrated that Mgels are not toxic to CM and are optimizing the growth of CMs (up to 14 days currently). Building on these promising preliminary results, we proceed to carry out the remaining steps of our research plan, including: characterising CM functionality in the Mgels and identifying how MNPs affect CM properties, developing magnetic and electric controls, and most importantly, developing an in vitro–in vivo extrapolation methodology.

Conclusion
So far, synthesis of the material is fully mastered and biocompatibility is now demonstrated. Our end goal is to determine the effect of electro mechanical stimulation, by evaluating the variation of the pace and of the number of sarcomeric unit of cardiomyocytes over different conditions.
Scientific Gap and concept
Currently, there is not in vitro system that can emulate the forces applied on the heart.

Preliminary results
(Top) The experimental design that will culminate in the establishment of a new in vitro platform for cardiac research. (Bottom) Preliminary results which demonstrate a proof of concept.

Introduction

Lung cancer is the leading cause of cancer death around the world and non–small cell lung cancer (NSCLC) is the most frequent histologic type. Among the different type of NSCLC, adenocarcinoma is the most common one (about 40% of lung cancer) and arises from the epithelial alveolar cells [1]. The development of safe and effective therapies is currently constrained by the lack of a robust preclinical and experimental models that can reproduce the behaviour of the lung tissue. For these reasons, there is a crucial need for in vitro models that can quickly and reliably predict drug safety and efficacy in humans. In literature, several examples of microfluidic lung-on-a-chip devices were reported reproducing the physiological multicellular composition, 3D architecture and vascular perfusion of the human lung [2,3]. However, reported devices did not mimic the extracellular environment due to the use of non-biomimetic materials (mainly polydimethylsiloxane microporous membranes)[4,5]. Importantly, new biomaterial-based structures with ECM biomimetic features should be designed to have a physiological, district specific and bioartificial composition. Here, we propose the implementation of a novel technological biomimetic device to mimic the physiological condition by reproducing the basement membrane of alveolar wall and the physical stimuli characteristic of the blood-air barrier.

Experimental Methods

The biomimetic lung-on-a-chip device consists of an upper and a bottom layer made of polydimethylsiloxane (PDMS) moulded from two poly (methyl methacrylate) (PMMA) masters obtained through laser ablation method. These two layers are separated by an ECM-like electrospon membrane of Polycaprolactone/Gelatin (PCL/GL) that resembles the structural properties of the alveolar basement membrane serving as a substrate for the co-culture of epithelial and endothelial alveolar cells (Fig 1. a). The upper layer consists of a 3 mm central well completely open to atmosphere for recreating the air-liquid interface (ALI) culture condition of alveolar epithelial cells. The bottom layer has a central channel (1.5 x 16 mm) which allows the seeding of the endothelial cells in the bottom side of the membrane and guarantees cell survival by fresh medium flow. In addition, two lateral channels have been created in both layers for mechanical stimulation of the PCL/GL membrane to mimic breathing. HULEC-5a cells (human lung microvascular endothelium cells) were seeded on the bottom side of membrane and the chip was flipped over to promote cell adhesion. After 2 h, the chip was flipped over and A549 cells (human alveolar basal epithelial cells) were cultured on the upper holed chamber. To recreate the ALI condition, the culture medium on the upper chamber was removed when confluence of A549 cells was reached. Immunostaining and Live/Dead assays were performed to assess cell adhesion, proliferation and viability. Then, the formation of epithelial tight junction was investigated.

Results and Discussion

Leakage tests were performed to evaluate the successful sealing of the device channels. The bottom channel was filled with water containing blue dye and observed under optical microscope. Fig 1. b shows that the liquid flowed and remained in the channel, which demonstrated good sealing. Live/dead assay demonstrated the viability of cells after 72 h. The nuclei of A549 and HULEC-5a cells were stained with DAPI (Fig 1. c, d) confirming the adhesion of Page 1910 of 2028
cells on the two sides of the electrospun membrane. Furthermore, after 72 h in ALI condition, A549 cells demonstrated to express cell type-specific markers of both type I and II epithelial alveolar cells and the formation of epithelial tight junctions.

**Conclusion**

A biomimetic lung-on-a-chip device was obtained to better mimic the architecture of the basement membrane of the alveolar wall. The obtained results suggest that the proposed microfluidic system could be used to reproduce the microenvironment of both healthy and pathological tissues with higher fidelity thanks to the implementation of dynamic and three-dimensional cell culture conditions.

Introduction

Bacterial aggregates are one of the most relevant causes of persistent infections. At least 65% of all bacterial infections are associated with it. Mucus is a human-designed barrier that in the lungs protect us against the constant exposure to inhaled pathogens, particles and toxic molecules, as well as physical insults. Yet, in some airway disorders, like cystic fibrosis (CF), mucus hypersecretion and accumulation provide a suitable site for bacterial infections to thrive resulting in chronic infections that lead to morbidity and mortality of patients. Infections of CF patients are characterised by the presence of different bacteria, which microbial complexity and microenvironment are difficult to recreate in current bacterial culture substrates and animal models. Therefore, novel models are needed to either screen already available antimicrobial agents in a patient-specific manner or design new molecules to tackle airway mucus infections [1]. Antimicrobial treatment of airway CF infections has been of main importance to increase the survival rates in patients with CF. However, bacteria in CF airways evolve in the form of aggregates, which makes them difficult to eradicate.

Experimental Methods

Three-dimensional mucus models were adopted, CF-Muc³Gel, as models of CF mucus to recreate lung microbiota in vitro. CF-Muc³Gel is mostly composed of 2.5 % (w/v) commercial mucins (porcine stomach type III that contains Muc5AC - one of the most important mucins found in airway mucus) and 0.71 % (w/v) NaCl that fall within the ranges determined on CF sputum. Extensive rheological analyses were carried out to characterize the viscoelastic properties of CF-Muc³Gel. In vitro infections were induced within CF-Muc³Gel by culturing Pseudomonas aeruginosa and/or Staphylococcus aureus, the prevalent bacteria colonizing the airway CF mucus. The bacterial organization was characterized through confocal microscopy. Vertical microprofiles of oxygen tension throughout the CF-Muc³Gel structure were determined through O₂ microsensor measurements of chemical gradients with or without cultured bacteria. The ability of CF-Muc³Gel to act as a platform to determine antimicrobial susceptibility was further assessed by treating the different generated in vitro infections with three antimicrobial agents routinely employed in the clinics to manage chronic infections by these bacteria. Their effectiveness was further compared to standard bacteria cultures.

Results and Discussion

CF-Muc³Gel exhibits similar viscoelastic properties alterations to those reported for CF mucus with the presence of structural gradients. CF-Muc³Gel successfully sustained the growth of P. aeruginosa and S. aureus either in monoculture or co-culture with a bacterial number representative of CF patients after 24 h of infection. Bacteria cultured within CF-Muc³Gel exhibited many pathophysiological features, as these not only were able to colonise all its structure but also generate microcolony aggregates, which size and shape resembled those observed in the...
mucus of CF patients. CF-Muc\textsuperscript{3}Gel was also able to sustain the growth of \textit{P. aeruginosa} and \textit{S. aureus} derived from clinical isolates. Measurements of O\textsubscript{2} microprofiles in CF-Muc\textsuperscript{3}Gel without bacteria, revealed a gradual decrease of O\textsubscript{2} tension. Similar to what was previously reported in CF sputum with chronic \textit{P. aeruginosa} airway infections, CF-Muc\textsuperscript{3}Gel infected with either \textit{P. aeruginosa} or \textit{S. aureus} exhibited dual O\textsubscript{2} distribution with an upper aerobic region and a lower region that was completely anoxic after 48 hours of infection. The interplay of all these features resulted in a similar barrier to antimicrobial treatment. Bacteria resulted more susceptible to antimicrobial treatment under planktonic conditions than when cultured within CF-Muc\textsuperscript{3}Gel, where these instead displayed increased antibiotic tolerances even at high concentrations of antimicrobial drugs (10 MIC). The sensibility differences between CF-Muc\textsuperscript{3}Gel and planktonic cultures confirmed the well-reported mismatch between planktonically cultured bacteria and clinical outcomes.

**Conclusion**

CF-Muc\textsuperscript{3}Gel is a very versatile bacteria culture substrate that can be further complicated with other components, such as proteins, which can integrate different culture media and be exploited for different culture applications to model the mucus of different body districts. In addition, from the antimicrobial studies, rheological data and microstructural inspections, it is possible to propose CF-Muc\textsuperscript{3}Gel as a new, valid tool for the screening of antimicrobial agents for the research and development of new antimicrobial agents. CF-Muc\textsuperscript{3}Gel is ready-to-use without requiring any technical skills and offers superior reproducibility.

Introduction
Scientists have made several advances over the years in order to study tumor pathophysiology. Formerly, usually artificial 2D cultures have been used but their results are often not transferable to the in vivo situation. There has been a trend to more natural 3D models that have a more promising outcome. Additionally, the field of biofabrication has provided the possibility to enhance these models even more, for in vitro as well as in vivo applications.

Experimental Methods
With this study, we created a printable hydrogel consisting of alginate, hyaluronic acid, and gelatin (Alg/HA/Gel). We characterized its printability, mechanical properties, and suitability as a basis for in vitro melanoma models mimicking the tumor microenvironment and, in vivo, its effect on tumor progression, vascularization, and metastasis in a defined and isolated arteriovenous (AV) loop model in the rat.

Results and Discussion
The hydrogel had mainly elastic properties with a storage modulus of 10.5 kPa at 1 rad s⁻¹ using dynamic mechanical analysis. In vitro, the bioink showed good printability and shape-fidelity with high survival rates of the human melanoma cell line Mel Im. Cell cycle analysis visualized with a FUCCI cell cycle reporter of these cells revealed no impact on cell cycle populations over one week. Adipose-derived stem cells were able to differentiate into the adipogenic and the osteogenic lineage over 21 days, demonstrated via Oil Red O and Alizarin red stainings, and qPCR. Using a GpL fusion protein producing cell line, diffusion of proteins with a size of 150 kDa through the hydrogel was confirmed. In vivo, the hydrogel facilitated good tumor progression, vascularization and reliable metastases, closely resembling the human morphology and course of disease, over four weeks. Histological sections (HMB-45) and whole-mount light sheet fluorescence microscopy (anti-CD31) of the explants supported these findings.

Conclusion
In summary, this makes the bioink a versatile tool for basic and applied cancer research. In combination with the AV loop model, it is a unique in vivo model to study melanoma and possible therapis.

Introduction
Cardiac fibrosis is a maladaptive remodeling of the myocardium hallmarked by a contraction impairing, adverse, extracellular matrix deposition (ECM). The disease's progression, nevertheless, remains poorly understood and present treatments are not capable of stopping the scarring process. This lack correlates with the absence of physiologically relevant, easily operable, and low cost \textit{in-vitro} models, which are of the utmost importance to uncover pathological mechanisms and highlight possible targets for anti-fibrotic therapies. In classic models, fibrosis' features are obtained using substrates with scar mimicking stiffnesses and/or supplementation of morphogens such as Transforming growth factor b1 (TGF-b1). Qualities such as the interplay between activated fibroblasts (FBs) and cardiomyocytes (CMs) and the mechanically active, three-dimensional (3D) environment, are, however, neglected or obtained at the expense of the experimental yield.

Experimental Methods
We engineered a micro-physiological system (MPS) where multiple 3D microconstructs can be subjected to cyclical stretching. Up to six different biologically independent samples are obtained in a single device, increasing the experimental throughput, paving the way for higher yielding drug screening campaigns. We studied the effect of different ratios of neonatal rat FBs and CMs in the assumption and modulation of fibrosis traits, without the addition of morphogens, and in soft substrates.

Results and Discussion
The expression of contractile stress fibers and of degradative enzymes, as well as the deposition of fibronectin and type I collagen were superior in microtissues with a low amount of CMs. Moreover, high CMs-based microconstructs, simulating a ratio similar to that of healthy tissues, subjected to both cyclic stretch and TGF-b1 did not show any of the investigated fibrotic signs, indicating a CMs fibrosis modulating effect.

Conclusion
Overall, this \textit{in vitro} wound healing model could help to uncover new disease aspects, studying with higher throughput and in a mechanically active, physiologically relevant environment the crosstalk between the most abundant cell types involved in fibrosis.

Surface modification of neural electrodes via Pulsed-DC Electrophoretic Deposition and their *in-vivo* application

Vaijayanthi Ramesh¹, Christoph Rehbock¹, Svilen D. Angelov², Kerstin Schwabe², Joachim K. Krauss², Stephan Barcikowski¹

¹ University of Duisburg-Essen, Institute of Technical Chemistry I, Essen, DE; ² Hannover Medical School, Department of Neurosurgery, Hannover, DE

**Introduction**

Motor neuron diseases like Parkinson’s can induce severe tremors in later stages, which seriously impair the daily life of elderly patients, particularly when drug-based treatments have ceased to work. A possible way to improve the patients’ quality of life is deep brain stimulation (DBS) treatments. Here, platinum neural electrodes are implanted into the brain, providing electric pulses to stimulate the subthalamic nucleus (STN) and in turn tune neuronal activity[1]. Even though this treatment is routinely applied in clinical practice, difficulties such as low stimulation efficiency and reduced battery capacity of the pulse generator due to the increase of impedance over time between electrode tip and brain tissue occur[2].

**Experimental Methods**

Here we show that the impedance of neural electrodes can be significantly reduced in case their surface area is increased by sub-monolayer deposition of ligand-free laser-fabricated platinum nanoparticles (PtNPs)[3]. The coating of 3D electrode surfaces is done using electrophoretic deposition (EPD) in a custom-designed chamber as depicted in Figure 1 with a field strength of 5 V/cm and a platinum mass concentration of 100 µg/ml. We compared the impact of DC (5 min) and pulsed-DC EPD (period of 1 µs and a duty cycle of 50%, 10 min) on stimulation conditions.

**Results and Discussion**

Our findings reveal that the pulsed-DC coating procedure yields a more homogeneous surface coating and also the impedance is significantly reduced in contrast to the uncoated controls (Figure 2), an effect which could not be observed for DC-EPD, as previously described in literature[2].

**Conclusion**

In consecutive studies, the coated electrodes will undergo long term *in vitro* stimulations in saline solutions and *in vivo* stimulations in rat models and the influence of DC and pulsed DC electric fields on their functionality will be evaluated.

Antioxidant polyphenolic implant coatings for improved wound healing

Florian Weber, Quang Huy Quach, Per H Nilsson, Hanna Tiainen

1 University of Oslo, Department of Biomaterials, Institute of Clinical Dentistry, Oslo, NO; 2 University of Oslo, Department of Immunology, Institute of Clinical Medicine, Oslo, NO; 3 Linnaeus University, Department of Chemistry and Biomedical Sciences, Kalmar, SE

Introduction
Biomaterial associated infections and lack of tissue integration are still a widespread problem preventing the long-term success of implants.[1] To overcome the risk of implant failure and revision surgeries, various surface modifications are being studied to alter the foreign body response and prevent microbial colonization. Thereby, the aim is to create a close contact of the surrounding tissue to the implant surface forming a natural barrier, which prevents infections.

Improved tissue integration is closely connected to the inflammatory response governed by the foreign body reaction and the surgical trauma. To relieve this inflammatory response and support wound healing processes, polyphenolic molecules have emerged as potential candidates.[2] Their anti-inflammatory properties are attributed to their capability to reduce oxidative stress and inhibit pro-inflammatory cytokine expression. Further, polyphenolic surface modifications may cope with adverse foreign body reactions.[3] Therefore, we evaluated innate immune response towards tannic acid and pyrogallol coatings. In particular, the effect of these polyphenolic coatings on blood coagulation and complement activation was assessed.

Experimental Methods
Tannic acid (TA) and pyrogallol (PG) coatings were prepared by immersing Ti substrates in 100 mM HEPES buffered solutions containing 1 mg/ml TA or PG. TA solutions contained 600 mM NaCl and 100 mM Siaq at either pH = 6.8 or pH = 7.8. PG solutions contained 100 mM MgCl₂ at pH = 7.0.

Human whole blood was obtained from three donors. Informed written consent was obtained from each donor and experiments with human blood were performed according to the ethical guidelines from the declaration of Helsinki with the approval of local ethical committee. Blood was collected in polypropylene tubes containing 0.5 ml of 500 mg/ml lepirudin. 400 ml aliquots were incubated with one coin each of the different surfaces in a rolling incubator at 37°C. Coagulation markers (TAT and F1+2) and complement markers (C3bBbP, C4d, TCC) were determined by ELISA assays after 30 min. Further, platelet, monocyte and granulocyte activation was determined after 30 min using flow cytometry. Expression of inflammatory cytokines was evaluated after 4 h using MultiPlex system. Experiments with blood from each donor were performed in triplicates (nₑ = 9).

Results and Discussion
The activation product of the classical and the lectin complement pathway, C4d, was detected at elevated levels on all surfaces (Figure 1A). Similarly, the marker of the alternative pathway, C3bBbP, was found in all samples (Figure 1B). This is in agreement with known activation of the alternative pathway on surfaces bearing nucleophiles, such as polyphenolic hydroxyl groups, and on protein layers formed on surfaces.[4] Regardless of the activation, all pathways of the complement system converge to form terminal complement complex (TCC). Although elevated levels of C4d and C3bBbP were detected for all surfaces, polyphenolic coatings did not induce increased levels of TCC (Figure 1C). These results suggest that the modified surfaces may inhibit the further amplification process of the complement cascade.

Ti surfaces and polyphenolic coatings induced high levels of both thrombin activation markers TAT and F1+2 (Figure 1D, E). High activation of the coagulation system by Ti is in accordance to literature and often correlated to the...
remarkable tissue integration of Ti surfaces. Our results showed that the coated surfaces maintain the thrombogenic activity of bare Ti, despite their altered surface chemistry. Activation of the coagulation system was also corroborated by platelet activation (Figure 2A).

The activation of monocytes and granulocytes was assessed as a hallmark for acute inflammation. Both activation markers CD11b and CD35 remained unchanged at the background level observed in the negative control (Figure 2B, C). These results imply that although different surface coatings activated the complement system, the stimulation was not sufficient to elicit a cellular response. This finding was in agreement with the expression profile of inflammatory cytokines (Figure 2 D-F). While TA-coated surfaces did not induce a significant change in expression of pro-inflammatory cytokines, PG coatings upregulated leukocyte chemotactic cytokines.

**Conclusion**

TA and PG coatings activated the complement system similar to Ti surfaces. However, the formation of TCC was reduced on the TA and PG coated surfaces. The thrombogenic properties of Ti were retained by TA and PG coated surfaces, which led to platelet activation. In contrast, monocytes and granulocytes were not activated by Ti or polyphenolic coatings, which was represented in the cytokine expression. Therefore, we conclude that polyphenolic coatings did not elicit inflammation or an adverse foreign body response, and are promising candidates for the further development of antioxidant implant coatings to support wound healing and tissue integration.

**A bio-inspired antimicrobial peptide coating for dental magnesium implants**

**Dennis A. Böhner, Kathrin Bellmann-Sickert, Annette G. Beck-Sickinger**

*Leipzig University, Institute of Biochemistry / Faculty of Life Sciences, Leipzig, DE*

**Introduction**

The progressive aging of the population, which implies an increase in degenerative bone diseases, has significantly increased the market for dental implants. Traditionally, dental implants are made of stainless steel, titanium or cobalt-chromium alloys, which generally have a high overall survival rate. Nevertheless, material-related inflammation and post-operative infections are a high-risk factor for implant failure due to periprosthetic bone loss and subsequent loss of osseointegration [1]. Bacterial infections are associated with biofilm formation on the implant surface, which exhibits a higher resistance to antimicrobial agents. Thus, prevention of bacterial colonization at the implant surface is of high interest but remains challenging [2]. Recently, we developed a bio-inspired surface-binding peptide containing L-3,4-dihydroxyphenylalanine (DOPA) for the coating of titanium, polystyrene and polycaprolactone-collactide [3-5]. By immobilizing cell-binding peptides on titanium we significantly enhanced cell-surface interaction and cell viability of osteoblast-like cells [3]. Furthermore, functionalization of the carrier-peptide with chemokines such as the CXC chemokine ligand 12 improved wound healing [4]. Transferring this approach to dental implants has the potential to decrease to the risk of post-operative infections and implant failure. Here, we report on the synthesis of a surface-binding peptide for magnesium alloys.

**Experimental Methods**

For the synthesis of a DOPA-containing surface-binding peptide, we applied solid phase peptide synthesis using standard Fmoc/tBu strategy. For detection on magnesium surfaces, a biotin moiety was incorporated. Using biotinylated peptides, the immobilization was investigated by an on-surface ELISA-like assay with streptavidin coupled to an enzymatic reporter. To assess the antimicrobial power of the target antibiotics, broth dilution assays were used to determine the minimal inhibitory concentration of amoxicillin and ciprofloxacin against *Escherichia coli*.

**Results and Discussion**

Using on-surface ELISA the efficient surface binding of the carrier peptide on magnesium alloys was demonstrated. Further, we demonstrate the antimicrobial activity of two commonly applied antibiotics in a cell-based setup.

**Conclusion**

Our surface-binding peptide represents a promising approach to immobilize different antibiotics like amoxicillin and ciprofloxacin commonly used in dental surgeries on magnesium alloy implants.

Development and morphological tuning of Plasma Electrolytic Oxidation titania coatings in a novel sodium borate electrolyte in galvanostatic and pulsed conditions

Matteo Pavarini, Monica Moscatelli, Luigi De Nardo, Roberto Chiesa

Politecnico di Milano, Department of Chemistry, Materials and Chemical Engineering, Milano, IT

Introduction
Plasma Electrolytic Oxidation (PEO) is a simple and effective electrochemical surface modification technique that can be applied to the so called “valve metals”, such as titanium and its alloys, to produce thick oxide coatings. This process has raised great interest in the biomedical field for its ability to produce porous biocompatible surfaces [1], especially by fine tuning of the electrochemical process parameters. However, conventional PEO electrolytes, mainly based on Ca-P containing compounds, typically need strict thermal control to produce optimal coatings or conversely require very high applied current densities and voltages, thus reducing efficiency. Thereby, alternative electrolytes, such as borates and silicates, can be useful to overcome those limitations: the former can produce very hard and compact oxide film [2], while the latter lead to surfaces with high porosity [3].

In our work, we focused on the development of an efficient PEO treatment, in both galvanostatic and pulsed conditions, capable to produce coatings with a surface morphology tuned for bone-contact applications.

Experimental Methods
Grade 2 titanium specimens were treated in a novel alkaline electrolyte made of 0.1M Na₂B₄O₇, 0.1M NaOH and 0.02M Na₂SiO₃. The PEO treatment in galvanostatic conditions was conducted by applying different current densities (25 ÷ 200 mA/cm²) and voltage limits (180 ÷ 400V) for variable times (30 s ÷ 15 min), at room temperature. In pulsed DC conditions, three different duty cycles (10%, 50% and 90%) and two treatment frequencies (100 and 800Hz) were explored. The treated samples were then observed via SEM and characterized in terms of pore diameters and average porosity through the ImageJ software, to identify possible relations between the applied treatment parameters and the coatings’ properties. The cross-sectional features of the coatings were then assessed by direct observation of their metallographic sections.

Results and Discussion
The borate-based electrolyte showed high thermal stability in all the treatment conditions. In galvanostatic regime, the pore size and porosity of the coatings showed a similar trend as a function of the applied current densities and final voltages, with a constant increase up to a certain threshold (50mA/cm², 300V), after which wider deviations, ascribable to an increase in surface inhomogeneity, could be observed. As for the process duration, samples treated for more than 7 min didn’t show any further difference in the coatings’ morphology, because of the discharge process’ interruption at constant voltage.

The coatings produced with optimized parameters (J=50mA/cm², 300V, 7 min) showed a microporous surface morphology (Fig. 1a), featuring “volcano-like” pores, with an average pore diameter of 900 nm and an 8% porosity. Moreover, the coatings’ cross-section shows an interesting bilayer structure (Fig. 1b), with a compact inner layer and a more porous surface one, probably due to the predominant presence of borate and silicate, respectively.

In pulsed conditions, the surface features of the produced coatings highlight clear trends with varying process parameters (Fig. 2): as the duty cycle is raised, the average pore size and surface homogeneity increase, with a steeper variation for duty cycles up to 50%, and only slight variations above this threshold, while, at high treatment frequency, the pores are smaller and less homogeneously distributed. Similar trends can be observed for the coating
thickness, with thicker oxide layers produced at low frequencies and high duties. In all the explored conditions, except for 10% duty, the obtained pore size is potentially optimal for perspective orthopedic applications, since pores with characteristic dimensions similar to the typical bacteria involved in periprosthetic joint infections (0.5÷2.5 µm) can inhibit their adhesion and proliferation [4] while promoting osteogenic cells’ growth.

Conclusion
The newly developed sodium borate electrolyte allowed the production of homogeneous and porous PEO coatings, with features optimized by the tuning of the process parameters in both galvanostatic and pulsed conditions, showing promising topographical features for potential use in bone-contact applications.

Immobilization of gelatin on electrospun fibers: a comparative analysis of aminolysis-based procedure and physisorption for three aliphatic polyesters

Oliwia Jeznach, Dorota Kołbuk, Paweł Sajkiewicz

Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, PL

Introduction
Immobilization of adhesive proteins, such as gelatin, collagen, fibronectin on the scaffold surface has become a widely reported method that can improve the interaction between scaffold and cells. It is achieved through various methods originated from chemical binding or physical interaction between biomolecule and polymer [1,2]. In this study, we modified the surface of three types of electrospun fibers using chemical immobilization of gelatin basing on aminolysis and glutaraldehyde cross-linking or physisorption of gelatin and evaluated the change of materials properties as well as L929 cells response.

Experimental Methods
Poly(caprolactone) (PCL), poly(L-lactide-co-caprolactone) 70:30 (PLCL) and poly(L-lactide) (PLLA) fibers were obtained by electrospinning. The aminolysis reaction was carried out by immersing nonwovens in ethylenediamine solution in isopropanol under various treatment conditions to test the susceptibility of fibers to the reaction. Two sets of conditions were chosen to evaluate immobilization for samples with lower and higher concentrations of free NH₂ groups. Then, gelatin was chemically immobilized on the surface of given samples using glutaraldehyde as a cross-linking agent. Samples with physisorbed gelatin were prepared by simple immersion in gelatin solution. Ninhydrin test and BCA test were used to measure the density of amine groups and gelatin on the surface, respectively. Change of morphology, average molecular weight and crystallinity were determined using scanning electron microscopy, gel permeation chromatography and wide-angle X-ray scattering technique, respectively. The wettability of modified samples was measured by a goniometer. Mechanical properties were determined using uniaxial tension testing. The stability of the coating originated from chemical binding or physical interaction was verified via incubation in phosphate-buffered saline (PBS) from 1 to 90 days. L929 cells were cultured on modified samples to investigate the biological response to modified samples after 3 and 5 days.

Results and Discussion
It was shown that aminolysis-based immobilization could provide a higher concentration of gelatin on the fiber surface in the case of all investigated polyesters (Fig.1.). However, gelatin concentration was relatively high in the case of physisorption, especially when comparing to samples aminolyzed under mild reaction conditions. However, the incubation test showed that the chemically immobilized gelatin layer is more stable than physisorbed one. After 90 days of immersion, more than 60% of the initial concentration of protein was detected for a physically modified PCL sample while the values were higher than 90% and 80% for aminolyzed samples with lower and higher concentration of free NH₂ groups, respectively (Fig.2.). Despite a similar concentration of free NH₂ groups among all polyesters, the concentration of gelatin was significantly higher in the case of PCL fibers. The cause of this phenomenon could be the difference in the accessibility of groups on the surface, the difference in fiber diameter or roughness, which could influence the amount of immobilized gelatin for each polymer. For chosen conditions, there was no difference in fibers morphology between chemically and physically modified samples, however, it is known that aminolysis could cause fracturing of fibers [3]. Gelatin immobilization contributed to the change of the fibers properties from hydrophobic to completely hydrophilic after each studied modification. Additionally, the time of water drop absorption...
was correlated with the density of gelatin on the surface of the fibers. Young's modulus, stress and strain at break results were very similar for samples subjected to physisorption and mild chemical immobilization. In the case of PLCL and PLLA samples, aminolysis conditions that were applied to provide a higher concentration of free NH2 groups result in a significant decrease of stress and strain at break. PCL sample with a similar concentration of free NH2 groups was much more resistant to loss of mechanical strength. Improvement of L929 cells morphology and metabolic activity was observed for all modified samples, wherein the nonsignificant differences between samples subjected to physisorption and mild chemical immobilization were observed.

Conclusion

Our study showed that aminolysis-based chemical immobilization of gelatin could provide a higher concentration of protein on the surface than physisorption. Chemically attached gelatin was additionally more stable than a physisorbed one. However, it is important to optimize reaction conditions depending on the scaffold application because aminolysis can significantly reduce the average molecular weight of the polymer and the resulting mechanical properties of the scaffold. Morphology and metabolic activity of L929 cells were improved in the case of each modification, but the most significant differences were observed for PCL samples and PLLA sample with a higher concentration of free amine groups.

Engineering micro/nanoscale surface topographies for corneal tissue regeneration

Gozde Sahin, Nello Formisano, Rhiannon Grant, Roman Truckenmüller, Stefan Giselbrecht

Maastricht University, Department of Instructive Biomaterials Engineering / MERLN Institute for Technology-Inspired Regenerative Medicine, Maastricht, NL

Introduction
The cornea is a transparent tissue located at the outer part of the eye, whose function is to protect the eye from external damage and to provide most of its refractive power. Trauma or disease affecting the cornea can cause vision loss and subsequent blindness. This can be overcome via corneal transplantation, but suitable donor tissue is only available to a fraction of patients worldwide [1]. One of the most explored alternative approaches to address this shortage is to expand primary corneal cells in vitro. However, current cell culture protocols result in limited expansion of corneal cells and loss of their phenotypes. To overcome this limitation, instructive culture substrates comprising topographical features and materials properties that mimic essential cues present in their native corneal microenvironment may be a key tool. Fabricating multiscale structures with precise control over micro/nano-features, as those present in in vivo corneas, is challenging to achieve by a single technique and would likely require a combination of multiple nanofabrication techniques, some of which have not been entirely employed in this field [2]. To address this challenge, we created a library of tools for fabricating substrate topographies from micro- to nanoscale on various biocompatible polymer films to systematically screen for desired cell responses.

Experimental Methods
First, to test and optimize the fabrication of surface topographies by conventional photolithography, we designed and produced polygonal features with lateral dimensions between 10 μm and 100 μm (Figure 1a). Then, we established soft-lithography and nanoimprint lithography protocols to replicate these topographies onto thin thermoplastic biocompatible polymer films (Figure 1b-e), such as polycarbonate (PC), polystyrene (PS), polylactic acid (PLA), poly(methyl methacrylate) (PMMA) and cyclic olefin copolymers (COC).

Results and Discussion
The imprinting quality (incomplete filling, surface roughness, demoulding damages, etc.) is characterized for each engineered substrate by optical profilometry and scanning electron microscopy (SEM). Preliminary results indicate that cell morphology, alignment and proliferation can be tuned by these cell substrates. Further analysis of these parameters, together with analysis of phenotypical markers of corneal cells will be performed for the engineered substrate.

Conclusion
These engineered surfaces serve as a novel, high-throughput and robust method of screening instructive substrates for corneal cells, increasing cell proliferation and maintaining their corneal phenotype. Subsequently, this platform can be expanded to provide an infinite cell source for cell-based therapies and tissue-engineered equivalents to overcome the shortage of cornea donors, and other tissue types.

Development of advanced bioactive glass-based coatings by electrostatic spray deposition

Verónica Müller¹, Matías Jobbagy², Elisabeth Djurado¹

¹ Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, Grenoble INP, LEPMI, Grenoble, FR; ² Univ. Buenos Aires, FCEyN, INQUIMAE-DQIAQF, Buenos Aires, AR

Introduction

Bioactive glasses (BG) are the subject of intensive investigation as a bone replacement material since the discovery of a 4-component glass in 1969 by Hench, nowadays known as 45S5 (46.1 SiO₂ – 24.4 Na₂O – 26.9 CaO – 2.6 P₂O₅ % mol) [1]. However, due to brittleness and poor mechanical properties, direct BG clinical applications are limited to non-load-bearing implants. Nevertheless, BG can be employed as coatings on a metallic substrate to combine their biological performance with mechanical strength. Many deposition processes are currently investigated to produce BG coatings [2]. However, the fabrication of BG coatings by sol-gel method coupled with the electrostatic spray deposition (ESD) has never been attempted to the far of our knowledge.

Based on electrohydrodynamics laws, ESD is a simple and low-cost technique that allows the deposition of films with precise control of thickness, microstructure, and chemical composition. In our previous work, by coupling the sol-gel method with the ESD technique, we have obtained a robust, one-step method for the fabrication of single-phase nanocrystalline hydroxyapatite coatings [3]. This study focuses on manufacturing BG coatings belonging to the SiO₂-CaO-P₂O₅ system, starting from homogeneous liquid precursor solutions deposited on Ti6Al4V substrates. Here, through this technique, we have successfully obtained one-step coatings with optimized S85 (85 SiO₂ – 10 CaO – 5 P₂O₅ mol. %), S75 (75 SiO₂ – 20 CaO – 5 P₂O₅ mol. %) and S58 (58 SiO₂ – 37 CaO – 5 P₂O₅ mol. %) compositions [4].

Experimental Methods

Bioactive glasses (BG) coatings were prepared using a vertical ESD set-up on polished commercial Ti6Al4V ELI plates. Precursor solutions were prepared by using either triethyl phosphate, referred to as TEP (Aldrich, 99.9%) or H₃PO₄ (Aldrich, 85 %) as P(V) source, tetraethyl orthosilicate, TEOS (Aldrich, 99.999%) as Si(IV) source and Ca(NO₃)₂·4H₂O (Merck, 99.95%) as Ca(II) source. Methanol (CH₃-OH, MetOH), Ethanol (CH₃-CH₂OH, EtOH), and diethylene glycol monobutyl ether, referred to as butyl carbitol (C₄H₉(OCH₂CH₂)₂OH, BC), were chosen as solvents for the preparation of the precursor solution. To investigate the influence of processing conditions on the characteristics of the coatings, such as composition, structural and microstructural properties, several ESD parameters were considered -i.e. nature of P(V) precursor, absolute precursor solution concentrations, solvent composition, substrate temperature, and deposition time.

The microstructure and composition of the obtained coatings were characterized by scanning electron microscopy (SEM) coupled with an EDS probe. Their structural properties were determined using X-ray diffraction (XRD) and Raman spectroscopy.

Assessment of in vitro bioactivity was carried out in simulated body fluid solution (SBF) according to the ISO standard norm (22317: 2014) on optimized S85, S75, and S58 coatings.

Results and Discussion

All BG-coatings deposited by ESD displayed an amorphous character as detected by XRD. Microstructures from denser to coral-like and highly porous morphologies were successfully obtained regardless of the coating composition (Fig. 1). EDX analyses show the presence of silicon, calcium, and phosphorus homogeneously distributed in the volume of films, according to the above formulations. Besides, their bioactivity behavior has been studied by Page 1932 of 2028
immersion in SBF solution for 24 h. The biological performance of BG was found to be strongly dependent on their texture. Highly porous coatings led to remarkable bioactivity of the films with S75 and S58 compositions, compared with more compacted ones. The films with S85 compositions, whatever is the morphology, were found highly reactive. Indeed, almost complete dissolution was carried out within 24 h of immersion.

**Conclusion**

The present work introduces an innovative preparation of glass-based coatings, prepared for the first time by coupling the sol-gel method with ESD. Coatings with S85, S75, S58 compositions were successfully obtained after optimization of i) the precursor solution and ii) the substrate temperature. All the obtained deposited coatings were crack-free and presented an amorphous environment with original coating microstructures. Morphologies ranging from highly porous coral-like toward more compact cauliflower-type were obtained showing the potential of ESD for easily tune the coating texture. Furthermore, the ESD method has proven to be very successful for developing highly reactive bioactive glass coatings that offer complete transformation into an apatite layer after 24 h of soaking in SBF for S75 and S58 BG coatings.

The Role of Surface Properties of Inorganic Materials for Improved Biological and Antimicrobial Response: Wettability, Zeta Potential and Biological Functionalization

Mari Lallukka, Francesca Gamna, Marta Miola, Sara Ferraris, Silvia Spriano, Enrica Verné

Politecnico di Torino, Turin, IT

Introduction
Surface properties of a biomaterial are one of the most influencing parameters in the context of a successful implant. Especially the complex phenomena occurring at the material - implant interface upon contact with physiological fluids and biological environment are yet to be completely understood. Here suggested innovative surface engineering methods could have potential to improve implant longevity through enhanced and selective protein adsorption and cell response, while simultaneously preventing biofilm formation.

Experimental Methods
In this work, a range of biomaterial surfaces are characterized and compared in terms of their zeta potential, wettability, and surface chemistry. The focus is especially on silica-based bioactive glasses, either doped with antibacterial silver (Ag) or copper (Cu) ions via ion exchange, or with other ions with therapeutic effects directly incorporated in the composition of the glass (zinc (Zn) ans strontium (Sr)). A separate focus is on the titanium alloy Ti64ELI surface treated to be suitable for functionalization.

The pristine and modified surfaces are characterized by means of SEM-EDS, XRD, zeta potential titration curves, and contact angle measurements. Furthermore, the release of therapeutic ions from the doped bioactive glasses either in Simulated Body Fluid (SBF) or in acidic (pH 5) sodium acetate buffer up to four weeks is evaluated by means of ICP-OES analysis. Finally, biological functionalization by grafting antimicrobial peptide nisin is studied and evaluated on both titanium and glass surfaces.

Results and Discussion
Silver and copper ions were successfully introduced on the bioactive glass surfaces without unwanted crystallization phenomenon, and without negatively affecting hydroxyapatite formation, and hence, bioactivity. The introduced ions also affect the surface zeta potential and wettability of the doped glasses. The release test of the antibacterial and osseoinductive ions, and the evaluation of the antibacterial efficacy of grafted nisin are in progress.

Introduction

Due to the demographic development with an increasing number of patients with reduced healing capacities, there is a high need for treatment options improving the regeneration of damaged tissue, e.g. bone. Mimicking the cellular microenvironment by including components of the extracellular matrix (ECM) is one promising option to derive novel functional biomaterials for promoting tissue regeneration. In bone, glycosaminoglycans (GAG) like chondroitin sulfate (CS) or chemically sulfated hyaluronan (sHA3) have been implicated in supporting regenerative processes in vitro and in vivo [1]. As multifunctional components of artificial ECM (aECM), CS and sHA significantly influence bone healing by enhancing osteogenic differentiation of mesenchymal stem cells (hMSC) and premature osteoblast [1, 2]. Specifically, for bone-related applications, silicate-based bioactive glass nanoparticles (BGN) show unique properties for tissue regeneration and repair due to their small size and high specific surface area [3]. Based on their bioactivity and their capability of releasing ions like silicon and calcium, BGN can induce favorable cellular responses and promote rapid bone formation [4]. The aim of this study was to evaluate the potential synergistic effects of CS or sHA3 in combination with BGN on the osteogenic differentiation of hMSC as an important aspect of bone healing.

Experimental Methods

Tissue culture polystyrene samples were coated with collagen type I (col), col/CS or col/sHA3 and compared to similar coatings containing SiO₂-CaO BGN with diameters in the range of 300 - 400 nm. The stability of aECM coatings was qualitatively and quantitatively assessed by colorimetric assays directly after preparation and after incubation in phosphate buffered saline (PBS) for up to 31 days in the absence of cells. The morphology of coatings was assessed by scanning electron microscopy (SEM), while the viscoelastic properties were determined by oscillatory rheology. These aECM were further investigated regarding their effects on hMSC on osteogenic differentiation, comparing medium with and without dexamethasone (Dex) supplementation. Cellular proliferation and osteogenic differentiation were quantified via DNA content, alkaline phosphatase activity and calcium phosphate deposition (CPD) using hMSC isolated from the bone marrow of four different donors. The release of calcium and silicon ions from aECM coatings during cell culture but also in the absence of cells was quantified via inductively coupled plasma- optical emission spectrometry (ICP-OES).

Results and Discussion

Sirius red and Toluidine blue staining of aECM revealed the presence of collagen and GAG in the respective coatings as well as their homogeneous distribution irrespective of the presence of BGN. Directly after preparation, the collagen content was between 410–500 µg/cm² for GAG-containing aECM and up to 875 µg/cm² for collagen only. The initial
GAG amounts were between 50–85 µg/cm². Within the first day, we observed an initial release of collagen and GAG in PBS at 37°C that gradually ceased at later time points. After 13 days of incubation, more than half of the initial collagen content was still present. Neither the initial amounts nor the release was markedly influenced by the presence of BGN. The fibrillar structure of the collagen-based coatings was confirmed via SEM, while BGN formed equally distributed agglomerates. All samples exhibited viscoelastic behavior with predominantly elastic deformation. The complex viscosity of the coatings increased in the presence of BGN up to one order of magnitude. Cell proliferation was significantly increased on aECM without BGN compared to those with BGN, which was further enhanced by Dex. GAG and BGN promoted both, ALP activity and CPD. ALP activity was in particular increased on BGN-containing aECM in the presence of Dex. The CPD was increased on BGN-containing aECM irrespective of the presence of Dex, while, in case of coll/shA w/o BGN, Dex was necessary to induce CPD. For selected but not all donors a slightly synergistic effect of shA3 and BGN could be shown. Silicon ions were released into the cell culture supernatant from all BGN containing aECM and its concentration was significantly higher in the presence of cells.

**Conclusion**

aECM composed of col, GAG and BGN are promising bioinspired functional biomaterials for rapid mineralization in bone healing applications, which might be attributed to silicon release but also to GAG content and aECM stiffness. Further studies will investigate the mechanisms behind this effect as well as exploring the combination with physical stimulation, e. g. pulsed electric fields.

Hydrolysis, Plasma and Aminolysis: how a surface activation method affects gelatin attachment to PLCL nanofibres

Judyta Dulnik, Oliwia Jeznach, Paweł Sajkiewicz

Institute of Fundamental Technological Research, Polish Academy of Sciences, Laboratory of Polymers and Biomaterials, Warsaw, PL

Introduction
Aliphatic polyesters are materials widely used in tissue engineering because of a number of reasons – they can be formed with many different methods, resulting in a broad range of mechanical properties, they are biodegradable and biocompatible. To overcome their hydrophobicity and the lack of bioactivity, among other approaches, surface modification has been an extensively researched technique. Introducing proteins that are naturally present in the extracellular matrix to the surface of a scaffold material is a great way of solving both of these issues. Collagen, and its derivative – gelatin, has been shown to have a beneficial effect on mammalian cells’ proliferation and spreading [1]. Immobilization of gelatin through crosslinking to the surface of electrospun nanofibres made of aliphatic polyesters has been studied in our laboratory in the past years with the use of an aminolysis as a surface activation technique [2]. In this work a series of experiments were performed on poly(L-lactide-co-caprolactone) 70:30 (PLCL) nanofibres in order to compare three methods of surface activation - hydrolysis, cold oxygen plasma treatment and aminolysis, which were used as a first step of the process of gelatin immobilization to the material’s surface.

Experimental Methods
Nonwoven material was obtained through solution electrospinning of PLCL dissolved in hexafluoroisopropanol (HFIP) on a rotating drum collector. Alkaline hydrolysis (with NaOH solution) and plasma treatment were first optimized through a series of tests with varying process conditions in order to select a limited number of them for the final step of comparison. Aminolysis reaction conditions were chosen based on our previous results [2]. PLCL materials after hydrolysis and plasma treatment underwent gelatin crosslinking with 1-(3-dimethylaminopropyl)-N’-ethylcarbodimide hydrochloride/N-hydroxysuccinimide (EDC/NHS). For samples after aminolysis glutaraldehyde was additionally used.

Gel permeation chromatography (GPC), electron microscopy (SEM) and water contact angle measurement were used to assess how surface activation affected the samples. Toluidine blue O staining was used to assess the amount of COOH- groups on the surface of the fibres after hydrolysis and plasma treatment. The efficiency of gelatin immobilization, as well as how strong it was attached was measured with bicinchoninic acid assay (BCA) before and after biodegradation test.

Results and Discussion
GPC showed that each activation method affected the molecular weight of the polymer differently. Small change was observed for hydrolyzed samples, but a new peak for a very low molecular weight has appeared. Among the remaining two methods aminolysis proved to cause a greater drop in the molecular weight. Samples after both hydrolysis and plasma treatment showed elevated levels of COOH- groups on the surface of the fibres compared to control, but between the two methods hydrolysis resulted in up to 3 more times higher value. Apart from samples treated with aminolysis the rest gained hydrophilicity after surface activation, but later after biodegradation test all achieved 0°, which means that the water drop was immediately soaked into the material.

All tested methods were successful in gelatin immobilization as well maintaining its attachment after biodegradation test compared to control. Samples treated with aminolysis were leading in the strength of gelatin attachment.
treated materials were able to retain the highest amount of protein. Hydrolyzed samples in comparison, except for the one treated with the most concentrated NaOH solution, achieved average results in both regards. SEM imaging showed no significant change in fibres morphology, except for the ones treated with higher NaOH molarities. With increasing NaOH concentration a progressing in the damage of the very surface of the fibres would be observed. We believe these samples had achieved surprisingly high BCA result, as a consequence of their increased surface area caused by the frayed outer layer of the fibres.

Conclusion
All three tested surface activation methods were successful being a first step of the surface gelatin immobilization. Depending on the method, some properties of the electrospun PCLC material were affected more. The decision of which method is the most suitable should be based on a specific function that the final scaffold material is expected to fulfill and the properties it should have.

Hybrid HAp/tantalum-based bioactive coatings on titanium substrate

Amanda Bartkowiak¹, Yevhen Zabila¹, Elzbieta Menaszek², Arkadiusz Zarzycki¹, Marcin Perzanowski¹, Marta Marszalek¹

¹ Institute of Nuclear Physics Polish Academy of Sciences, Department of Magnetic Materials and Nanostructures, Krakow, PL; ² Jagiellonian University Medical College, Faculty of Pharmacy, Krakow, PL

Introduction

Tantalum (Ta) is recently attracting growing attention thanks to superior over other metals physicochemical stability, biocompatibility and osteoconductivity [1]. However, high density and stiffness unmatched with bone tissue, along with expensive costs of manufacturing, make bulk Ta material unsuitable for medical implants. One way to gain remarkable biological properties with currently used metallic implants is to modify their surface with Ta films. Another material used for successful surface modification to promote osseointegration at the implant-tissue interface is hydroxyapatite (HAp) [2]. Among different deposition techniques, hydrothermal method was found to produce highly crystalline and uniform HAp coatings on titanium (Ti), dealing with complex shapes typical for orthopedic implants [3]. To take full advantage of the beneficial properties of tantalum and hydroxyapatite, we modified the surface of commercially used titanium foil with hybrid HAp/tantalum-based bioactive coatings. Fabrication of the hybrid coatings was achieved by two methods approach: magnetron sputtering and hydrothermal synthesis. Samples were investigated for their structure, in vitro bioactivity and biocompatibility using osteoblast-like cell culture. In this study, we show that the synergetic properties of tantalum-based films and HAp coating have positive and superior effect on the osteoblast-like cells compared to titanium substrates only with HAp coatings.

Experimental Methods

Development of HAp/tantalum-based bioactive coatings was divided into two steps: (1) magnetron sputtering of tantalum on titanium foil and (2) hydrothermal synthesis of HAp coatings. Sample with intermediate tantalum oxide film was produced by thermal oxidation of the sputtered Ta film. The hydrothermal synthesis was carried out in an autoclave at 200°C from solution containing: calcium salt hydrate, diammonium phosphate and calcium chelating agent. The morphology and microstructure of prepared specimens were characterized using XRD, SEM/EDS and fluorescent microscopy. Cell viability was investigated using human osteoblast-like cell culture (MG-63) after 3 and 7 days of incubation. Bioactivity was assessed in vitro by immersion in simulated body fluid (SBF).

Results and Discussion

High crystallinity of HAp coating for implant applications is desirable since low crystallinity accelerates the speed of dissolution of HAp in the living body, causing the disappearance of coatings that bond with bone tissue at an early stage after implantation. The structural and morphological analysis confirmed that both tantalum and tantalum oxide films induce nucleation and growth of highly crystalline HAp coating under hydrothermal conditions. Cells cultured on these hybrid coatings were numerous, well spread and connected with filopodia extensions to form a cell network without any cytotoxic effect.

Conclusion

In this study, we present highly biocompatible and bioactive HAp/tantalum-based coatings on titanium substrates that were shown to enhance cell growth in vitro. The two method approach used to produce these hybrid coatings may be easily applicable on any other metallic substrate used in orthopedic field.
